In most cases, a theoretical analysis of these factors is a recommended preliminary step. Such an analysis can predict the reaction mechanism (i.e., the path of the reaction as it forms the deposit), the resulting composition of the deposit (i.e., its stoichiometry), and the structure of the deposit (i.e., the geometric arrangement of its atoms). This analysis may then provide guidelines for choosing the appropriate CVD parameters, thereby avoiding a strictly empirical approach to the desired product. Computer programs are available to facilitate these studies (Ref 4, 5).

However, when a reaction is kinetically controlled, and when only one single condensed phase can form, the theoretical thermodynamic modeling of a CVD reaction has very limited applicability. It is becoming more evident that a useful modeling approach requires an examination of the chemical equilibrium aspects of the reaction, as well as the fluid dynamic aspects of the reactor system, to improve process efficiency. Many computational fluid-dynamic codes are now being used to design reactors that maximize the possible yields from a given reaction. These codes account for the reaction rate theory, thermodynamic equilibrium aspects, and the constraints imposed by the design of the deposition chamber. This means that one can design a complete CVD reactor on a computer workstation, change parameters to model fluid flow, velocity, and temperature profiles, and optimize deposition rates, *instead of* building the equipment and then using trial-and-error methods to optimize the process.

CVD Processes and Equipment

Like all chemical reactions, CVD reactions require activation energy to proceed. This energy can be provided, in practice, by several methods. Thermal activation is the original process, and it is still the major method for the chemical vapor deposition of metals and ceramics.

In thermal CVD, the reaction is activated by high temperature, generally above 900 °C (1650 °F) (Ref 6). A typical thermal CVD apparatus consists of three interrelated components: the reactant-gas supply system; the deposition chamber, or reactor; and the exhaust system (Fig. 1). A fourth component that is often used is a closed-loop process-control monitor, which is now available in a PC-based design.

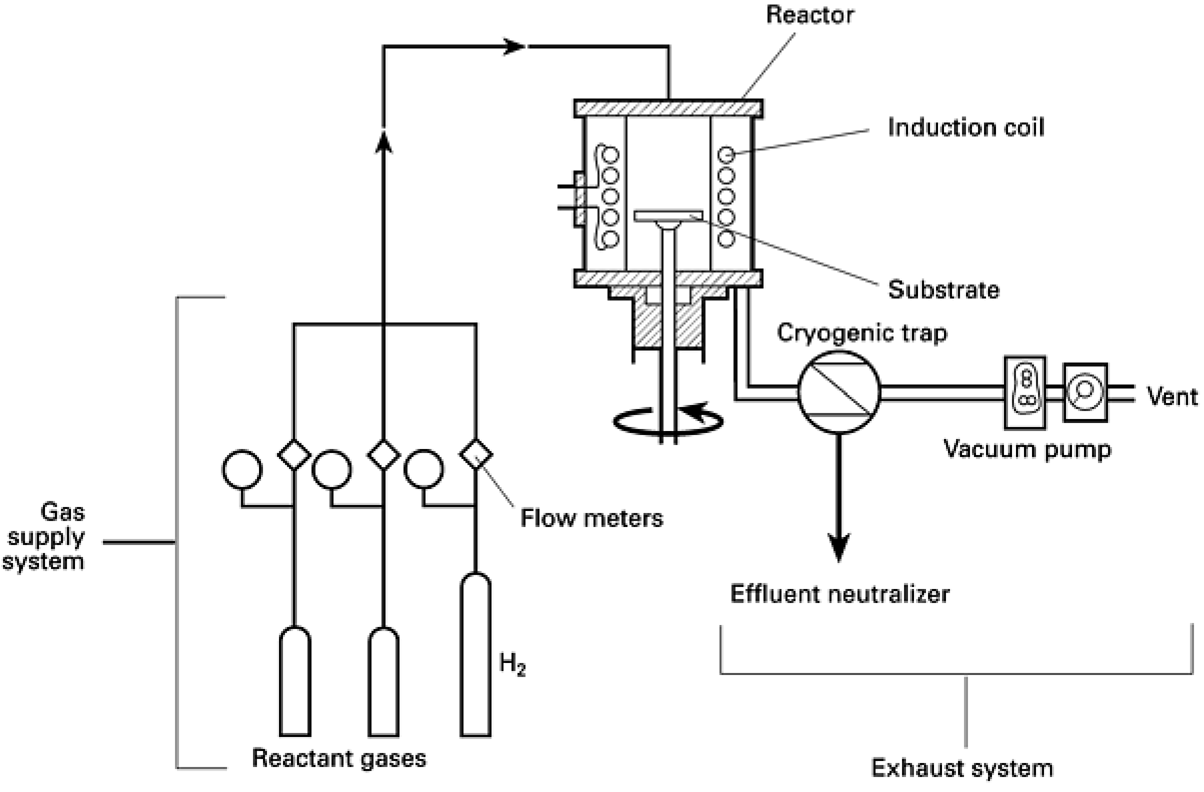

Fig. 1 Thermal CVD reactor

Plasma CVD is a method that operates at lower temperatures than thermal CVD. The reaction is activated by a plasma at temperatures between 300 and 700 °C (570 to 1290 °F). The process was developed because the high deposition temperature of thermal CVD precludes the use of many substrates, such as low-melting-point metals; materials that undergo solid-state phase transformation over the range of deposition temperatures; polymers; and others. In addition, large mismatches in the thermal expansion of a substrate and a coating will generate stresses that can lead to cracking and delamination or spalling during cooling (Ref 7, 8). In the plasma CVD process, the stress that is due to thermal-expansion mismatch is reduced, and temperature-sensitive substrates can be more readily coated. Table 1 compares the deposition temperatures for thermal and plasma CVD for several commercially important coatings.

Table 1 Typical deposition temperatures for thermal and plasma chemical vapor deposition

Material	Deposition temperature

	Thermal CVD		Plasma CVD	
	°C	**°F**	**°C**	**°F**
Silicon nitride	900	1650	300	570
Silicon dioxide	800-1100	1470-2010	300	570
Titanium carbide	900-1100	1650-2010	500	930
Titanium nitride	900-1100	1650-2010	500	930
Tungsten carbide	1000	1830	325-525	615-975

Plasma CVD was initially developed in the 1960s for use in the semiconductor industry, but applications have been expanding ever since and are now common in the nonsemiconductor applications discussed in this article. Most plasma CVD systems use radio frequency (RF) with operating frequencies of 450 KHz or 113.56 MHz. A typical RF reactor with parallel electrodes is shown in Fig. 2. Microwave glow discharge is also used at a standard frequency of 2.45 GHz.

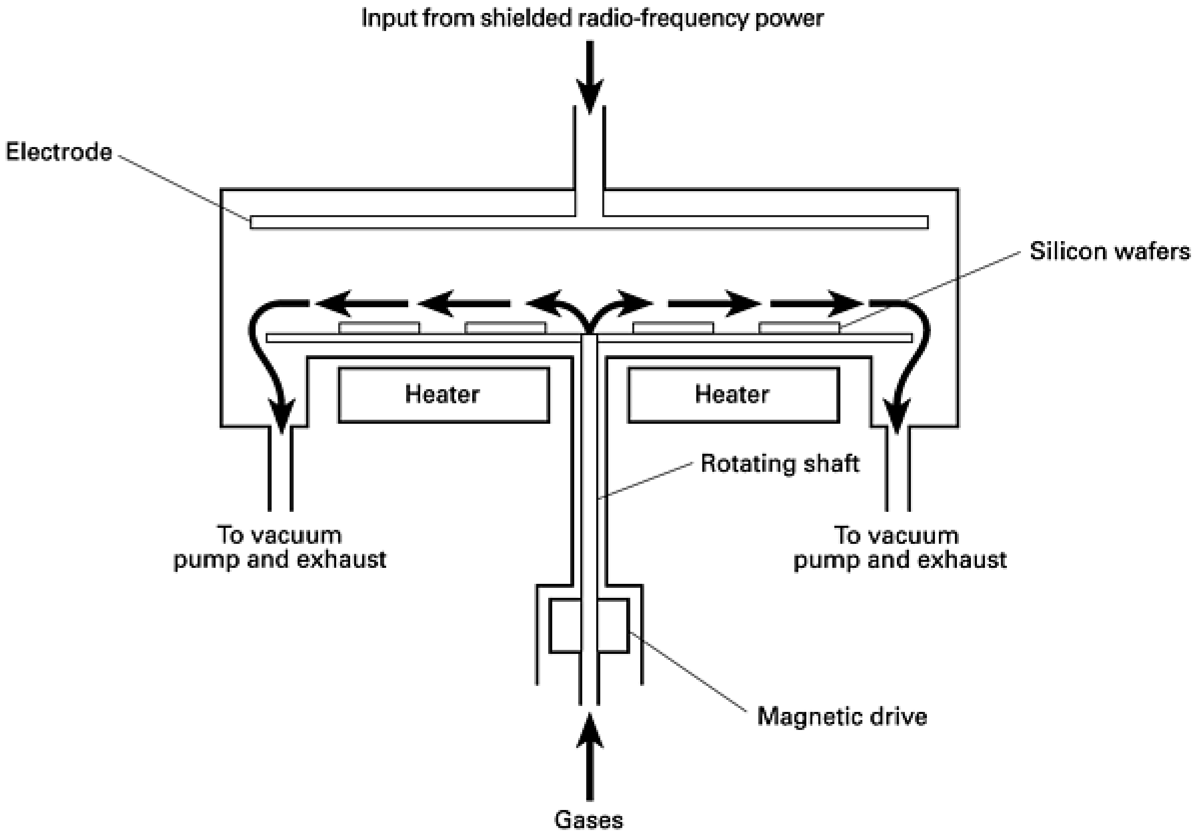

Fig. 2 Radio-frequency plasma CVD reactor configured for deposition on silicon wafers

A recent and promising development in the production of plasma is based on electron cyclotron resonance (ECR) and the proper combination of an electric field and a magnetic field (Ref 9). Cyclotron resonance is achieved when the frequency

of the alternating electric field matches the natural frequency of the electrons orbiting the lines of force of the magnetic field. An ECR plasma reactor is shown schematically in Fig. 3. ECR and other plasma techniques are used extensively in semiconductor production but so far have remained mostly experimental in other areas of application (Ref 10).

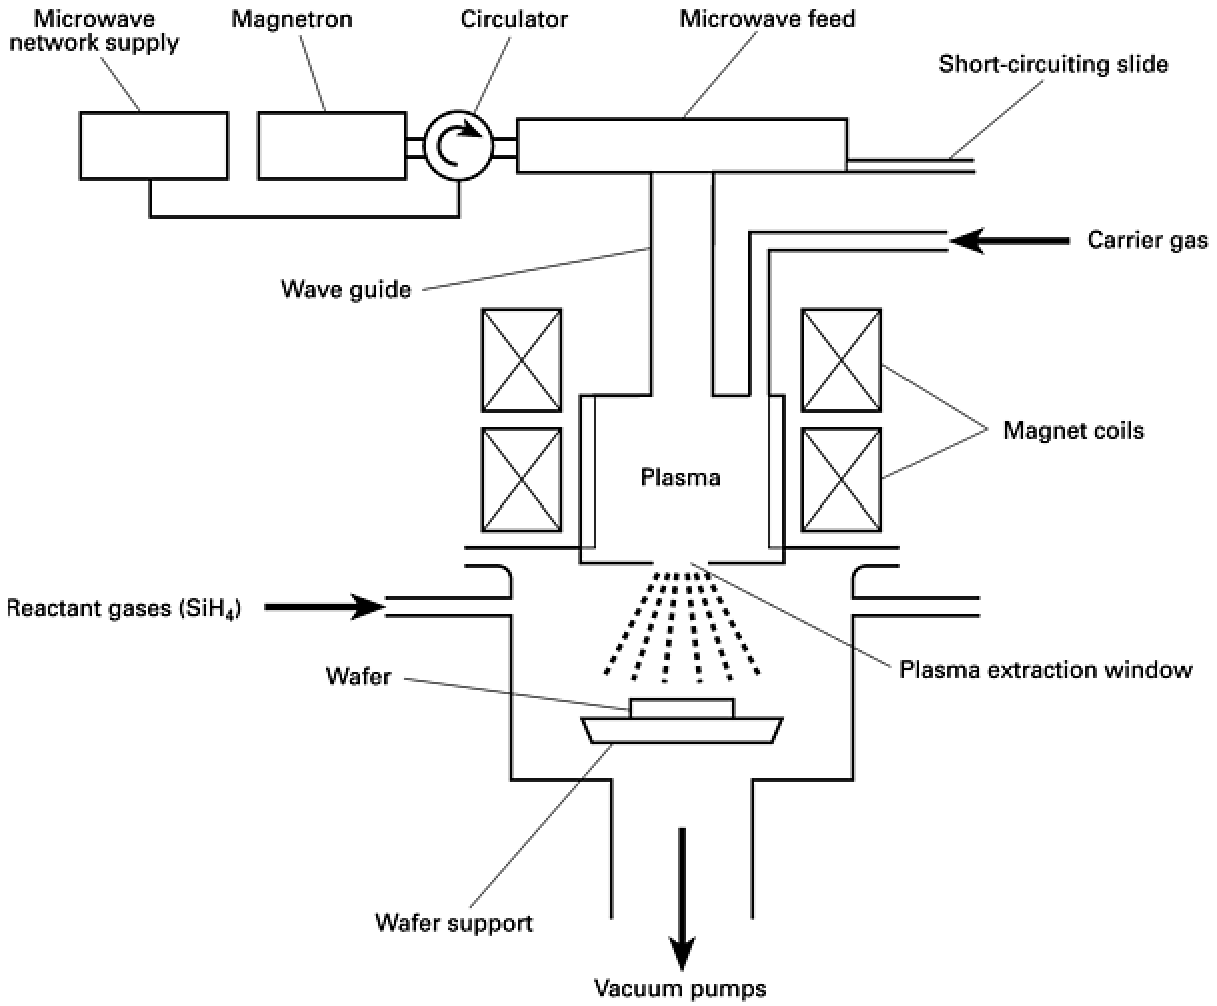

Fig. 3 Microwave/electron cyclotron resonance (ECR) plasma CVD reactor

Laser CVD. Two other activation methods based on a laser have recently been developed (Ref 8, 11). As of the mid-1990s, the thermal-laser and photo-laser CVD methods are still essentially in the experimental stage, but have great potential, at least in specialized areas. The materials that can be deposited include oxides, nitrides, tungsten, aluminum, and others.

Thermal-laser CVD (Ref 12), or laser pyrolysis, occurs when the laser thermal energy contacts and, thereby, heats an absorbing substrate. The wavelength of the laser can be such that little or no energy is absorbed by gas molecules. Because the substrate is locally heated, deposition is restricted to the heated area. Figure 4 illustrates the deposition of a thin stripe by moving a laser beam linearly across the substrate.

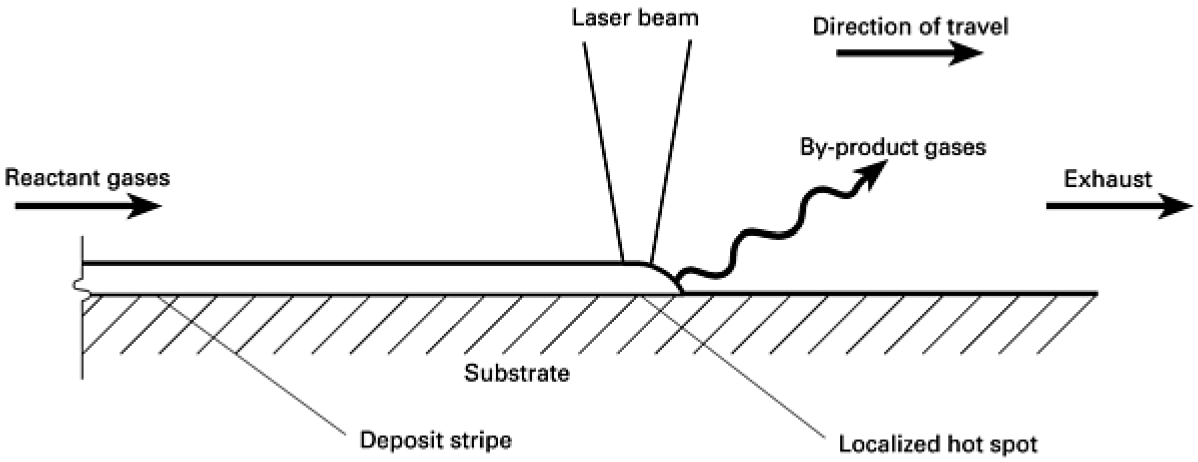

Fig. 4 Thermal-laser CVD growth mechanism

In photo-laser CVD, the chemical reaction is induced by the action of light, specifically ultraviolet (UV) radiation, which has sufficient photon energy to break the chemical bonds in the reactant molecules. In many cases, these molecules have a broad electronic absorption band and are readily excited by UV radiation. Although UV lamps have been used, more energy can be obtained from UV lasers, such as the excimer (e.g., excited dimer) lasers with photon energies ranging from 3.4 eV (XeFlaser) to 6.4 eV (ArFlaser). A typical photo-laser CVD system is shown in Fig. 5.

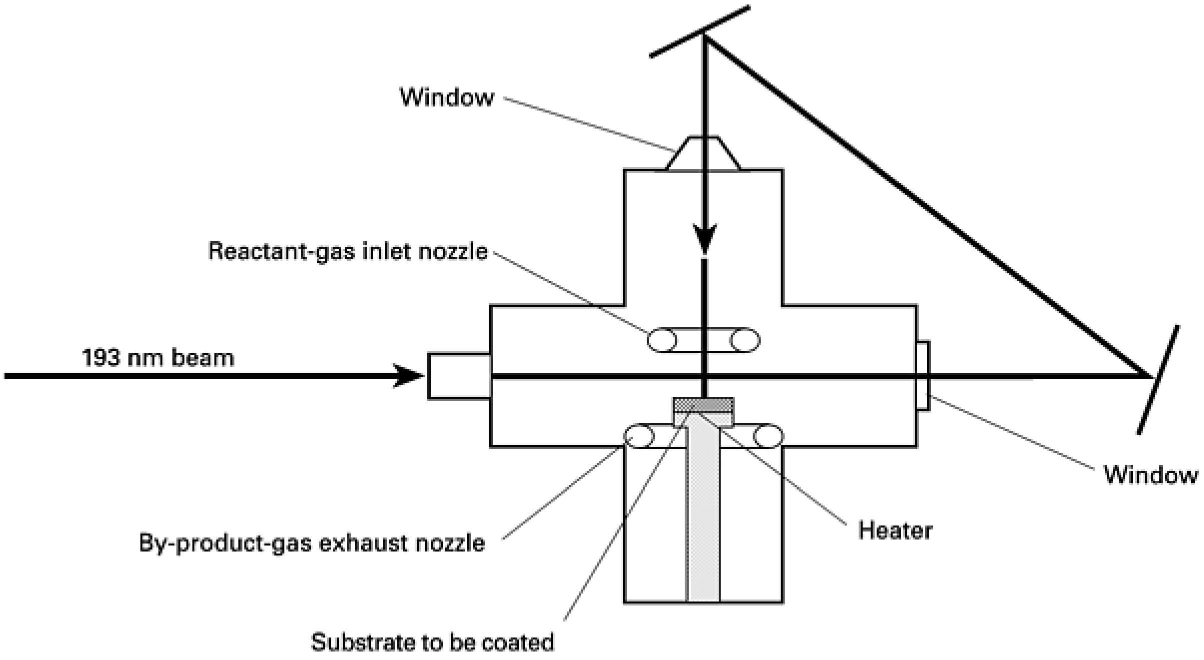

Fig. 5 Photo-laser CVD apparatus

Photo-laser CVD differs from thermal-laser CVD in that it does not require heat, because the reaction is photon-activated, and the deposition essentially occurs at room temperature. Moreover, there is no constraint on the type of substrate that can be used. It can be opaque, absorbent, transparent, or even temperature-sensitive.

A limitation of this method that has, to date, restricted its application is a slow deposition rate. If higher-power excimer lasers can be made more economical, then the process could compete with thermal CVD and thermal-laser CVD, particularly in critical applications where low temperature is essential.

Closed-Reactor CVD or Pack Cementation. The CVD systems described above use open reactors, in which reactants are introduced continuously and flow through the reactor (Ref 1). Another important system utilizes a closed reactor. The chemical vapor deposition in such a system is also known as pack cementation (Ref 13).

The entire process is carried out isothermally, because the driving mechanism for the reaction is not a difference in temperature, as in thermal CVD, but rather a difference in chemical activity between a metal in the free state and a metal in solution with another metal. A common reaction involves coating iron objects (such as turbine blades) with chromium, using chromium powder and ammonium iodide as reactants and aluminum oxide as an inert filler. Parts and chemicals are loaded in a molybdenum container that is then sealed, as shown schematically in Fig. 6. Pack cementation is a common industrial process with large-scale applications in chromizing, aluminizing, and siliconizing.

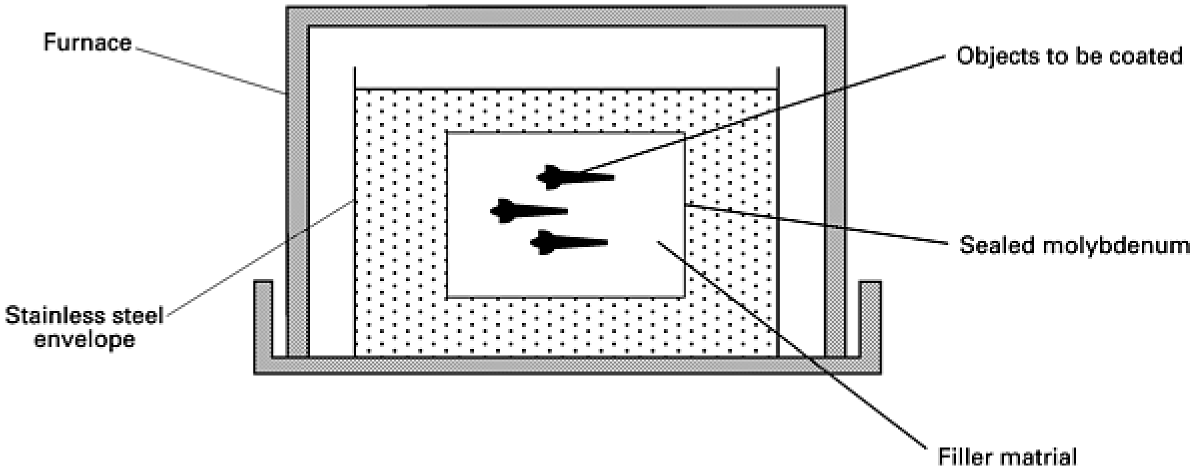

Fig. 6 Pack-cementation chromizing/siliconizing apparatus. Pack material composed of 3 wt% Cr, 11 wt% Si, 0.25 wt% NH_4I, and balance, Al_2O_3

Chemical vapor infiltration (CVI) refers to the particular CVD process in which gaseous reactants infiltrate a porous structure, such as an inorganic open foam or a fiber array. Deposition occurs on the foam or fiber, and the structure is gradually densified to form a composite (Ref 14).

In a typical CVI system (Fig. 7), both the gas inlet and substrate are water cooled, and only the top of the substrate is heated. Under pressure, the gaseous precursors enter the cool side of the substrate and flow through it to reach the hot zone, where the deposition reaction occurs.

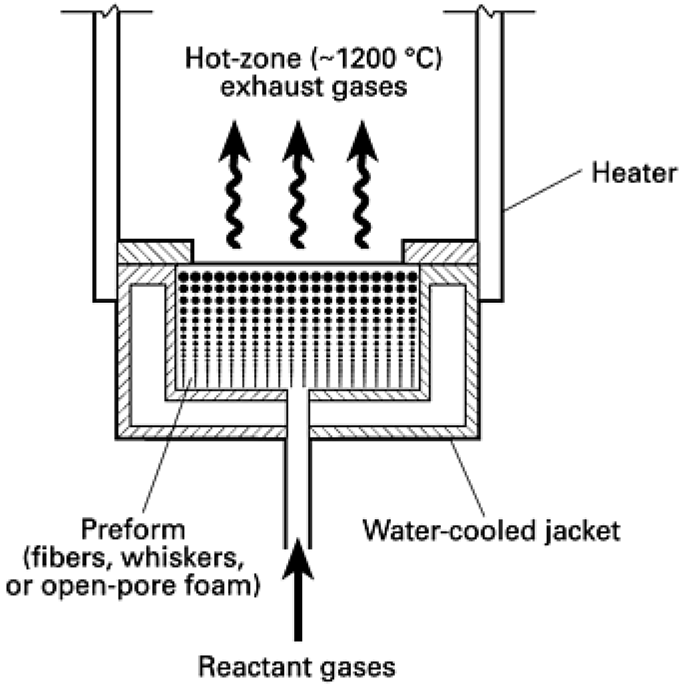

Fig. 7 Chemical vapor infiltration apparatus. Source: Ref 15

This process is used to produce high-strength silicon carbide and carbon-carbon composites, as well as other reinforced metal or ceramic composites. As contrasted with sintering, CVI does not require high pressure, and the processing temperatures are lower. As a result, mechanical and chemical damage to the substrate is minimized.

The major limitation of this method is the necessity for the interdiffusion of reactants and byproducts through relatively long and narrow channels. Chemical vapor infiltration is a slow process that can take several weeks. Full densification is nearly impossible to obtain because of the formation of closed porosity.

Metal-organic CVD (MOCVD) is a specialized process that utilizes organometallic compounds as precursors, usually in combination with hydrides or other reactants. Most MOCVD reactions occur at temperatures between 600 and 1000 °C (1110 and 1830 °F). When the most precise controls and high-purity gases are used, extremely thin deposits (<10 nm, or 0.4 μin.) with abrupt interfaces (<1 nm, or 0.04 μin.) can be produced. Because MOCVD equipment and chemicals are expensive and production costs are high, this method is considered most often when high performance is essential or when substrates are temperature sensitive.

The MOCVD method is being used extensively in microwave and optoelectronic applications, as discussed in detail in the article "Chemical Vapor Deposition of Semiconductor Materials" in this Section of the Volume. In addition, it is being introduced in wear and corrosion applications. An example of a nonsemiconductor application of MOCVD is the deposition of iridium via the decomposition of iridium acetylacetonate for oxidation protection (up to 2200 °C, or 3990 °F) of the maneuvering thruster nozzle of a spacecraft satellite (Ref 16). Additional information on the use of MOCVD in nonsemiconductor applications is provided in Ref 8.

Typical CVD Materials and Reactions

A wide variety of materials can be produced by CVD but, as mentioned earlier, only the most important of those related to hard, tribological, and high-temperature coatings and to free-standing structures are reviewed here. The CVD of other materials is described in Ref 1 and 17.

The metals most often deposited by the CVD technique include molybdenum, nickel, rhenium, and tungsten.

Molybdenum (Ref 17, 18). The hydrogen reduction of the chloride is most commonly used to deposit molybdenum:

$$MoCl_6 + 3H_2 \rightarrow Mo + 6HCl$$

The reaction temperature ranges from 400 to 1350 °C (750 to 2460 °F). The best deposits are obtained at the high end of this range and at low pressure (<2.7 kPa, or 20 torr).

Another well-established reaction is the decomposition of the carbonyl:

$$Mo(CO)_6 \rightarrow Mo + 6CO$$

The reaction temperature ranges from 300 to 700 °C (570 to 1290 °F), and pressure ranges from approximately 0.13 to 101 kPa (1 to 760 torr) in a hydrogen atmosphere.

Nickel (Ref 19, 20). The decomposition of nickel carbonyl is the most frequently used reaction to deposit nickel:

$$Ni(CO)_4 \rightarrow Ni + 4CO$$

The reaction temperature ranges from 180 to 200 °C (355 to 390 °F), and the pressure can be as high as 101 kPa (760 torr). More ductile nickel is obtained at low deposition rates.

Rhenium (Ref 21, 22) is generally deposited by the hydrogen reduction of the fluoride:

$$ReF_6 + 3H_2 \rightarrow Re + 6HF$$

The reaction temperature ranges from 500 to 900 °C (930 to 1650 °F). The best deposits are obtained at 700 °C (1290 °F) and at low pressure (<2.7 kPa, or 20 torr).

Another common reaction is the pyrolysis of the chloride:

$$2ReCl_5 \rightarrow 2Re + 5Cl_2$$

The reaction temperature ranges from 1000 to 1250 °C (1830 to 2280 °F). The best deposits are obtained at low pressure (<2.7 kPa, or 20 torr). This reaction usually gives a more ductile and purer material than the reaction given in Eq 4, although a higher temperature is necessary.

Tungsten (Ref 23, 24, 25) is usually obtained by the hydrogen reduction of the halide:

$$WF_6 + 3H_2 \rightarrow W + 6HF$$

The reaction temperature ranges from 300 to 700 °C (570 to 1290 °F), and pressure ranges from 1.3 to 101 kPa (10 to 760 torr). Deposition at a lower temperature (500 °C, or 930 °F) gives a finer grain structure with high strength (83 MPa, or 12 ksi) than deposition at a high temperature (700 °C, or 1290 °F).

Another deposition reaction for tungsten is the hydrogen reduction of the chloride:

$$WCl_6 + 3H_2 \rightarrow W + 6HCl$$

The reaction temperature ranges from 900 to 1300 °C (1650 to 2370 °F), and the pressure ranges from 2.0 to 2.7 kPa (15 to 20 torr). This reaction, which yields high-purity deposits, is used to coat x-ray targets and to produce structural parts.

Graphite (Ref 26). The CVD of graphite, which is relatively simple, is obtained by the thermal decomposition of a hydrocarbon. The most common precursor is methane, which is generally pyrolyzed at 1100 °C (2010 °F) and at a pressure ranging from approximately 0.25 to 101 kPa (2 to 760 torr):

$$CH_4 \rightarrow C + 2H_2$$

Another common precursor is acetylene (C_2H_2), which decomposes at temperatures between 300 and 750 °C (570 and 1380 °F) and at pressures up to 101 kPa (760 torr) in the presence of a nickel catalyst. A third precursor is propylene (C_3H_6), which decomposes at temperatures between 1000 and 1400 °C (1830 and 2550 °F) and at low pressure (13 kPa, or 100 torr).

Diamond (Ref 26, 27, 28). The CVD of diamond requires the presence of atomic hydrogen, which selectively removes graphite and activates and stabilizes the diamond structure. To dissociate hydrogen requires a high-energy source. In addition to the need for atomic hydrogen, other factors, such as energy input and the presence of oxygen, have been shown to be important, as well.

The deposition mechanism is complex and not fully understood at this time. The basic reaction involves the decomposition of a hydrocarbon, such as methane:

$$CH_4 \rightarrow C(\text{diamond}) + 2H_2$$

The reaction can be activated by microwave plasma, thermal means (hot filament), or plasma arc.

Diamond-like carbon (DLC) represents a new form of carbon coating that is neither diamond nor graphite. A common deposition method is a high-frequency RF gas discharge (13.56 MHz) generated in a mixture of hydrogen and a hydrocarbon, such as methane (CH_4), *n*-butane (C_4H_{10}), or acetylene (C_2H_2).

The technology of CVD diamond and DLC has progressed considerably, and applications are reaching the production stage in electronics, optics, and tribology. Cutting tools coated with CVD diamond have performed remarkably well and should enter the market soon.

The deposition of ceramics usually involves titanium diboride, boron carbide, silicon carbide, titanium carbide, boron nitride, silicon nitride, titanium nitride, or alumina, each of which is described below.

Titanium diboride (Ref 29) is deposited by the hydrogen reduction of the halides. A typical reaction is:

$$TiCl_4 + 2BCl_3 + 5H_2 \rightarrow TiB_2 + 10HCl$$

The reaction temperature ranges from 800 to 1100 °C (1470 to 2010 °F), and the pressure ranges from approximately 0.25 to 101 kPa (2 to 760 torr) in a hydrogen atmosphere. Titanium diboride also can be deposited with diborane as the boron and hydrogen source in the same pressure range, but at a reaction temperature ranging from 600 to 1000 °C (1110 to 1830 °F):

$$TiCl_4 + B_2H_6 \rightarrow TiB_2 + 4HCl + H_2$$

Boron carbide (Ref 30) is commonly deposited by this reaction:

$$4BCl_3 + CH_4 + 4H_2 \rightarrow B_4C + 12HCl$$

The reaction temperature ranges from 1200 to 1400 °C (2190 to 2550 °F), and pressure ranges from 1.3 to 2.7 kPa (10 to 20 torr).

Boron carbide also is deposited from diborane in a plasma:

$$2B_2H_6 + CH_4 \rightarrow B_4C + 8H_2$$

The reaction temperature is typically 400 °C (750 °F).

Silicon carbide (Ref 31, 32). Silicon carbide coatings and free-standing shapes are both important applications of the CVD process. A common CVD reaction is the decomposition of methyl trichlorosilane (MTS):

$$CH_3SiCl_3 \rightarrow SiC + 3HCl$$

The reaction temperature ranges from 900 to 1400 °C (1650 to 2550 °F), and pressure ranges from 1.3 to 6.7 kPa (10 to 50 torr) in a hydrogen atmosphere. The deposition rate and the crystallite size increase with the increasing partial pressure of MTS. Other precursor combinations are $SiCl_4/CH_4$, $SiCl_4/CCl_4$, SiH_2Cl_2/C_3H_8, and $SiHCl_3/C_3H_8$, usually in a hydrogen atmosphere.

Titanium carbide (Ref 33) is of major industrial importance in the coating of wear-resistant tools by the CVD process. The most common deposition system is the reaction of the metal chloride with a hydrocarbon:

$$TiCl_4 + CH_4 \rightarrow TiC + 4HCl$$

The reaction temperature ranges from 850 to 1050 °C (1560 to 1920 °F), and pressure varies from less than 0.13 to 101 kPa (1 to 760 torr) in a hydrogen atmosphere. Other carbon sources are toluene ($CH_3C_6H_5$) and propane (C_3H_8).

Boron nitride (Ref 34) is produced in a hydrogen atmosphere by the reaction of boron trichloride and ammonia:

$$BCl_3 + NH_3 \rightarrow BN + 3HCl$$

At a deposition temperature of 1300 °C (2370 °F), a low-density (1.5 g/cm^3) boron nitride is obtained. Density increases with increasing temperature and reaches 2.0 g/cm^3 at 1600 °C (2910 °F). Vapor-phase precipitation can be a problem in the high-temperature range. A more convenient reaction uses boron trifluoride:

$$BF_3 + NH_3 \rightarrow BN + 3HF$$

The reaction temperature ranges from 1100 to 1200 °C (2010 to 2190 °F), and the pressure is 101 kPa (760 torr).

Low-temperature deposition is possible with diborane:

$$B_2H_6 + 2NH_3 \rightarrow 2BN + 6H_2$$

The reaction temperature ranges from 300 to 400 °C (570 to 750 °F), and the pressure is less than 0.13 kPa (1 torr).

Silicon nitride (Ref 35) is deposited by the reaction of silicon tetrachloride with ammonia:

$$3SiCl_4 + 4NH_3 \rightarrow Si_3N_4 + 12HCl$$

The reaction temperature is 850 °C (1560 °F), and the pressure can go up to 101 kPa (760 torr). Silicon nitride also is deposited by the reaction of dichlorosilane and ammonia with a high nitrogen dilution:

$$3SiH_2Cl_2 + 4NH_3 \rightarrow Si_3N_4 + 6HCl + 6H_2$$

The reaction temperature ranges from 755 to 810 °C (1390 to 1490 °F). When a high-frequency (13.56 MHz) plasma is used, the deposition temperature is lowered (400 to 600 °C, or 750 to 1110 °F).

Titanium Nitride (Ref 36). A common reaction for the CVD of TiN uses N_2 $TiCl_4$ at temperatures above 900 °C (1650 °F) and at pressures up to 101 kPa (760 torr). Another reaction uses ammonia as a nitrogen source, as follows:

$$TiCl_4 + NH_3 + \frac{1}{2}H_2 \rightarrow TiN + 4HCl$$

Alumina (Ref 37, 38). A common reaction for the deposition of alumina is the hydrolysis of the aluminum trichloride:

$$2AlCl_3 + 3H_2 + 3CO_2 \rightarrow Al_2O_3 + 3CO + 6HCl$$

This reaction takes place in excess hydrogen, at an optimum temperature of 1050 °C (1920 °F) and at low pressure (approximately 0.13 kPa, or 1 torr).

Applications

Wear-, erosion-, and corrosion-resistance applications extensively utilize CVD coatings, as do applications that require low friction characteristics. Table 2 lists the properties of typical CVD coating materials for these applications. Some materials, such as titanium diboride, titanium carbide, and silicon carbide, provide extremely low wear rates. Table 3 lists specific production applications for the wear-, erosion-, and corrosion protection provided by CVD coatings.

Table 2 Selected wear and corrosion properties of CVD coating materials

Material	Hardness		Thermal conductivity, W/m · K	Coefficient of thermal expansion at 25 °C (77 °F), 10^{-6}/K	Remarks
	GPa	10^6 psi			
Titanium carbide	31.4	4.5	17	7.6	High wear and abrasion resistance, low friction
Titanium nitride	20.6	3.0	33	9.5	High lubricity; stable and inert
Titanium carbonitride	24.5-29.4	3.5-4.3	20-30	8	Stable lubricant
Chromium carbide	22.1	3.2	11	10	Resists oxidation to 900 °C (1650 °F)
Silicon carbide	27.4	4.0	125	3.9	High conductivity, shock resistant
Titanium diboride	33.0	4.7	25	6.6	High hardness, high wear resistance
Alumina	18.8	2.7	34	8.3	Oxidation resistant, very stable
Diamond-like carbon	29-49	4.2-7.1	200	. . .	Very hard, high thermal conductivity
Diamond	98	14.2	180	2.9	Extreme hardness and high thermal conductivity

The cutting-tool industry relies heavily on coatings. The technology associated with CVD has made some of its most important gains in this area. Major applications are represented by titanium carbide coatings on the majority of cemented (cobalt-bonded) tungsten carbide tools and both titanium nitride and carbonitride coatings on high-speed tool steel and cemented carbide tools.

The materials identified in Table 2 can be used as multilayer structures that utilize the strongest characteristics of each layer of material. Nearly all coatings are multilayer systems that combine titanium nitride for lubricity and galling resistance; alumina for chemical inertness and thermal insulation; and titanium carbide, as well as titanium carbonitride, for abrasion resistance. Selecting the optimum combination of materials depends on the type of machining operation, the material to be machined, and other factors. Criteria for such a selection are summarized in Table 4.

Table 4 Criteria for selecting coating materials for cutting tools

Property	**Best materials**[(a)]
Oxidation and corrosion resistance; high-temperature stability	Al_2O_3, TiN, TiC
Crater-wear resistance	Al_2O_3, TiN, TiC

Hardness and edge retention	TiC, TiN, Al_2O_3
Abrasion resistance and flank wear	Al_2O_3, TiC, TiN
Low coefficient of friction and high lubricity	TiN, Al_2O_3, TiC
Fine grain size	TiN, TiC, Al_2O_3

Source: Ref 39

(a) Al_2O_3, alumina; TiN, titanium nitride; TiC, titanium carbide. For each property, best material is identified first.

Titanium nitride, the most common coating material, is generally combined with a very thin undercoating of titanium carbide or titanium carbonitride to promote adhesion. Alumina coatings are preferred in high-speed machining applications in which oxidation resistance and high-temperature stability are the critical factors. Like titanium nitride, alumina is deposited on an intermediate titanium carbide layer.

A large variety of free-standing structures of refractory metals and ceramics are produced by the CVD process (Table 5).

Table 5 Free-standing structures produced by CVD

High-strength structural parts of nickel alloyed with small amount of boron
Shapes such as tubes, rods, and plates
Furnace muffles (tungsten)
Hollow spheres with thin walls (tungsten)
Boats and crucibles for liquid-phase and molecular-beam epitaxy (pyrolytic graphite), and crucibles for silicon single-crystal processing (silicon nitride)
Electrodes for plasma etching (pyrolytic graphite)
Trays for silicon-wafer handling (pyrolytic graphite)
Heating elements for high-temperature furnaces (pyrolytic graphite)
Aircraft disk brakes (carbon-carbon)
Re-entry heat shields, rocket nozzles, and other aerospace components (carbon-carbon)
High-temperature turbine blades and components for internal combustion engines (silicon nitride)
Heart valves and dental implants (pyrolytic carbon)

Note: Pyrolytic carbon is a generic term commonly used for CVD carbon, but usually applied to the low-temperature form (900 to 1400 °C, or 1650 to 2550 °F) with limited preferred orientation. Pyrolytic graphite is the higher-temperature product (1900 to 2300 °C, or 3450 to 4170 °F) with a high degree of preferred orientation in the "C" direction.

Ultrafine Powders by CVD. Powder is precipitated from the gas phase if the temperature and supersaturation of a CVD reaction are sufficiently high. The powder has few impurities, small diameter, and great uniformity, which are important factors in the production of high-quality hot-pressed or sintered ceramic bodies with good mechanical and electrical properties. In addition, the sintering temperatures required for CVD powders are lower than those for conventional powders.

The following powders are made experimentally or on a production basis:

- Beta SiC powder from methyl-trichlorosilane in the presence of hydrogen in an argon plasma or from tetramethylsilane in a flow-through reactor between 850 and 1500 °C (1560 and 2730 °F) (Ref 40)
- An amorphous silicon nitride powder produced by laser CVD from halogenated silanes and ammonia with an inert sensitizer such as SF_6 (Ref 41)

- Aluminum nitride produced from aluminum alkyl, and magnesium oxide produced from magnesium vapor and O_2 at 800 °C (1470 °F) and tungsten carbide (Ref 42)
- Iron, nickel, cobalt, molybdenum, and tungsten powders produced by the pyrolysis of the metal carbonyls or halides

CVD ceramic powders, such as SiC and Si_3N_4, are used either experimentally or in production in applications such as reciprocating engines, gas turbines, turbochargers, bearings, machinery, and process equipment.

Metallic and ceramic powders as small as 5 μm (200 μin.) in diameter can be coated with nickel or iron by CVD by the fluidized bed technique. A typical application is the coating of tungsten particles to promote sintering in powder metallurgy. Sintering time, sintering temperature, and grain growth are reduced, contamination is lessened, and properties are improved (Ref 43).

Boron and silicon carbide fibers are produced industrially by CVD (Ref 44, 45, 46). A monofilament starter core is required that is capable of being heated resistively, such as a tungsten or graphite fiber.

Boron fibers are produced by the hydrogen reduction of boron chloride at 1300 °C (2370 °F). The "boron" fiber actually consists of a boron envelope surrounding a tungsten boride core, which typically occupies 5% of the fiber cross section. The fiber has high strength, high modulus, and low density, but it also has a tendency to further grain growth at high temperatures, is highly reactive with many metals, and is costly.

CVD silicon carbide fibers are a recent development that show promise, and if the production cost can be reduced they may take over some of the applications of CVD boron fibers or other refractory fibers. They are generally produced by the reaction of silane and a hydrocarbon in a tubular glass reactor (Fig. 1). The substrate is a carbon monofilament that is precoated with a 1 μm (40 μin.) layer of pyrolytic graphite to ensure a smooth deposition surface and a constant resistivity.

SiC fibers have properties similar to those of CVD boron fibers, except that SiC is more refractory and less reactive than boron. The fibers retain much of their mechanical properties when exposed to high temperatures in air, up to 800 °C (1470 °F) for as long as 1 h. Most applications of CVD silicon carbide fibers are still under development, including:

- Reinforcement for ceramic and polymer composites
- Reinforcement for metal-matrix composites with such metals as titanium, titanium aluminide, aluminum, magnesium, and copper. Applications for these fibers are found mostly in advanced aerospace programs and include fan blades, drive shafts, and other components.

Advantages and Disadvantages of CVD

The CVD process has a number of important advantages that often make it the preferred method when producing hard, tribological, and high-temperature coatings and free-standing structures:

- Refractory materials can be deposited at temperatures far below their melting point or sintering temperatures.
- Near-theoretical density is readily achieved.
- Preferred grain orientation and grain size can be controlled.
- Processing at atmospheric pressure is possible.
- Good bonding to a substrate is generally obtained.

Furthermore, the process is not restricted to line-of-sight deposition, as it is for most PVD processes. Deep recesses, high-aspect-ratio holes, and other difficult three-dimensional configurations can usually be coated with relative ease.

In addition, the deposition rate is high and thick coatings can be readily obtained (in some cases, centimeters thick). The process also is generally competitive and, sometimes, even more economical than other coating processes.

Finally, the equipment is relatively simple, does not require ultrahigh vacuum, and generally can be adapted to many process variations. Its flexibility allows many composition changes during deposition, and the codeposition of compounds is readily achieved.

However, the CVD process is not the universal coating panacea. Because it is most versatile at a temperature of 600 °C (1110 °F) or higher, its applications are limited to substrates that are thermally stable at such a temperature. (The development of the plasma and metal-organic CVD processes partially offsets this problem.)

A second problem is that some chemical precursors are hazardous or extremely toxic, which necessitates a closed system.

A third problem is that many reactions either leave solid byproducts or generate solid byproducts with neutralizing solutions. These byproducts can be toxic and corrosive, which necessites the careful consideration of disposal procedures and incurs additional costs. The Environmental Protection Agency (EPA) has been very active, even stringent, in this regard, as have the state regulators of the EPA and Occupational Safety and Health Administration.

A fourth problem is that energy requirements can be high, especially when high deposition temperatures are required.

Finally, the efficiency of the process is sometimes low, resulting in high costs.

Chemical Vapor Deposition of Semiconductor Materials

Manijeh Razeghi, Northwestern University

Introduction

CHEMICAL VAPOR DEPOSITION (CVD) is the deposition of thin, solid films from gas-phase precursors. Growth usually occurs through heterogeneous reactions catalyzed by a heated surface, although homogeneous reactions also can occur in the gas phase. Gas-phase, or parasitic, reactions should be avoided, because they deplete the precursor process and may produce deleterious solid particles, or "dust."

Epitaxial deposition is a process that produces single-crystal films with the same crystallographic orientation as the underlying substrate. Epitaxial growth from a CVD process is sometimes referred to as vapor-phase epitaxy (VPE). Other epitaxial processes that have been developed since 1960 include molecular-beam epitaxy (MBE) and liquid-phase epitaxy.

The vapor-phase methods that are discussed in this article have several advantages, when compared with liquid-phase epitaxy. One is the flexibility of depositing films with distinctly different compositions than the substrates. Even disparate chemistries can be used to deposit epitaxial films, as long as the lattice constant is matched sufficiently to the substrate. An example is the growth of gallium arsenide on silicon. A second advantage is the availability of high-purity gaseous precursors. The refinement of liquid sources is much more difficult, and it limits the quality of the resultant films. Vapor-phase techniques permit the growth of multilayered structures with excellent compositional and dimensional control, as well as abrupt interfaces. A third advantage is that selected gas-phase processes can be scaled to large areas and batch processing for commercial production.

The ability to grow thin, epitaxial films and multilayers on a variety of substrates has led to the development of new devices and technologies. Silicon epitaxial films are used routinely in the manufacture of high-performance bipolar and complementary metal-oxide semiconductor (CMOS) integrated circuits. The deposition of compound semiconductors with direct bandgaps has led to the production of millimeter and microwave devices, as well as optoelectronic devices, such as lasers, light-emitting diodes, and high-efficiency photovoltaic cells. The ability to grow thin, multilayered structures with very fine dimensional and compositional control has made possible quantum-well devices and strained-layer superlattices. The development of devices with novel capabilities and higher performance levels will certainly continue as the control and understanding of the growth process matures.

This article describes vapor-phase growth techniques that are applied to the epitaxial deposition of semiconductor films. The growth of Group III-V compounds via the metal-organic CVD (MOCVD) method is emphasized, because that method has become the most widely used and commercially important process for depositing these materials. The advantages of MOCVD, when compared with techniques such as MBE and VPE, are defined. The thermodynamic and kinetic processes responsible for epitaxial growth also are presented.

Technique Principles

Vapor-Phase Epitaxy. Tietjen and Amick (Ref 1) demonstrated the growth of gallium arsenide phosphide (GaAsP) by VPE in 1966. The growth of materials based on indium phosphide (InP) can be achieved in a horizontal reactor with two temperature zones, such as a fused-silica tube surrounded by multiple furnace windings. High-purity hydrogen (H_2) is a common carrier gas, and arsine (AsH_3) and phosphine (PH_3) are used as the arsenic and phosphorus sources, respectively. Pure indium metal is used as the Group III elemental source. Gaseous species are generated in the first zone (source zone), which is held at a higher temperature than the second zone (deposition zone). For the growth of InP, gaseous species are generated at 750 to 800 °C (1380 to 1470 °F), according to the reactions:

$$2\ In + 2\ HCl \rightarrow 2\ InCl + H_2 \quad \textbf{(Eq 1)}$$

$$4PH_3 \rightarrow P_4 + 6H_2 \quad \textbf{(Eq 2)}$$

Deposition occurs in the temperature range of 650 to 750 °C (1200 to 1380 °F) in the second zone, according to the reaction:

$$P_4 + 4\ InCl + 2\ H_2 \rightarrow 4\ InP + 4\ HCl \quad \textbf{(Eq 3)}$$

To achieve the growth of multilayered structures, the substrate must be moved between reactors that use different chemistries. It is therefore difficult, if not impossible, to achieve layer thicknesses on the order of 5 nm (50 Å), as required for quantum-well or superlattice structures. Fine compositional manipulation favors the techniques of MBE or MOCVD, where the transport of source materials, rather than substrates, is controlled.

The MOCVD process uses at least one metal-organic chemical as a deposition precursor. The growth of Group III-V compounds from metal-organic and hydride sources was first reported by Manasevit in 1960 (Ref 2). In that experiment, InP was deposited from trimethylindium (TMIn) and PH_3 in a closed-tube system. Later, it was established that many common compound semiconductors could be deposited from metal-organic materials (Ref 3, 4, 5, 6). Manasevit coined the MOCVD acronym, which is used in this article. Other authors refer to organometallic CVD (OMCVD). When applied to the growth of epitaxial films, this technique is sometimes called metal-organic vapor-phase epitaxy or organometallic VPE. As used for the epitaxial growth of compound semiconductors, MOCVD has advanced rapidly since the mid-1980s. It has become established as a unique and important epitaxial crystal growth technique, yielding high-quality, low-

dimension structures for fundamental semiconductor physics research and production of useful electronic and photonic semiconductor devices.

A typical MOCVD reactor is shown in Fig. 1. Gaseous precursors are introduced to the reaction chamber from the gas manifold. To achieve the growth of Group III-V compound semiconductors, Group III alkyls and Group V hydrides can be introduced to the reaction chamber. The substrate, located on a hot susceptor, has a catalytic effect on the decomposition of the gaseous products. Growth occurs primarily on this hot surface. The MOCVD technique is attractive because of its relative simplicity, when compared with other growth methods. Excellent control over film composition can be achieved by precisely metering the amounts of gaseous species introduced to the chamber. Thus, MOCVD can be used to produce heterostructures, multiquantum wells, and superlattices with very abrupt transitions in composition, as well as alloys with tailored doping profiles.

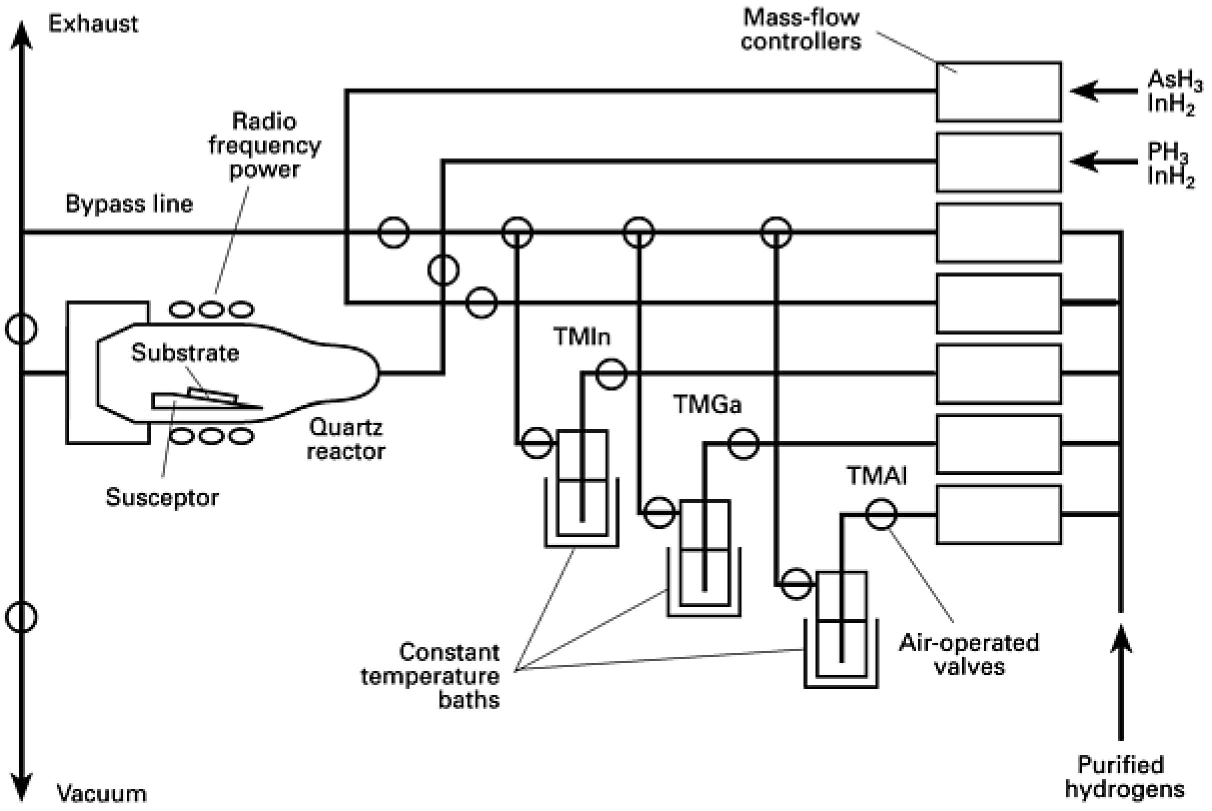

Fig. 1 Typical reactor design for metal-organic chemical vapor deposition. Source: Ref 7

Uniform layers with low background doping densities and sharp interfaces have been grown using MOCVD. Some reactor configurations in use are scalable to large areas, and are therefore attractive for commercial applications. This technique also has been used to produce multilayer structures with layers as thin as a few atomic layers (Ref 8, 9). These abrupt changes in composition produce quantum size effects (Ref 10, 11), and permit the study of two-dimensional electron gases (Ref 12, 13, 14, 15), two-dimensional hole gases (Ref 16, 17), and other charge-transport effects observed in a variety of Group III-V compound semiconductors, heterojunctions, and multilayers (Ref 18, 19). It is also possible to tailor the doping level or alloy composition of ternary and quaternary compounds. Varying the film composition results in a change in the bandgap (Ref 20). This ability to engineer the bandgap has created entirely new classes of electronic and photonic devices (Ref 21). Another recent advance is the ability to grow strained-layer superlattices, in which the crystal lattices of the two materials are purposely mismatched to produce a built-in strain in each layer (Ref 22, 23, 24, 25, 26).

A major disadvantage of MOCVD is the need for large quantities of toxic gases, such as AsH_3 and PH_3. However, less hazardous precursors, such as tertiarybutylphosphine (TBP) (Ref 27, 28) and tertiarybutylarsine (TBAs) (Ref 29, 30), are being developed to address this problem.

The MBE technique has been used to prepare epitaxial films of Group IV (Ref 31, 32), III-V (Ref 33, 34), and II-VI (Ref 35, 36) semiconductors, as well as metals (Ref 37, 38). In this technique, elemental sources are evaporated at

controlled rates by heating and then condensed onto a crystalline substrate surface held at a suitable temperature. This is an ultrahigh vacuum (UHV) technique, in which the beams of evaporated molecules or atoms are focused on the substrate. UHV conditions are necessary to ensure sufficient film purity. The use of UHV has two advantages. First, atoms and molecules reach the growth surface in a very clean condition. Second, the growth process can be monitored by in-situ diagnostic techniques as the crystal grows one atomic layer at a time (Ref 39). The diagnostic techniques that are used include reflection high-energy electron diffraction (RHEED), Auger electron spectroscopy (AES), x-ray photoelectron spectroscopy (XPS), low-energy electron diffraction (LEED), secondary-ion mass spectroscopy (SIMS), and ellipsometry.

The MBE technique is recognized as an excellent crystal growth technology for the production of complex and varied structures, especially for GaAs-based multilayer structures. It provides extremely precise control of layer thickness and doping profile. However, this technique is expensive because it requires UHV apparatus.

Another major problem is the incorporation of specific dopants. The typical approach is to add dopants by effusion of the elemental impurity, which leads to difficulty when the dopant vapor pressure is either too high (Ref 40) or too low (Ref 41) to be handled conveniently in an ultrahigh vacuum system. Because the MBE process is a near-equilibrium one, dopant incorporation can be hindered by low incorporation probabilities (Ref 42) or surface segregation effects (Ref 43). Phosphorus is one such dopant that suffers from a low incorporation probability. Instead of becoming incorporated into the growing film, it tends to "bounce around" the system, and eventually collects in the vacuum pumps. In addition, the growth of alloys containing both arsenic and phosphorus is particularly difficult because of surface segregation effects.

Hybrid MBE and CVD Techniques. Versatile growth techniques have been developed by combining the beneficial aspects of MBE and CVD. These hybrid techniques employ the gas-handling system of MOCVD and the growth chamber of MBE.

To overcome the limitations of growing phosphide compounds, elemental Group V sources are replaced by those that can decompose AsH_3 and PH_3. This technique is called gas-source molecular-beam epitaxy (Ref 44). In addition, Group III elemental sources can be replaced by simple metal-organic compounds to create the metal-organic molecular-beam epitaxy growth technique (Ref 45, 46). This technique is also known as chemical-beam epitaxy or metal-organic chemical-beam deposition (MOCBD).

The MOCBD technique has numerous advantages, when compared with MOCVD, including:

- Use of a fraction of the amount of PH_3 and AsH_3 for the growth of GaAs- and InP-based materials and the elimination of chemical waste-disposal systems, such as the scrubbers normally used in MOCVD
- Elimination of parasitic reactions in the gas phase because of UHV conditions
- Possible use of in-situ surface diagnostic techniques
- Improvement in homogeneity, composition uniformity, and reproducibility of InP-based materials over large-area substrates
- In-situ etching and removal of oxide during the growth of InP on silicon substrates
- Reduction of contamination from previous chemistries (the memory effect) during *p*-type doping
- Reduction of boundary-layer thickness on hot substrate surfaces
- Compatibility with other high-vacuum, thin-film processing techniques, such as plasma etching, metal evaporation, ion-beam etching, and ion implantation

Fundamentals of CVD

The fundamental processes that occur during crystal growth are commonly categorized into thermodynamic and kinetic components. Thermodynamics determine the driving force behind the overall growth process, whereas kinetics define the rates at which the various processes occur. Figure 2 depicts the fundamental processes involved in MOCVD. A study of the dependence of a macroscopic quantity, such as growth rate, on external parameters, such as substrate temperature and input precursor (source) flow rates, provides insight into the overall growth mechanism.

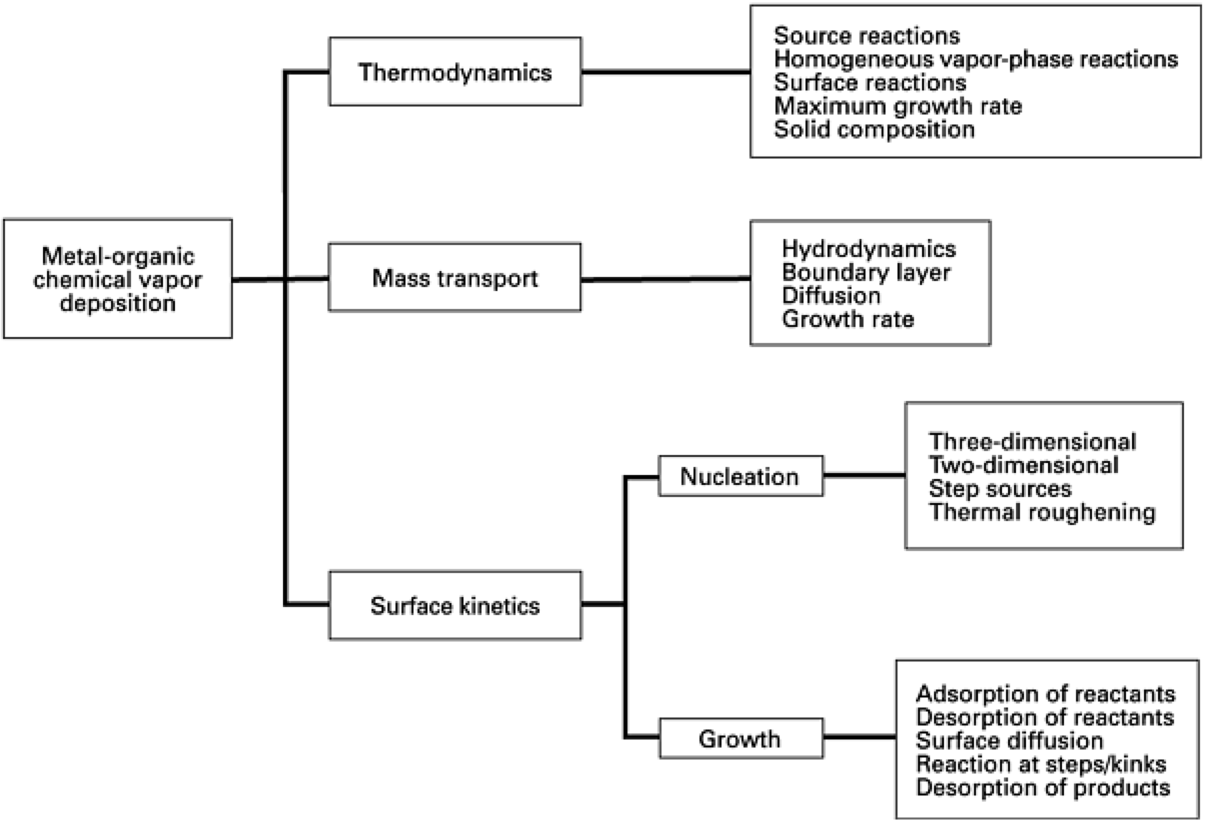

Fig. 2 Fundamental processes involved in metal-organic chemical vapor deposition. Source: Ref 47

Thermodynamics

The goal of thermodynamics is to define the composition of various phases in an equilibrium system at a constant temperature and pressure. Although many aspects of MOCVD growth are nonequilibrium, thermodynamics limits the possible outcomes. Thermodynamics can be used to describe the driving force for epitaxy and to specify the maximum growth rate. In addition, thermodynamic calculations often give an accurate account of the composition of multicomponent solids grown by MOCVD.

Equilibrium is the state that minimizes the Gibbs free energy, G, of the system:

$$G = H - TS \quad \textbf{(Eq 4)}$$

where H is the enthalpy, S is the entropy, and T is the temperature of the system. Entropy is a measure of the degree of randomness in a system, and enthalpy is a measure of the heat content, which can be defined as:

$$H = E + PV \qquad \textbf{(Eq 5)}$$

where E is the internal energy and V is the volume. The quantities G, H, S, E, and V are all extensive quantities, that is, they depend on the size of the system. They are therefore expressed on a per mole basis. For a system containing two phases, α and β, equilibrium is attained when a redistribution between phases causes no further decrease in free energy. This can be expressed mathematically as:

$$\left(\frac{\partial G'}{\partial n_i}\right)^{a}_{T,P,n_j} - \left(\frac{\partial G'}{\partial n_i}\right)^{b}_{T,P,n_j} = 0 \qquad \textbf{(Eq 6)}$$

where G' is the total free energy of the system (as opposed to the free energy per mole). The change in G' with respect to n_i is considered as all other variables (temperature, pressure, and molar amount of other components) are held constant. The partial derivative of G' with respect to n_i is such an important thermodynamic concept that it is given its own name, the chemical potential (μ_i). Thus, equilibrium is reached when:

$$m_i^a = m_i^b \qquad \textbf{(Eq 7)}$$

for each component, i, in the system.

When a system is not at equilibrium, the thermodynamic driving force to restore equilibrium is:

$$\Delta\mu = m_i^a - m_i^b \qquad \textbf{(Eq 8)}$$

This also is the driving force for epitaxial growth. In MOCVD, a nonequilibrium situation is intentionally created, in which the chemical potential of the solid phase differs from that of the vapor. The system restores equilibrium by producing the desired solid phase. The maximum quantity of solid produced is that which is needed to establish equilibrium. It is thus limited by the thermodynamics and size of the system.

The growth rate observed in MOCVD is almost always less than that calculated from thermodynamic principles. Kinetic factors, that is, either surface reaction rates or the diffusion of gas species through the vapor phase, are what limits the growth rate because they hinder the establishment of equilibrium. Driving forces for epitaxial growth are created in the vapor phase and the diffusion boundary layer, and at the interface between the solid and vapor, as depicted in Fig. 3(a). This diagram shows the driving forces necessary to sustain the flux for mass-transport processes ($\Delta\mu_D$) and surface reactions ($\Delta\mu_s$).

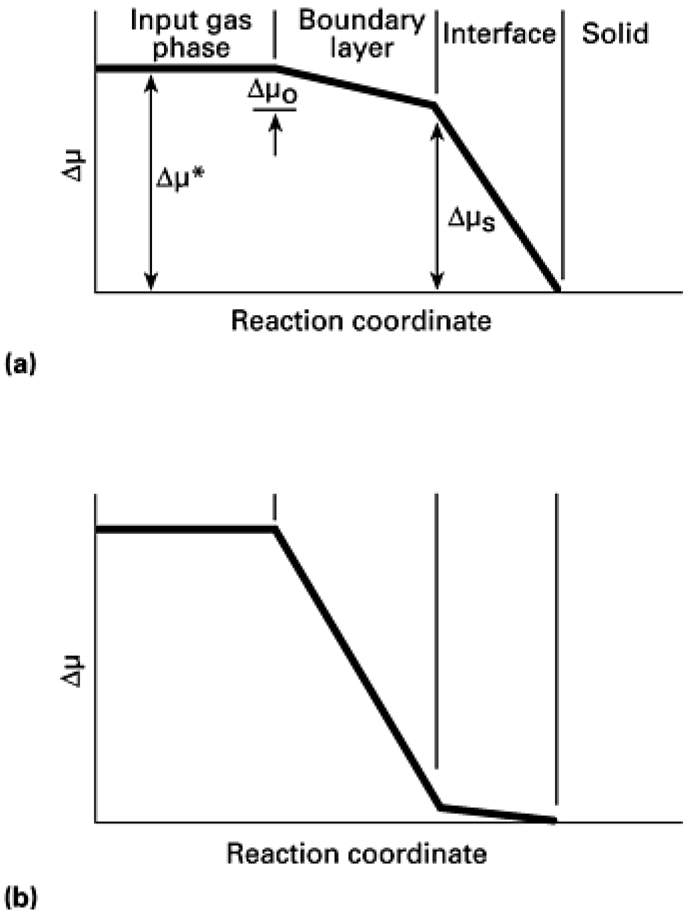

Fig. 3 Chemical potential in metal-organic chemical vapor deposition processes. (a) General case. (b) Mass-transport limited growth. Source: Ref 48

In any given MOCVD process, the shape of the Fig. 3(a) diagram depends on whether growth is limited by mass transport or by surface reactions. Even when there is a large supersaturation in the input vapor phase (a high degree of nonequilibrium), near-equilibrium conditions can exist near the growing surface. This occurs when the surface reactions are much faster than mass transport through the vapor. This situation, termed mass-transport limited growth, is depicted in Fig. 3(b).

Besides describing the driving force for epitaxy, thermodynamic calculations often give an accurate indication of the composition of multicomponent solids grown by MOCVD. Phase diagrams, calculated from the free energy of mixing, specify the number and composition of the phases in equilibrium at a constant temperature, pressure, and overall composition. An important quantity needed for the calculation of solid-solid, solid-liquid, and solid-vapor-phase equilibria is the heat of mixing in the solid, ΔH^M. This quantity, coupled with the assumption that constituents distribute randomly on their respective sublattices, allows calculation of the free energy of mixing of the solid alloy.

The simplest model that describes the free energy of mixing of semiconductor liquid and solid solutions is the regular-solution model. A regular solution, as defined by Hildebrand (Ref 49), is nonideal, but comprises a random arrangement of constituents. Two additional assumptions are that interactions occur only between nearest neighbors, and that atoms reside on a lattice, where each atom is surrounded by Z neighbors. For a solution consisting only of A and C atoms, the nearest neighbor bond energies that must be considered are H_{AC}, H_{AA}, and H_{CC}. The entropy of mixing is simply the ideal configurational entropy of mixing:

$$\Delta S^M = -R[x\ln x + (1 - x)\ln(1 - x)] \quad \textbf{(Eq 9)}$$

The enthalpy of mixing is obtained by summing the nearest neighbor bond energies:

$$\Delta H^{M} = x(1 - x)\Omega \qquad \textbf{(Eq 10)}$$

where the interaction parameter, Ω, is:

$$\Omega = ZN^{\circ}\left[H_{AC} - \frac{1}{2}(H_{AA} + H_{cc}\right] \qquad \textbf{(Eq 11)}$$

where N^0 is Avogadro's number.

Phase-diagram calculations are based on the free energy of mixing:

$$\Delta G^{M} = \Delta H^{M} - T\Delta S^{M} \qquad \textbf{(Eq 12)}$$

where the values for ΔH^M and ΔS^M are provided by Eq 9 and 10.

The regular-solution model does not provide much physical insight into the bonding and mixing of semiconductor solutions. As an empirical model, however, it can be used to interpolate and extrapolate phase-diagram information from limited experimental data. The regular-solution model has been used to calculate the phase diagrams in binary, ternary, and quaternary semiconductor systems.

Phase diagrams of many multicomponent systems are available in the literature (Ref 50, 51, 52). Thermodynamic analyses of solid composition against vapor composition have been published for the systems $GaAs_{1-x}P_x$, $InAs_{1-x}P_x$, $In_{1-x}Ga_xAs$ (Ref 53), and for the quaternary $Ga_{1-x}In_xAs_{1-y}P_y$ (Ref 54). Generally, good agreement between calculations and experimental results is obtained.

Kinetics and Gas-Phase Transport

Thermodynamics determine the state of a closed system at equilibrium and indicate what to expect from the reactants on a surface (substrate) at a given temperature. However, the MOCVD process is not, by definition, an equilibrium process. Thermodynamics can only define certain limits for the growth process. It is not possible to use thermodynamics to predict the time required to attain equilibrium, what steps to take to achieve the lowest energy state, or the rates at which various processes occur during the transition from precursors to solid. These problems can only be approached in terms of kinetics (Ref 48).

Deposition Reactions. Several types of reactions occur in the CVD growth process. Reactions that occur entirely in the gas phase are called homogeneous, whereas those that occur at a solid surface are called heterogeneous. Homogeneous and heterogeneous reactions are usually either unimolecular or bimolecular. The unimolecular process involves a single energetically activated species, and the bimolecular process requires the collision of two species to produce an activated complex. The probability of higher-order reactions is extremely low.

A simplified depiction of the growth processes for Group III-V compounds that occur near and at the substrate surface is shown in Fig. 4. This figure exemplifies the growth of GaAs by trimethylgallium (TMGa) and AsH_3. Several steps are involved in the growth of GaAs. First, both AsH_3 and TMGa, which are carried by hydrogen gas, diffuse through the boundary layer to reach the substrate. Second, gas-phase reactants are adsorbed on the surface through a series of surface reactions. Third, these species are incorporated into the solid GaAs film. Finally, the reaction products are removed. This four-step description is an oversimplification, because many individual reactions actually occur in the gas phase and at the substrate surface to achieve thin-film growth. Table 1 lists those gas-phase and surface reactions that likely operate in the growth of GaAs from TMGa and AsH_3.

(S25)	$As^* + As^* \rightarrow As_2 + CH_4$
(S26)	$GaCH_3^* + As^* \rightarrow GaAs + CH_3^* + S_G + S_A$

Note: * refers to surface adsorption, S_A to arsenic site, and S_G to gallium site.

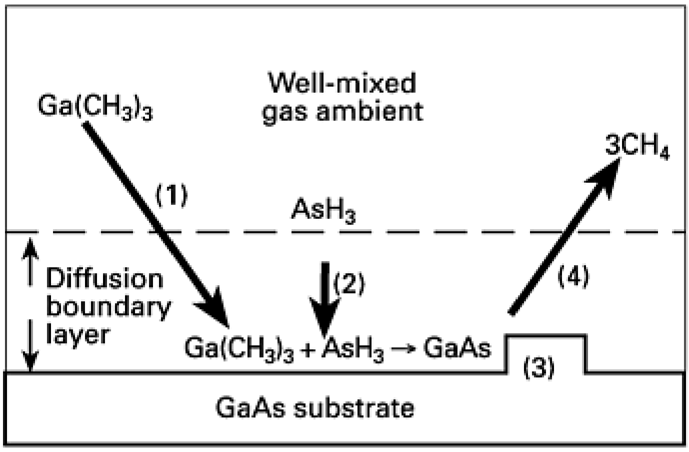

Fig. 4 Processes involved in the growth of gallium arsenide from trimethylgallium and arsine

A physicochemical model of the MOCVD process that combines models of fluid flow and heat transfer for a typical horizontal MOCVD has been presented by Jensen (Ref 55). This model predicts GaAs growth rates and carbon incorporation trends as a function of temperature, pressure, and Group V/III ratio.

In the general case of film growth from precursors, the chemical reaction pathways are not clearly understood. The surface reaction mechanism for growth is complicated by the large number of possible reactions. In Table 1, the general reaction pathway involves chemical reaction processes such as multistep pyrolytic decomposition of metal-organics and reactions with hydrogen radicals in the gas phase (G1 to G17) (Ref 56, 57, 58, 59), heterogeneous decomposition (S11 to S13), and surface adsorption and desorption (S1 to S13). The growth of the GaAs solid phase occurs via reactions between gallium- and arsenic-containing surface precursors (S22 and S26). Volatile reaction byproducts are removed from the surface by adsorption, interaction with colliding gas-phase radicals (S14 to S17, S24) and bimolecular surface recombination reactions (S18 to S21, S23, S25). Carbon incorporation occurs because of reactions S8 to S10.

Gas Flow Patterns. The gas velocities and temperature gradients in the vicinity of the hot susceptor play a significant role in the deposition process. The problems of reactor cell design and their solutions are best discussed in terms of the hydrodynamics of the reactant gas flowing into the cell. Important parameters include pressure, viscosity, volume, and temperature variation.

Laminar and Turbulent Flow. Consider a case of steady fluid flow through a uniform pipe. The flow may start uniformly, but can soon become nonuniform. After traversing a distance, *z*, which is the velocity entry length, the flow velocity $v(r)$ attains a parabolic profile, as shown in Fig. 5(a):

$$v(r) = -\frac{1}{4h}\frac{dp}{dz}(a^2 - r^2),\ for(0 \le r \le a) \quad \textbf{(Eq 13)}$$

where d*p*/dz is the pressure gradient, *a* is the cross-section radius, *r* is the radial axis, and ηis the dynamic viscosity. The flow in Fig. 5(a) is steady, nonuniform, and laminar. In laminar flow, the velocity is always the same at a fixed position. Each element of the reactive species travels smoothly along a simple, well-defined path, and each element starting at the same place follows the same path.

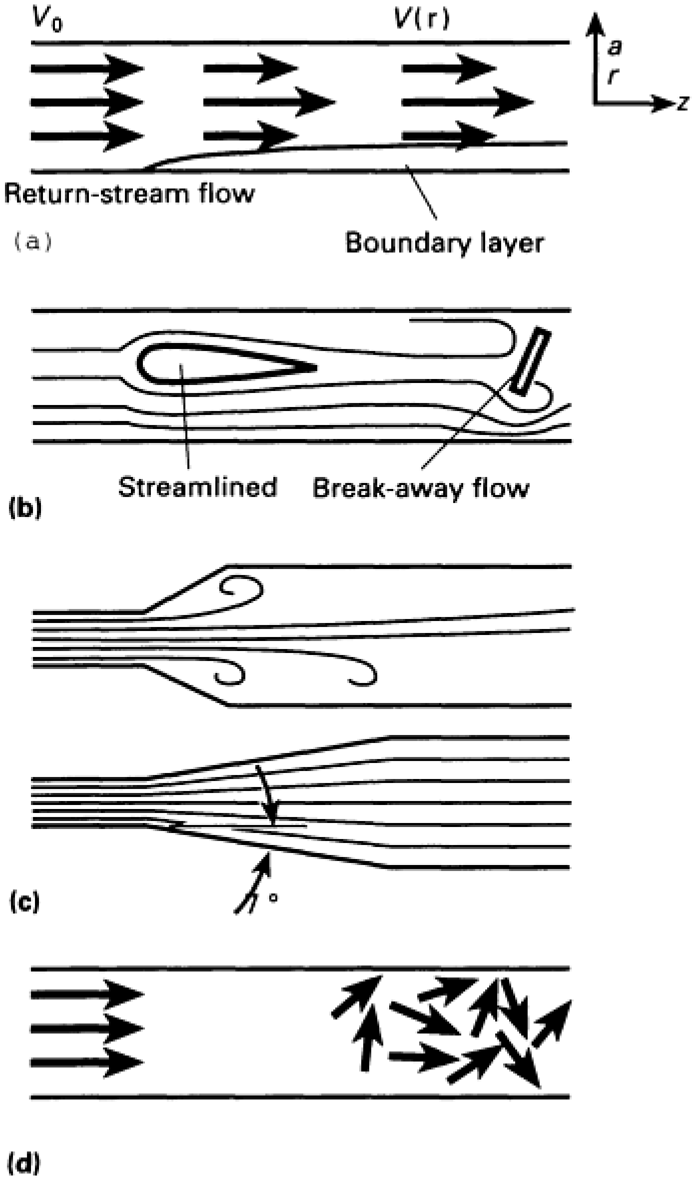

Fig. 5 Different gas flow patterns possible in chemical vapor deposition reactors. (a) Boundary layer of a gas flowing in a pipe and velocity distribution. (b) Stream lines showing adhered flow and break-away flow. (c) Flow patterns effected by expansion angle of tubes. (d) Effect of Reynolds number on flow properties. Source: Ref 48

The laminar pattern can easily be disturbed by either putting a barrier in the flow path (Fig. 5b) or changing the tube diameter (Fig. 5c). Stream lines are used to show the direction of gas molecules. In Fig. 5(b), the stream lines illustrate gas molecules that both break away from, and adhere to, the wall. In the first barrier in Fig. 5(b), a stream line adheres along the whole of its surface. The second barrier produces a break-away flow. The stream line that touches the edge of the barrier does not touch the plate anywhere else. The flow breaks away from the surface at this point. The wave behind the break-away flow may rotate slowly and form a stable eddy wave. When a susceptor is placed inside the reactor chamber at a large angle with respect to the flow direction, a break-away and return-stream flow is produced. This type of flow should be avoided because it can produce a "memory effect," that is, the composition of the growing layer is contaminated by residual gases used to grow previous layers.

Figure 5(c) illustrates gas flowing in a pipe that has a sudden change in cross-sectional area. When the cross-sectional area either increases or decreases, the gas will experience either a decrease or an increase in pressure, respectively. This kind of sudden momentum change can produce vortices. More importantly, vortices can be created by high flow velocities. As the mean velocity becomes larger, the velocity gradients also increase. The friction between adjacent layers of flow can become so high that local velocity components normal to the flow direction are no longer smoothed out. Instead, they progressively develop into turbulent or chaotic flow. When a pipe expands, the rate of decrease in pressure determines whether or not flow is smooth or turbulent. The rule of thumb for maintaining laminar flow is to avoid linear expansion angles, θ greater than 7° (Ref 55, 60).

When the flow becomes turbulent, it develops a highly random character with rapid, irregular fluctuations of velocity in both space and time. In this case, an element of gas flow will follow a highly irregular, distorted path (Fig. 5d). Different elements starting at the same place will follow different paths, because the pattern of irregularities changes all the time (Ref 61). The irregular motions do not affect all the molecules at the same instant, so that when the velocity is averaged out, it can still be thought of as a steady flow with a steady average velocity. The criteria that establish whether a gas will flow in a turbulent or laminar regime are characterized by the Reynolds number, R_e, which is defined as:

$$R_e = \frac{r v d}{h} \quad \textbf{(Eq 14)}$$

where ρ is the density in kg/m^3, ν is the average flow rate in m/s, and d is the diameter of the tube in m. When R_e is small (< 100), the flow regime is laminar.

Consider the case of parallel flow over a flat plate. The velocity distribution in the fluid phase is shown in Fig. 6. The flow is uniform, with velocity V_0, before the plate is inserted into the system. After the plate is introduced, a contiguous, low-velocity boundary layer develops. The width of the resulting boundary a layer for the condition $z > \delta_0$ is given by:

$$\delta_0 \approx 4.56\,(Dz/V_0)^{1/2} \quad \textbf{(Eq 15)}$$

where z is the distance measured from the leading edge of the susceptor, D is the diffusion coefficient, and V_0 is the entry velocity (Ref 62). The boundary layer width is proportional to the square root of z and inversely proportional to the square root of V_0.

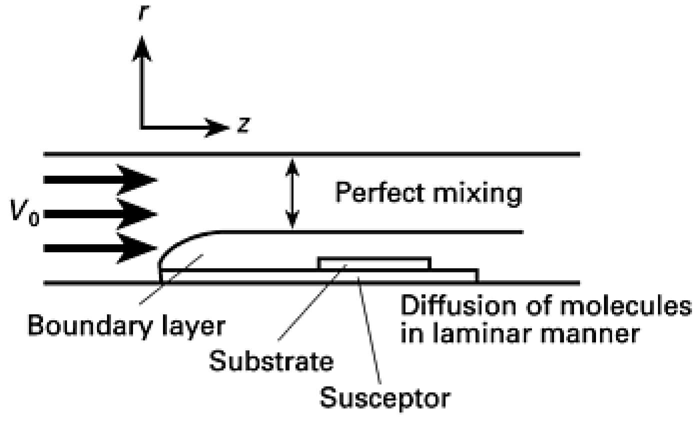

Fig. 6 Gas flow in a horizontal reactor

Effect of Substrate Heating. The introduction of heat adds another dimension of complexity to the gas flow, because convection is important in controlling gas flow along length of pipe. In a horizontal reactor chamber, the temperature difference from the chamber wall to the heated susceptor is enough to influence the flow of gas. When the thermal diffusivity is large and the temperature difference is small, the exchange of momentum is so fast, on a microscopic scale, that no real macroscopic gas-density gradients can develop. Hence, no buoyancy is observed, and the gas is said to be metastable. For higher temperature gradients and smaller heat diffusivities, the heavy, cold gas moves downward and the

light, hot gas near the susceptor moves upward. The buoyancy forces are so large that free convection occurs. The onset of free convection is characterized by the Rayleigh number, *Ra*:

$$\mathrm{R}a = \frac{a\, g C_p\, r^2 h^3 \Delta T}{h\, k} \qquad \textbf{(Eq 16)}$$

where α is the coefficient of thermal expansion in 1/K, *g* is the gravitational constant in m/s^2, C_p is the specific heat in J/kg · K, ρ is the gas density in kg/m^3, *h* is the free height above the susceptor in m, ΔT is the difference in temperature between the susceptor and the reactor wall, η is the dynamic viscosity in kg/ms, and *k* is the thermal conductivity in J/m · s · K). When *Ra* is less than or equal to 1700, the gas is stable. When *Ra* is greater than 1700, free convection occurs.

The flux, J_i, of a chemical species, μ_i, toward the susceptor surface now depends on the local temperature, the local temperature gradient, and the creation or annihilation of molecules during the reaction (Ref 63). Flux can be expressed as:

$$J_i = \frac{D_i}{RT}\left(\frac{P_1}{P_1 + (n-1)P_i}\frac{\partial P_i}{\partial z} + a\,\frac{\partial T}{\partial z} \right) \qquad \textbf{(Eq 17)}$$

where $D_i(T) = D_0(T/T_0)^2$ is the binary diffusion coefficient of species *i* as a function of *T, R* is a gas constant equal to 8.31 J/mol · K, P_t is the total pressure, P_i is the partial pressure of component *i*, *n* is the ratio of the number of molecules after and before the reaction, *z* is the direction normal to the susceptor surface, and α_i is the thermal diffusion factor for species *i*.

Modeling Gas Flow Patterns to Optimize Reactor Design. Two approaches are used to study gas flow patterns and the effect of reactor geometry on those patterns. The first approach is based on experimental observations, whereas the second is based on numerical calculation.

Flow patterns can be visualized by using smoke particles (Ref 64, 65, 66). Generally, titanium dioxide smoke is used. These experiments provide information about the existence of a boundary layer adjacent to the susceptor, the presence of temperature gradients perpendicular to the flow, and additional evidence of a convection-induced gas motion. Flow visualization experiments also provide a qualitative insight into the momentum transfer in the gas phase. The problem with a smoke test is that it does not give a clear boundary layer thickness, because smoke is heavier than the process gases.

Giling used holographic interference techniques to visualize temperature gradients (Ref 63). In this method, a light beam that passes through the reactor is compared with a reference beam that does not pass through the reactor. Small differences in the light paths become visible as interference patterns. If the flow is turbulent, then all fringe lines will move around, giving an incoherent image. When the flow is convective, the isotherms will be curved such that an upward or downward flow can be recognized. When the flow is laminar and stable against convection, fringes parallel to the hot surface will be formed. Giling analyzed flow images for hydrogen, nitrogen, argon, and helium carrier gases.

Berkman et al. (Ref 67) developed a detailed model of the flow dynamics, mass, and thermal gradients in a horizontal cold-walled reactor heated from below. The engineering formulas derived from hydrodynamic flow theories are easy to apply and correlate well with experimental observations.

There are two distinct zones above the susceptor in a reactor. The gas near the susceptor flows in a nearly laminar manner. Above that, the gas flow is turbulent, with oscillations of 3 to 5 Hz. The turbulence is caused by both thermal entry effects and buoyancy forces originating at the leading edge of the hot susceptor. The Berkman model treats the upper turbulent zone as a cold finger of well-mixed gas that acts as a reservoir of reactants. The lower zone acts like a laminar boundary layer, with a velocity profile that has average characteristics of both laminar and turbulent flow, through which the reactant is transported by diffusion. For a flat susceptor, the growth rate decreases exponentially along the susceptor as:

$$\exp(-Az) \qquad \textbf{(Eq 18)}$$

where

$$A = {2D_T}/{VTb_o^2} \quad \textbf{(Eq 19)}$$

and where V_T is the temperature-corrected gas velocity, D_T is the reactant diffusion coefficient at temperature T, and b_0 is the initial channel height above the susceptor. The exponential variation can be nullified by tilting the susceptor at an angle, θ_c (3 to 5°), such that:

$$\sin(q_c) = \frac{2D0}{b_0V_0}\left(\frac{T_a}{T_0}\right)^{0.88} \quad \textbf{(Eq 20)}$$

where D_0 is the diffusion coefficient of the precursor molecule measured at room temperature (T_0), T_a is the average temperature of the gas above the susceptor, and V_0 is the initial horizontal gas velocity at T_0 in front of the susceptor. Low-pressure MOCVD (~10 kPa, or 0.1 atm) increases V_0, allowing $\sin(\theta_c)$ to approach zero.

The rigorous simulation of mass transport in epitaxial systems involves solving the mass continuity equation and the Navier-Stokes equation of momentum conservation, according to the appropriate boundary conditions set by the geometry of the reactor, the heating method, and gas inlet and outlet flow (Ref 68). With the rapid advances in computation speed and memory over the last decade, numerical models have expanded from simple boundary-layer descriptions, to two-dimensional models, to three-dimensional descriptions of horizontal reactors (Ref 55).

The numerical modeling effort has focused on different reactor cells, such as return cells (Ref 69, 70), horizontal reactors (Ref 71, 72), and recirculation cells in the vertical reactor configuration (Ref 73, 74). The influence of inlet flow rate, pressure, and geometry on the flow pattern has been studied to understand the origin and nature of mixed-convection flows. Two-dimensional simulations of flow patterns have been generated for both horizontal and vertical reactor configurations (Ref 73, 74, 75).

The modeling of three-dimensional flow patterns for the growth of GaAs using TMGa and AsH_3 has been reported (Ref 55). The following boundary conditions were used to simplify the solution of the partial differential equations:

- No slip at solid walls
- Constant wall temperature or insulated side walls
- No flux on nonreacting surfaces or a flux balanced by the rate at which the species is incorporated into the growing film

Surface adsorptions are also considered in boundary conditions. The partial differential equations and the associated boundary conditions were transformed into a large set of nonlinear algebraic equations (on the order of 40,000 to 90,000) that were solved on a supercomputer using Newton's method.

The MOCVD Growth Technique

This section describes not only the reactor systems and hardware, but the engineering considerations that optimize growth, the MOCVD starting materials, and the growth parameters for a variety of Group III-V, II-VI, and IV semiconductors.

Reactor Systems and Hardware

The growth of Group III-V or II-VI compound semiconductors is achieved by introducing source materials into a reaction chamber (quartz tube or stainless steel) that contains a substrate on a heated susceptor. The hot susceptor has a catalytic effect on the decomposition of the gaseous products. Therefore, growth occurs primarily on this hot surface A typical MOCVD system (Fig. 1) consists of a gas-handling system, a reactor chamber, a heating system for pyrolysis temperatures, and an exhaust system and safety apparatus.

The purpose of the gas-handling system is to deliver the source alkyls and hydrides to the reaction chamber in precise, measured amounts. Gas manifolds, valves, flow controllers, and vacuum pumps are necessary to control the flow and mixture of gas. To grow high-quality layers, the gas-handling system must be clean. Stainless steel tubes are used to transport alkyls from the source to the reactor chamber, and electronic mass-flow controllers and thermal bath systems deliver precisely controlled amounts of gas.

Starting-material purity is one of the most important issues in modern semiconductor technology. Every material used in an MOCVD process is purified to avoid any kind of contamination. Gases used in an MOCVD reactor, including hydrogen, nitrogen, and helium carrier gases, can introduce contaminants to the semiconductor films. Contaminants can also be introduced by following improper procedures for gas-cylinder changing and vacuum-system maintenance.

Tubing, fitting, and valve selection is essential for the growth of high-purity films. Because some of the metal-organic sources and gases used in MOCVD are highly corrosive, components must be constructed of corrosion-resistant

materials. Most MOCVD reactors use seamless 316 stainless steel tubing that has been electropolished inside. Selecting the proper gasket materials in fittings and valves is equally important. More information on the selection of tubes and fittings is given in Ref 76.

Hydrogen Purifier. The standard purity of the hydrogen supplied by many gas companies is 99.99 vol%. The major impurities are oxygen and water. Standard purity is inadequate for the growth of high-quality semiconductors. Research-grade hydrogen gas, with a purity on the order of 99.9995 vol%, is an expensive solution. The normal practice is to use standard-purity hydrogen gas that is run through a purifier at the point of delivery. Besides economics, this approach minimizes any water contamination introduced in the tubing between the cylinder and purifier.

In a hydrogen purifier, the impure hydrogen is passed through a palladium alloy membrane that serves as the diffusion medium. The palladium is inside a cell, which is heated to between 400 and 425 °C (750 and 800 °F). At these temperatures, only hydrogen diffuses through the membrane; all other elements are blocked. This type of purifier effectively delivers ultra-pure hydrogen gas to the system.

Thermal Bath. The vapor pressure of metal-organic sources is a sensitive function of temperature. To ensure controlled and reproducible source delivery, the source must be kept in a well-regulated thermal bath. Commercial thermal baths are able to control the temperature with an accuracy of ±0.1 °C (0.2 °F). Temperatures can be varied in the range of -30 to 100 °C (-20 to 210 °F).

Electronic mass-flow controllers are used to regulate the amount of gas flowing into the chamber. The carrier gas flows through the metal-organic bubbler to transport the source vapor into the chamber. Gaseous hydrides are delivered directly. Each must be precisely controlled to dictate the composition of the semiconductor film. Mass-flow controllers use a closed-loop control system that compares the requested flow to the actual flow and adjusts accordingly. The typical accuracy of a mass-flow controller is ±1% of full scale. A significant advantage of electronic mass-flow controllers is the ease of automation and programming for the growth of individual layers. Mass-flow controllers from various vendors operate under different physical principles. Each has different strengths and weaknesses with respect to calibration, drift, temporal response, and maintenance.

The gas-mixing manifold is an important component of the MOCVD system. The proper design of this manifold is crucial for growing superlattices and quantum-well structures, and for reducing the memory effect associated with some dopant sources (Ref 77). Because the manifold must not introduce additional contaminants into the system, it is constructed of electropolished stainless steel tubing. Welding is used in lieu of compression fittings to avoid leakage. Because the manifold also must deliver uniformly mixed gases to the reactor, it is connected both directly to the chamber and through a bypass line to the exhaust. A process flow is first established and stabilized through the bypass line before being introduced into the chamber. The gas manifold utilizes pneumatically actuated valves to permit process automation.

Susceptor Heat System. Any of three types of heating methods are used to heat the susceptor: radio-frequency (RF) induction heating, radiant heating, and resistance heating. In RF induction heating, the graphite or silicon-carbide graphite susceptor is inductively coupled to an RF coil. This type of heating, which is used in big industrial reactors, is usually very complex. In order to avoid the complexity of RF heating, radiant heating is often used. Here the graphite susceptor is heated by absorbing the radiant energy from lamps. In resistance heating, metallic susceptors (aluminum and molybdenum) are heated by the resistance to electrical current flow. The temperature of the susceptor can be measured by using embedded thermocouples or a pyrometer. The temperature of the substrate on the susceptor usually cannot be measured directly, but is less than the susceptor temperature because of poor thermal contact.

The exhaust system is the most critical part of the MOCVD configuration in terms of safety. The two main functions of this system are to remove unreacted gases and byproducts from the reaction chamber and to provide a path for reactants to bypass the reaction zone. Unreacted gases can react in the exhaust system, creating solid particles. Because these particles can collect and block the exhaust system, great care must be taken to remove them. In addition, a blocked exhaust line can lead to sudden pressure changes in the reactor, creating a back diffusion of particles, which affects the growth quality and uniformity. The vented gas can contain unreacted sources that may be toxic, pyrophoric, or flammable. Various cleaning systems are available, such as scrubbing systems, particle filters, and burn boxes.

Effluent Scrubbing Systems. The semiconductor wafer fabrication industry uses a variety of corrosive, toxic, pyrophoric, and flammable chemicals. In order to control pollution by toxic materials, different types of scrubbers are used. In the past, it was commonly believed that many chemicals could be released into the environment without hazard if they were diluted to a safe concentration level, as determined by a regulating agency and dictated by the detection limits

of instrumentation or standards developed in response to exposure risks at the release site. The function of a scrubber was simply to reduce the concentration of contaminants produced to "safe levels." However, scientists have since demonstrated the negative impact of environmental contaminants at ever-diminishing levels. As a result, there has been a shift from scrubbers that simply dilute process gases to a new type of scrubber that can capture, isolate, and transform pollutants before allowing them to reach the environment.

As an example, a typical process for the epitaxial deposition of silicon requires the reaction of dichlorosilane (SiH_2Cl_2) and AsH_3. The scrubber is designed to remove the unreacted process gases in two stages. In the first stage, water removes unreacted SiH_2Cl by converting it to a complex mixture of solid silicon oxides. At the same time, hydrochloric acid (HCl) dissolves in the water and then exits the scrubber as aqueous HCl, which is neutralized. This reaction is summarized as:

$$SiH_2Cl_2 + AsH_3 + HCl \xrightarrow{H_2O} (SiO_2)_x + HCl_{(aq)} + AsH_3 + H_2 \qquad \textbf{(Eq 21)}$$

In the second stage, an oxidizing agent (e.g., potassium permanganate solution) oxides the arsenic to a solid residue, which then can be safely recovered for recycling. This reaction is written as:

$$AsH_3 + H_2 \xrightarrow{KMnO_{4(aq)}} As_2O_5 + MnO_2 + H_2 \qquad \textbf{(Eq 22)}$$

Because the solution used to remove toxic gases is expensive and its disposal difficult, scrubbers that use solid agents have been developed. By utilizing activated carbon, the toxic compounds from the effluent stream of MOCVD processes are adsorbed. In addition, controlled oxidation turns potentially harmful gases into solid oxides that have safer and easier disposal methods. This solid scrubbing is preferable to other methods, such as liquid scrubbers, burn boxes, and incinerators, which can cause back streaming or produce byproducts that are not wanted or have excessive disposal costs.

Burn boxes represent another way to dispose of unreacted materials from the exhaust. These boxes contain a furnace heated to a high temperature (900 to 1000 °C, or 1650 to 1830 °F), which cracks and oxidizes unreacted materials into less harmful compounds. Radical reaction products also condense on the quartz tube walls and are then removed as solids.

Particulate filters are used in conjunction with burn boxes or in front of pumping systems in low-pressure MOCVD systems. They must be able to remove particulates, resist clogging, minimize the exposure of maintenance personnel to arsenic dust, and contribute minimal internal outgassing.

Toxic-Gas Detectors. In the mid-1990s, almost all Group III-V growth systems use toxic gases such as AsH_3 and PH_3. Monitoring systems that are used to detect the presence of both AsH_3 and PH_3 provide a nearly instantaneous readout of concentration and initiate both warning and alarm signals whenever the preprogrammed concentration level for a particular gas and location is exceeded.

The solid-state gas sensors contain a heated resistor that is supplied with a specific voltage. When a gas enters the sensor, a voltage change is sensed because of the change in resistance. This voltage change is proportional to the concentration of the detected gas. The voltage is precalibrated in the factory for different gases and corresponding concentrations. The warning and alarm signals are set by the users, based on the safety level of each gas. Other types of toxic-gas detectors use chemically treated tape. Although they are more sensitive, they do not respond as quickly as solid-state detectors.

Engineering Considerations to Optimize Growth

Based on the study by Giling, as well as MOCVD growth practices (Ref 52), certain parameters are recommended for the growth of high-quality Group III-V semiconductor materials with sharp interfaces. First, laminar flows that are free of convection should exist by using a horizontal reactor, working at low pressure, and decreasing the reactor diameter. Second, temperature gradient should be present across the susceptor. Third, the memory effect should be eliminated by reactor geometries that prevent the development of vortices, and present no dead volumes. These conditions are designed to avoid parasitic reactions in the gas phase and condensation at the inlet of the deposition zone. Dead volumes should be avoided because they and the vortices will act as sources of unwanted materials that cannot be removed easily.

There have been at least 60 publications since the mid-1970s on the design of reactor cells and configurations. The essential factors in the design of horizontal cells have been established more recently (Ref 78, 79, 80, 81, 82, 83, 84). The ability to grow highly uniform compound semiconductors by MOCVD is influenced by a number of parameters in the

gas-handling manifold and the growth cell. Several reactor design modifications have been reported to improve uniformity. First, the manifold must incorporate a pressure-balanced vent-run system (Ref 78). In addition, gas mixing must occur on the atomic level to ensure sufficient homogeneity across the susceptor. Compositional nonuniformity is eliminated by using a variety of gas-mixing devices (Ref 85), including vanes, meshes, mixing jets, spray tubes, silica frits and orifices, and perforated plates that are either stationary or rotating (Ref 78). The expansion region must prevent flow separation from the cell walls that leads to recirculation, upstream deposition, and nonuniform layers (Ref 70, 84, 86, 87, 88, 89, 90). The space between the substrate and reactor wall must be small enough to prevent return flow (Ref 70).

To overcome gas-phase depletion and geometrical effects, the substrate can be rotated (Ref 91, 92, 93, 94). Another approach to this engineering problem is to levitate the wafer carrier on a gas foil (Ref 92). To avoid parasitic gas reactions and to improve layer quality (Ref 95), some reactors use two separate inlets.

The understanding of the MOCVD process, including gas flow patterns and chemical-reaction pathways, is still immature. Growth parameters, such as temperature, pressure, total gas flow, and Group III/V ratio, are optimized empirically. Material is grown and characterized by ex-situ techniques. These results are correlated with the deposition conditions to predict the best processing parameters.

MOCVD Starting Materials

The alkyls of Group II and III metals and the hydrides of Group V and VI elements are generally used as precursors in MOCVD. Dilute vapors of these chemicals are transported at or near room temperature to a hot zone, where pyrolysis reactions occur. For example, GaAs is formed by heating trimethylgallium, $(CH_3)3Ga$, or triethylgallium, $(C_2H_5)3Ga$, and AsH_3 over a suitable substrate, usually a single crystal of GaAs or silicon, at temperatures near 600 °C (1110 °F). The decomposition reactions can be expressed as:

$$(C_2H_5)_3Ga + AsH_3 \rightarrow GaAs + 3C_2H_6 \quad \textbf{(Eq 23)}$$

$$(CH_3)_3Ga + AsH_3 \rightarrow GaAs + 3CH_4 \quad \textbf{(Eq 24)}$$

The reaction for Group III-V compounds can be generalized as:

$$R_3M + EH_3 \rightarrow ME + 3RH \quad \textbf{(Eq 25)}$$

where *M* is the Group III metal (such as gallium, indium, or aluminum), *E* is the Group V element (such as arsenic, phosphorus, or antimony), and *R* is the alkyl radical (either CH_3 or C_2H_5).

Acceptable starting materials for MOCVD must be stable at room temperature and must not spontaneously decompose or polymerize. They also must vaporize in hydrogen, nitrogen, or helium gases without decomposing, be capable of purification, and have the lowest possible toxicity. Suitable starting materials and their physical properties are listed in Table 2. Each item in this table is either an alloy constituent or a dopant. Group III-V source materials will be discussed in detail, because they are primarily used in optoelectronic and high-frequency device applications.

Group III Sources. Trimethyl and triethyl alkyls have been used exclusively in the early development of MOCVD. The trimethyl sources are used most often because of their high vapor pressure and good stability. The triethyl sources, such as triethylaluminum (TEAl), triethylgallium (TEGa), and triethylindium (TEIn), are only marginally stable. The latter material has been observed to decompose in storage containers. It was also discovered that TEIn reacts with the Group V hydrides, AsH_3 and PH_3, to form nonvolatile adducts upstream from the substrates (Ref 50) in atmospheric-pressure MOCVD reactors. However, in low-pressure MOCVD reactors, TEGa and TEAl were used successfully to reduce the carbon concentrations in GaAs and AlGaAs (Ref 97). These materials evidently pyrolyze without producing the highly reactive methyl radicals that are generally believed to be the main source of carbon in the epitaxial layers. Recently, triisobutylgallium (TIBGa), which has an even lower thermal stability than TEGa, has been used to grow GaAs (Ref 98).

Trimethylindium is currently the most widely used source of indium. It avoids the stability problems associated with the use of TEIn. Parasitic reactions are not observed in atmospheric-pressure MOCVD growth when TMIn is used. However, TMIn has a nonuniform evaporation rate, because it is a solid at room temperature. It also has a tendency to explode. Alternative indium sources that are liquid below room temperature, have adequate vapor pressure, and exhibit good chemical stability are still being sought.

Knauf et al. combined the advantages of TMIn (less parasitic reactions) with those of TEIn (liquid during use) by producing a new compound, ethyldimethylindium (EDMIn) (Ref 99). This material is liquid at room temperature and has a vapor pressure of 115 Pa (0.85 torr) at 17 °C (63 °F), which is similar to the value for TMIn at 135 Pa (1 torr) and an order of magnitude greater than the vapor pressure of TEIn. In early experiments, EDMIn was not as pure as TMIn. However, it is now available in high-purity form, which makes it an attractive indium source.

The growth of semiconductors containing aluminum has always been difficult because aluminum is highly reactive and readily incorporates carbon and oxygen into the solid (Ref 100). The incorporation of carbon is particularly likely when trimethylaluminum (TMAl) is used, because it pyrolyzes to form aluminum carbide. Other alkyl sources, such as triethylaluminum (TEAl) and triisobutylaluminum (TIBAl), which decompose to aluminum metal, can be used to minimize carbon incorporation. However, they have low vapor pressures at room temperature. Heating to increase the vapor pressure requires that the gas lines and the reactor tube be heated along with the source. In addition, these compounds are not sufficiently stable to be effective. Kuech et al. has reported reduced growth efficiency, when these compounds are compared with other sources (Ref 97). This indicates the occurrence of parasitic reactions, predominantly premature pyrolysis, that create wall deposits upstream from the substrate. The most unstable of these compounds is TIBAl, which can decompose in storage containers at room temperature.

In order to provide an acceptable source of aluminum, new molecules with the appropriate properties must be developed. Dimethylaluminumhydride (DMAlH) has an acceptable vapor pressure of 265 Pa (2 torr) at 25 °C (77 °F) and pyrolyzes at a temperature as low as 250 °C (480 °F) (Ref 101). Both AES and SIMS analyses of films grown from DMAlH indicate little carbon contamination. It has been shown that DMAlH can produce excellent aluminum gallium arsenide (AlGaAs) epitaxial layers. The only problem is that the layers have a high background doping level, with an approximate *n*-type carrier concentration of $2 \times 10^{18}/cm^3$ ($33 \times 10^{18}/in.^3$). The background doping level is due to silicon and sulfur impurities in the DMAlH source. Preliminary photoluminescence data indicate that the carbon concentration is substantially less than levels produced in layers grown from TMAl.

Alternative sources for the MOCVD growth of Group III-V compounds are adducts. An adduct is a compound formed between a Group III alkyl, such as MR_3, that acts as an electron-acceptor molecule (Lewis acid) and a Group V alkyl, such as ER_3, that acts as an electron-donor molecule (Lewis base), according to the following reaction:

$$MR_3 + ER_3 \rightarrow R_3MER_3 \qquad \textbf{(Eq 26)}$$

Adducts were first proposed by Harrison and Tompkins for the growth of indium antimonide (InSb) and GaAs (Ref 102).

Since 1980, acid-base adducts, for example, TMIn-triethylphosphine (TEP) (Ref 103) and TMIn-trimethylphosphine (TMP) (Ref 104), have been used as alternative metal sources to eliminate parasitic reactions in the atmospheric-pressure MOCVD growth of InP (Ref 105, 106, 107). Adducts produce fewer parasitic reactions because of their high chemical stability. Today, trimethyl and triethyl alkyls produce less parasitic reactions because of their higher purity and improved, safer handling facilities. Nevertheless, the adducts are still used in many laboratories to produce high-quality InP (Ref 107, 108), GaInAs on InP quantum-well structures (Ref 109), and InP on silicon layers (Ref 106). The films exhibit almost the same quality and background doping levels as films grown from the alkyls using the same deposition conditions. The main advantages of adducts are their low reactivity with oxygen and water vapor, and their liquid form at room temperature. The adduct TEGa-TEP is used in place of TEGa because of its higher vapor pressure, compared to the gallium alkyls (Ref 110). The indium adducts, however, have rather low vapor pressures. They are normally used at temperatures above 60 °C (140 °F), and the gas lines of the MOCVD system must be heated to prevent condensation.

The development of new precursors with tailored physiochemical properties (vapor pressure, melting point, stability) is an emerging field of research. New, intramolecularly saturated dimethyl-3-dimethylaminopropylindium $(CH_3)_2In(CH_2)3N(CH_3)_2$ and the adduct trimethylindium-diisopropylamine, $(CH_3)3In\text{-}NH(C_3H_7)_2$, have been synthesized (Ref 111). The first epitaxial results with these compounds are very promising. Indium phosphide layers with electron mobilities of 50,000 $cm^2/V \cdot s$ (7750 $in.^2/V \cdot s$) at 77 K have been produced. Aluminum- and gallium-based semiconductors also have been successfully grown using these new sources. Moreover, such sources are expected to reduce carbon incorporation when combined with organometallic Group V sources, because they can be cracked to form stable organic molecules even in the absence of atomic hydrogen. For less stable organometallics, carbon incorporation seems to be lower. Plass et al. have employed TlBGa as a starting material, but impurities in the source caused the resulting layers to show a relatively high n-type conduction (Ref 98). Another type of alternative source has been investigated in order to provide a single source for both the metal and the Group V element. Maury et al. successfully grew GaAs layers using $(ClMe_2Ga\text{-}AsEt_2)_2CH_2$ and $(C_6F_5)_3Ga\text{-}AsEt_3$ without an additional arsenic source (Ref 112, 113, 114, 115, 116). However, the importance of such compounds is limited to the growth of binary materials. For atomic-layer epitaxy by MOCVD, More and Sasaoka et al. used $Ga(C_2H_5)_2Cl$ as a starting material (Ref 117, 118). Such reactants have not previously been used in a normal MOCVD process.

Group V Sources. The hydride gases commonly used as precursors for Group V elements are extremely hazardous and toxic. Both AsH_3 and PH_3 have threshold level values of 0.05 and 0.3 ppm, respectively. A summary of the effects on human exposure to arsenic and phosphorus hydrides is given by Hess and Riccio (Ref 119). In addition, these gases must be stored in high-pressure cylinders (equilibrium vapor pressures at 20 °C, or 70 °F, are 140 and 410 kPa, or 14 and 41 bars, for arsine and phosphine, respectively). Consequently, large quantities of these toxic gases may accidentally be released in a very short time. They must be handled very carefully, especially when changing cylinders. Thus, the utilization of AsH_3 and PH_3 requires costly and delicate equipment to protect the operators and the environment from hazards, and the products from atmospheric contamination. Less toxic and hazardous alternative sources are desired for safety reasons. A number of organometallic Group V sources are less toxic than the hydrides. Another advantage of the organometallic sources is that they have moderate vapor pressures. This results in a less hazardous working environment, because computer studies show that the dispersion of these materials is approximately two orders of magnitude slower than for the release of gases from high-pressure cylinders. A good review of nonhydride Group V sources is provided by Stringfellow (Ref 120).

Finding alternatives to the highly toxic AsH_3 has been the subject of recent research. Organoarsenic materials normally have much lower vapor pressures and threshold level values, which enable safer handling (Ref 121). The commonly used reactants are trimethylarsenic (TMAs) (Ref 122, 123) and triethylarsenic (TEAs). (Ref 52, 120, 122, 123, 124, 125). It was shown that TEAs is less stable than AsH_3 under normal growth conditions, enabling lower Group V-III ratios in the MOCVD process. However, in most cases, carbon incorporation is significant ($\geq 5 \times 10^{16}/cm^3$) (Ref 80, 126). In addition, epitaxial layer morphology is inferior, probably because of the incorporation of carbon and other atomic or molecular impurities.

Other materials, such as tertiarybutylarsine (TBAs) (Ref 30, 122, 127, 128), isobutylarsine (IBAs) (Ref 29, 129), dimethylarsine (DMAsH) (Ref 130), diethylarsine (DEAsH) (Ref 105), and phenylarsine ($PhAsH_2$) (Ref 122), have been used to overcome this problem. Some of them, especially TBAs and $PhAsH_2$, have shown promising results (Ref 30, 128). Most of the organoarsenic compounds mentioned above are commercially available. In addition to excess carbon incorporation, other disadvantages include their limited purity and high cost. The use of elemental arsenic seems to be unsuitable for a reliable epitaxial process (Ref 131).

Alternative phosphorus sources are also desired to minimize toxic waste and safety hazards. Initially, experiments were carried out using TMP and triethylphosphine TEP (Ref 132). However, they must be precracked before being introduced to the growth chamber because of their high thermal stability. This rather nonreproducible technique is therefore not suitable for MOCVD. The same holds true for elemental phosphorus sources, which were investigated by Naitoh et al. (Ref 133).

Larger organophosphorus molecules, such as TBP and IBP, have exhibited better growth results (Ref 28, 134, 135, 136). Tertiarybutylphosphine, in particular, has a favorable vapor pressure and is found to pyrolyze several hundred degrees lower than PH_3 (Ref 134). This can be an advantage when growing quaternary compounds (e.g., InGaAsP), which require arsenic and phosphorus sources with comparable thermal stability. Because the toxicity of TBP is much lower than that of PH_3, it is a good candidate for future investigations (Ref 120).

Group III-V Semiconductor Growth Parameters

Group III-V semiconductors are the major materials used in optoelectronic and high-frequency electronic device applications. The ability to tailor the band structure and lattice constant in ternary and quaternary alloys by varying the composition represents one of the desirable features of these materials.

The GaAs-based materials described below include not only GaAs, but gallium indium phosphide (GaInP), gallium aluminum arsenide (GaAlAs), and gallium indium arsenide phosphide (GaInAsP).

GaAs layers can be grown either at atmospheric or low pressure in the temperature range from 500 to 550 °C (Ref 52). TEGa or TMGa and AsH_3 have been used as gallium and arsenic sources. Pure hydrogen can be used as a carrier gas. The growth rate depends linearly on the flow rate of Group III (gallium) elements and is independent of AsH_3 flow rate, substrate temperature, and substrate orientation. This suggests that epitaxial growth is controlled by the mass transport of Group III species.

The growth of GaAs layers has been carried out on <100> GaAs substrates misoriented up to 2° toward the <011> plane. The substrates were etched in a H_2SO_4:H_2O_2:H_2O (5:1:1) solution for 20 s at 40 °C (105 °F), rinsed with deionized water, and dried under pure nitrogen. Before the growth process, the substrates were initially heated to the growth temperature under hydrogen and AsH_3 for 5 min to remove any surface oxides. Table 3 lists the optimum conditions for the low-pressure MOCVD growth of GaAs.

Table 3 Optimum growth conditions of gallium arsenide (GaAs), gallium indium phosphide (GaInP), and gallium indium arsenide phosphide (GaInAsP)

	GaAs	$Ga_{0.51}In_{0.49}P$	$Ga_{0.87}In_{0.13}As_{0.73}P_{0.27}$
Growth pressure, Pa (torr)	10,130 (76)	10,130 (76)	10,130 (76)
Growth temperature, °C (°F)	510 (950)	510 (950)	510 (950)
Total hydrogen flow rate, L/min (gal/min)	3 (0.8)	3 (0.8)	3 (0.8)
Arsine, cm^3/min ($in.^3$/min)	30 (1.8)	. . .	20 (1.2)

Trimethylindium, cm^3/min ($in.^3/min$)	. . .	200 (12)	150 (9)
Triethylgallium, cm^3/min ($in.^3/min$)	120 (7)	120 (7)	170 (10)
Phosphine, cm^3/min ($in.^3/min$)	. . .	300 (18)	200 (390)
Growth rate, nm/min (μin./min)	15 (0.6)	20 (0.8)	25 (1.0)

Note: For 808 nm (31.5 μin.) materials

Epitaxial GaAs layers are of the *n*-type in a wide range of Group V/III ratios and substrate temperatures. Suitable conditions, such as growth temperature, growth rate, total flow rate, purity of starting materials, and reactor design, are responsible for the high quality of the epitaxial layers.

GaInP layers can be grown on GaAs using MOCVD, either at atmospheric pressure or low pressure, in the temperature range from 500 to 600 °C (930 to 1110 °F) (Ref 137). Different Group III alkyls can be used for gallium and indium sources, whereas hydrides or alkyls can be used for the Group V phosphorus source. Chemical reactions that occur among these sources are:

$$0.51R_3Ga + 0.49\,R'_3In + EH_3 \text{-} Ga_{0.51}In_{0.49}P + nC_nH_{2n} \qquad \textbf{(Eq 27)}$$

where *R*, *R*', and *E* can be methyl, ethyl, alkyl, or hydride.

For example, one can use:

$$0.49(C_2H_5)_3In + 0.51(C_2H_5)_3Ga + PH_3 \rightarrow InGaP + nC_2H_6\text{, or} \qquad \textbf{(Eq 28)}$$

$$0.49(CH_3)_3In + 0.51(CH_3)_3Ga + PH_3 \rightarrow InGaP + nCH_4\text{, or} \qquad \textbf{(Eq 29)}$$

$$0.49(CH_3)_3In + 0.51(C_2H_5)_3Ga + PH_3 \rightarrow InGaP + nC_2H_6\text{, or} \qquad \textbf{(Eq 30)}$$

$$0.49(C_2H_5)_3In + 0.51(CH_3)_3Ga + PH_3 \rightarrow InGaP + nC_2H_6 \qquad \textbf{(Eq 31)}$$

The GaInP layers can be grown at the lower temperatures of 500 to 550 °C (930 to 1020 °F), by using TEGa, TMIn, and PH_3 in a hydrogen carrier gas. At optimum conditions (Table 3), the growth rate (dx/dt) of GaInP depends on the flow rates of TMIn and TEGa and is independent of the PH_3 flow rate and growth temperature. The undoped GaInP layer grown as specified has a free electron carrier concentration of $5 \times 10^{14}/cm^3$ ($80 \times 10^{14}/in.^3$), with a mobility of 6000 $cm^2/V \cdot s$ (930 $in.^2/V \cdot s$) at 300 K and 40,000 $cm^2/V \cdot s$ (6200 $in.^2/V \cdot s$) at 77 K. No GaAs buffer layer was grown in this case.

GaAlAs layers can be grown on a GaAs substrate in the temperature range of 600 to 750 °C (1110 to 1380 °F) by using TMGa, TMAl, and AsH_3 as the sources of gallium, aluminum, and arsenic, respectively. Oxygen incorporation, produced by the strong reactivity of aluminum with oxygen, can deteriorate the optical and electrical properties of the GaAlAs epitaxial layer (Ref 138). To solve this problem, graphite baffles are used for internal gettering. They absorb TMAl, which then reacts with oxygen to form the extremely stable, nonvolatile Al_2O_3 (Ref 139). It was later discovered that high-quality aluminum gallium arsenide (AlGaAs) can be grown at higher temperatures (<780 °C, or 1440 °F) without using oxygen-gettering techniques (Ref 140). This is because the aluminum suboxide that absorbs on surfaces at high temperatures is more volatile. It was demonstrated that at low aluminum concentrations, the photoluminescence intensity

increases by three orders of magnitude as the substrate temperature increases from 600 to 750 °C (1110 to 1380 °F). No effect occurs at high aluminum concentrations (Ref 141).

GaInAsP layers can be grown on GaAs by using low-pressure MOCVD within the entire composition range in which the quaternary is lattice matched to GaAs. Both TMIn and TEGa are used as the sources of indium and gallium, whereas AsH_3 and PH_3 are used as the sources of arsenic and phosphorus. The optimum conditions for the growth of GaInAsP (composition having a bandgap of 808 nm, or 31.5 μin.) on GaAs are listed in Table 3. The quality of the quaternary is comparable with that of the quaternary grown on InP substrates (Ref 142).

The InP-based materials described below include not only InP, but gallium indium arsenide (GaInAs) and gallium indium arsenide phosphide (GaInAsP) grown on InP.

High-quality InP layers have been grown by using MOCVD (Ref 52). Both TEIn and PH_3 are used as indium and phosphorus sources, respectively. A mixture of hydrogen and nitrogen is used as the carrier gas. The presence of hydrogen is necessary to avoid the deposition of carbon, and the presence of nitrogen is necessary to avoid the parasitic reaction between TEIn and PH_3.

The InP layers have been grown at 10 kPa (76 torr) and at low temperatures (between 500 and 650 °C, or 930 and 1200 °F) by using TEIn, PH_3, and a mixture of hydrogen and nitrogen as the carrier gas. The growth rate (ranging from 200 to 800 cm^3/min, or 12 to 48 $in.^3$/min) is linearly dependent on the TEIn flow rate, and is independent of PH_3 flow rate, substrate temperature, and substrate orientation. This suggests that epitaxial growth is controlled by the mass transport of Group III species.

Razeghi and Duchemin (Ref 18) have studied the growth of InP layers by using 100% hydrogen and mixtures of hydrogen and nitrogen as the carrier gas. The best morphology and the highest photoluminescence intensity were obtained by using 50% hydrogen and 50% nitrogen. Using argon instead of nitrogen produced InP layers with the same surface quality. Table 4 lists the optimum conditions used in this study for the MOCVD growth of InP in the temperature range of 550 to 650 °C (1020 to 1200 °F). The InP layers grown by MOCVD are less compensating at lower growth temperatures.

Table 4 Optimum growth conditions of indium phosphide

Growth temperature		Nitrogen-triethylindium bubbler flow rate		Phosphine flow rate		Total flow rate		Growth rate	
°C	°F	cm^3/min	$in.^3$/min	cm^3/min	$in.^3$/min	L/min	gal/min	nm/min	μin./min
550	1020	450	27	260	16	6	1.6	20±1	0.8±0.04
		225	14	200	12	6	1.6	10±1	0.4±0.04
650	1200	450	27	520	32	6	1.6	22±1	0.9±0.04
		225	14	400	24	6	1.6	11±1	0.4±0.04

GaInAs layers can be grown on InP substrates at 10 kPa (76 torr) in the temperature range of 500 to 650 °C (930 to 1200 °F), using either TEIn or TMIn, TEGa, and AsH_3 (Ref 52). When TEIn is used as the indium source, then pure hydrogen is used as the carrier gas. When TMIn is used, then a mixture of hydrogen and nitrogen is used as the carrier gas. The growth rate is linearly dependent on the combined flow rates of TEGa and TEIn. It is independent of the AsH_3 flow rate within the range of 60 to 90 cm^3/min (3.5 to 5.5 $in.^3$/min). This suggests, as in the case of InP, that epitaxial growth is controlled by the mass transport of Group III species. Uniform layers of $Ga_{0.47}In_{0.53}As$ have been deposited over

large areas (10 cm^2, or 1.5 $in.^2$) of InP substrates. The quality of the epitaxial layer is sensitive to the alloy composition, as in the case of GaInAs grown by other techniques.

The surface morphology of GaInAs grown on InP depends on the pretreatment of the substrate and is independent of the lattice mismatch, even when the mismatch is 0.01 or more. $Ga_{0.47}In_{0.53}As$ grown on InP exhibits an excellent surface morphology and state-of-the-art electron mobility when grown under the optimum conditions listed in Table 5.

Table 5 Optimum growth conditions of gallium indium arsenide/indium phosphide

Growth temperature, °C (°F)	550 (1020)
Total flow rate, L/min (gal/min)	7 (1.8)
Hydrogen-triethylindium bubbler flow rate, cm^3/min ($in.^3$/min)	450 (27)
Hydrogen-triethylgallium bubbler flow rate, cm^3/min ($in.^3$/min)	180 (11)
Phosphine flow rate, cm^3/min ($in.^3$/min)	90 (5)
Growth pressure, Pa (torr)	76 (0.6)
Growth rate, nm (μin.)	27 (1.05)

Note: Stoichiometry of material is $Ga_{0.47}In_{0.53}As$.

***$Ga_xIn_{1-x}As_yP_{1-y}$* layers** can be grown on InP substrates in the range of compositions that are lattice matched. Growth occurs at 10 kPa (76 torr) and at a substrate temperature between 630 and 650 °C (1170 and 1200 °F) using TEIn, TEGa, AsH_3, and PH_3 in a mixture of hydrogen and nitrogen carrier gas (Ref 52). The growth rate is linearly dependent on the sum of the partial pressures of TEIn and TEGa, and is independent of the arsenic and phosphorus partial pressures. The epitaxial layer quality is sensitive to the pretreatment of the substrate and the alloy composition. The optimum growth conditions for the lattice-matched composition, $Ga_{0.23}In_{0.77}As_{0.51}P_{0.49}$, are listed in Table 6.

Table 6 Optimum growth conditions of gallium indium arsenide phosphide/indium phosphide

Source	**Partial pressure**		**Temperature**	
	Pa	**mbar**	**°C**	**°F**
Triethylindium	0.85	0.0085	31	88
Triethylgallium	0.3	0.003	0	32
Arsine	31	0.31	25	77
Phosphine	700	7	25	77

nitrogen, 7 L/min (1.8 gal/min). Stoichiometry of material is $Ga_{0.28}In_{0.72}As_{0.61}P_{0.39}$.

Source: Ref 52

The nitride semiconductors described below include gallium nitride (GaN) and aluminum nitride (AlN).

High-quality GaN films have been very difficult to obtain because of the large mismatch in lattice constant and coefficient of thermal expansion with available substrates. The (001) plane of sapphire is often used, although the mismatch is large. Sun et al. recently discovered that the (012) plane is better matched with GaN and produces higher-quality GaN films (Ref 143). In the cited study, GaN was grown at atmospheric pressure in the temperature range of 900 to 1000 °C (1650 to 1830 °F), using TMGa and ammonia (NH_3) as the sources of gallium and nitrogen. The carrier gas was hydrogen. The precursors were mixed just before entering the reactor, in order to reduce the parasitic reactions between the metal-organics and NH_3. The total gas flow rate of 1600 sccm comprised 3 to 10 standard cm^3/min (sccm) TMGa, 500 to 1100 sccm NH_3, and carrier gas. The bubbler was kept at -10 °C (15 °F) for TMGa.

Aluminum nitride has been grown by using atmospheric-pressure MOCVD, with TMAl and NH_3 as the aluminum and nitrogen sources, respectively. The flow rates of each precursor were: 5 sccm of TMAl, 400 sccm of NH_3, and 1200 sccm of N_2. The TMAl was maintained in a bubbler at 25 °C (77 °F). The growth temperature was 1050 °C (1920 °F). Both the (001) and (012) planes of sapphire and the (100) plane of silicon were used as substrates. Thermal annealing under hydrogen and nitrogen caused no degradation of the crystalline quality, and improved the optical quality of the films (Ref 144).

The antimony-based materials described below include indium antimonide (InSb) and indium thallium antimonide (InTlSb).

Indium antimonide can be grown by using low-pressure MOCVD, with TMIn and trimethylantimony (TMSb) as sources for indium and antimony, respectively (Ref 145). Both InSb and GaAs (100) substrates were used in the growth process. Optimum growth conditions are listed in Table 7. The full width at half maximum of an x-ray rocking curve of 174 arc · s and a Hall mobility of 76,200 $cm^2/V \cdot s$ (11,820 $in.^2/V \cdot s$) at 240 K have been observed for a layer of 4.85 μm (190 μin.) grown under the optimum conditions.

Table 7 Optimum growth conditions of indium antimonide

Growth pressure, Pa (torr)	10,130 (76)

Source: Ref 145

Indium thallium antimonide was grown for the first time by using low-pressure MOCVD, with TMIn and TMSb as sources of indium and antimony, respectively, and cyclopentadienylthallium as the source of thallium (Ref 146). The optimum growth conditions are listed in Table 8.

Table 8 Optimum growth conditions of indium thallium antimonide

Note: TMG, trimethylgallium; PH_3, phosphine; TMSb, trimethylantimony; TEI, triethylindium; AsH_3, arsine; TMAl, trimethylaluminum; TMAs, trimethylarsenic; TMI, trimethylindium; TESb, triethylantimony

Group II-VI Semiconductor Growth Parameters

The Group II-VI semiconductors have been used for electroluminescent films (zinc sulfide and zinc selenide), infrared and far-infrared photodetectors (mercury cadmium telluride), thin-film photovoltaic devices (cadmium telluride), and, most recently, blue semiconductor lasers (zinc selenide).

The wide-bandgap materials described below include zinc selenide (ZnSe), zinc sulfide (ZnS), and zinc sulfide selenide (ZnS_xSe_{1-x}).

Both ZnSe and ZnS can be grown on GaAs or GaP substrates by using diethylzinc (DEZn) or dimethylzinc (DMZn) as the source of zinc, and either hydrogen sulfide (H_2S) or hydrogen selenide (H_2Se) respectively. However, the MOCVD growth of wide-bandgap selenides and sulfides has two major problems that are not encountered in the growth of Group III-V materials. The first is a premature reaction between DMZn and DEZn and H_2Se or H_2S, and the second is the formation of native defects, such as zinc, selenium, and sulfur vacancies at high growth temperatures. The first problem leads to poor surface morphology, whereas the second problem seems to be inherent to wide-bandgap semiconductors, especially materials that contain relatively high vapor pressure elements, such as ZnSe and ZnS.

The first problem can be solved by using both Group II and Group VI dialkyl sources, such as DMZn or DEZn and dimethylselenium (DMSE) or diethylselenium (DESe) because of the high decomposition temperature of these sources. The second problem can be reduced by decreasing the growth temperature. By using laser- or plasma-assisted MOCVD growth techniques, the growth temperature can be reduced to the range of 350 to 400 °C (660 to 750 °F) (Ref 155). Alternate precursors, such as Lewis acid-base adducts of dialkylzincs with dialkyl selenides or dialkyl sulfides and either H_2Se or H_2S, also reduce the growth temperature, although the premature reaction is not completely eliminated with these source combinations (Ref 156).

ZnS_xSe_{1-x} layers are lattice matched to GaAs and GaP substrates at x = 0.06 and x = 0.83, respectively. They can be grown at 500 °C (930 °F) using the precursors diethylsulfur (DES), DEZn, and DESe. The epitaxial layer shows excellent morphology, as evidenced by a narrow x-ray rocking curve (Ref 157). The growth temperature can be lowered by using an alternative source combination of the adduct, such as DMZn-DMSe, H_2S, and H_2Se, but it then becomes more difficult to control the alloy composition and attain lattice-matched layers. The growth mechanism that impedes control of the composition in this case is not clear. Photo-assisted CVD using alkyls of zinc, sulfur, and selenium as source materials is an effective low-temperature technique for the deposition of lattice-matched ZnSSe layers.

The narrow-bandgap materials described below include cadmium telluride (CdTe), mercury telluride (HgTe), and mercury cadmium telluride (HgCdTe).

Cadmium telluride can be grown by directly combining the vapors of the two elements, which are carried by hydrogen or nitrogen. Cadmium vaporizes at 756 °C (1390 °F), and tellurium, at 990 °C (1815 °F) (Ref 158). This material also can be grown by MOCVD through this reaction:

$$(C_2H_5)_2Te + Cd\ (vapor) + H_2 \rightarrow CdTe + 2C_2H_6 \qquad \textbf{(Eq 32)}$$

which takes place in the temperature range of 325 to 350 °C (620 to 660 °F), or through the reaction:

$$(C_2H_5)_2\,Te + (CH_3)_2Cd + nH_2 \rightarrow CdTe + \text{hydrocarbons} \qquad \textbf{(Eq 33)}$$

which takes place at substrate temperatures between 150 and 250 °C (300 and 480 °F) under the activation of an excimer laser (Ref 159).

Mercury telluride can be grown by using plasma-enhanced CVD, with dimethylmercury (DMHg) and dimethyltellurium (DMTe) as the mercury and tellurium sources, respectively. Williams et al. demonstrated a growth rate of 4 μm/h (160 μin./h) at a deposition temperature of 85 °C (185 °F), a pressure of 65 Pa (0.5 torr) and an RF power of 2 W at 15 MHz (Ref 160).

For HgCdTe, the selection of MOCVD growth temperature is a problem. The most commonly used tellurium precursor, diethyltellurium (DETe), pyrolyzes effectively only at a temperature of approximately 410 °C (770 °F). This is higher than the pyrolysis temperature of dimethylcadmium (DMCd), the Group II alkyl commonly used. The high temperatures

require a very high mercury pressure, which is supplied by heating elemental mercury. The combination of a high mercury concentration and a high molecular weight leads to convection cells in the vapor. It also results in the creation of large concentrations of mercury vacancies, which act as acceptors. Finally, the self-diffusion coefficients at 400 °C (750 °F) are large, precluding the growth of superlattice structures with abrupt interfaces. Lowering the growth temperature becomes the major consideration of the growth of HgCdTe. This material has been grown at 440 °C (825 °F) on GaAs and InSb substrates by using DETe and DMCd (Ref 161).

Group IV Semiconductor Growth Parameters

Silicon is the foundation of the present electronics industry. Epitaxial layers are used routinely in high-performance CMOS and bipolar technologies. Not surprisingly, the CVD process for silicon is the most mature. Germanium is another important Group IV semiconductor. Because both of these materials are grown from either chloride or hydride sources, they are categorized as CVD, rather than MOCVD, processes.

Epitaxial silicon (Si) layers can be grown at atmospheric pressure in the temperature range of 1050 to 1250 °C (1920 to 2280 °F), using either silicon tetrachloride ($SiCl_4$) or dichlorosilane (SiH_2Cl_2) as the source gas. Because this growth method is a high-temperature process, it is conducted during the initial stages of integrated-circuit manufacture. Lowering the deposition temperature minimizes dopant redistribution via solid-stage diffusion. Autodoping (the evaporation of dopants for the substrate and subsequent incorporation into the epitaxial layer) is reduced by operating at low temperatures and reduced pressures (Ref 162). Enhanced control of vertical dopant profiles permits the growth of thinner layers, which are necessary to achieve higher levels of integration. To achieve low-temperature growth, researchers have used lower-pressure processing and plasma-enhanced CVD (PECVD) methods, as well as silane (SiH_4) as a source gas.

The deposition temperature can be reduced to 825 °C (1520 °F) by using SiH_2Cl_2 in the pressure range of 1 to 3 kPa (8 to 25 torr) (Ref 163). By using SiH_4 as the source gas and utilizing very low pressures of 0.13 to 2.0 Pa (1 to 15 mtorr) to prevent parasitic reactions, epitaxial silicon can be deposited in the temperature range of 750 to 800 °C (1380 to 1470 °F) (Ref 164, 165). The growth temperature can be reduced to approximately 600 °C (1110 °F) by using a plasma-enhanced process (Ref 166). A review of PECVD methods is given by Reif and Kern (Ref 167).

Single-crystal germanium (Ge) can be grown by hydrogen reduction of the chloride in the temperature range of 600 to 900 °C (1110 to 1650 °F), according to the reaction (Ref 168):

$$GeCl_4 + 2H_2 \rightarrow Ge + 4\ HCl \qquad \textbf{(Eq 34)}$$

It is more widely grown by the decomposition of germane (GeH_4), usually at atmospheric pressure and at temperatures ranging from 600 to 900 °C (1110 to 1650 °F), according to the reaction:

$$GeH_4 \rightarrow Ge + 2H_2 \qquad \textbf{(Eq 35)}$$

Under low pressure (<130 Pa, or 1 torr), crystalline germanium can be grown in the temperature range of 350 to 400 °C (660 to 750 °F), using the above reaction (Ref 169).

Germanium also can be grown by using low-pressure MOCVD, with tetrapropylgermanium, $Ge(C_3H_7)_4$, and tetraethylgermanium, $Ge(C_2H_5)_4$, as the precursor and helium or hydrogen as the carrier gas. Growth temperatures range from 575 to 700 °C (1070 to 1290 °F) (Ref 170).

Silicon carbide (SiC) can be grown by the reaction of silane with a hydrocarbon such as propane or benzene, as expressed by the reactions:

$$3SiH_4 + C_3H_8 \rightarrow 3SiC + 10\ H_2 \qquad \textbf{(Eq 36)}$$

$$6SiH_4 + C_6H_6 \rightarrow 6SiC + 15\ H_2 \qquad \textbf{(Eq 37)}$$

The reaction temperature is about 800 °C (1470 °F), with a pressure of 1.3 KPa (10 torr) (Ref 171). The decomposition of methyl silane (Ch_3SiH_3) can be used to produce amorphous silicon carbide at 800 °C (1470 °F) and crystalline silicon carbide at 900 °C (1650 °F) (Ref 172).

Plasma-Enhanced Chemical Vapor Deposition

Prabha K. Tedrow, Consultant; Rafael Reif, Massachusetts Institute of Technology

---

Introduction

PLASMA-ENHANCED CHEMICAL VAPOR DEPOSITION (PECVD), also known as plasma-assisted CVD, is an important technique used for depositing films of a wide variety of crystalline and noncrystalline materials. Examples of

films that are commonly deposited using the PECVD process are noncrystalline materials such as oxides, nitrides, and oxynitrides of silicon (Ref 1), and crystalline materials such as polycrystalline silicon (Ref 2, 3, 4), epitaxial silicon (Ref 5, 6, 7), and refractory metals and their silicides. All of these materials are extensively used in microelectronic device fabrication, and PECVD is a critical process step in the fabrication of modern silicon devices. PECVD is also used in depositing optical coatings and other crystalline compounds such as titanium nitride, which is used in highly wear-resistant coatings on cutting tools (Ref 8).

Thermally driven atmospheric-pressure and low-pressure chemical vapor deposition (APCVD and LPCVD, respectively) are well understood and established methods for depositing films in integrated circuit (IC) fabrication technology (see the article "Chemical Vapor Deposition of Semiconductor Materials" in this Volume). However, the deposition temperatures in a thermally driven CVD process can be quite high (e.g., 700 to 900 °C, or 1300 to 1650 °F, for LPCVD silicon nitride deposition) (Ref 1, 9) and thus are detrimental to modern silicon devices. Plasma enhancement of the CVD process makes it possible to lower the deposition temperature significantly (e.g., to 250 to 300 °C, or 480 to 570 °F, for PECVD of silicon nitride) (Ref 1, 9) while maintaining a reasonable rate of deposition and film quality. Thus, some of the advantages of PECVD are that:

- Films can be deposited on substrates that would be unstable at higher temperatures (e.g., intermetallic dielectric layers deposited on aluminum or the encapsulation of ICs).
- Lower-temperature film deposition in microelectronic circuits allows precise control of dopant migration. The dimensions of modern microelectronic devices are getting smaller, increasing the importance of this control.

This article discusses application of the PECVD process in the deposition of amorphous and crystalline films from the point of view of microelectronic device fabrication. Plasma enhancement of the CVD process is discussed briefly, followed by a description of various types of PECVD reactors. Deposition techniques and the properties of some of the amorphous and crystalline films deposited by the PECVD process for IC fabrication are also described.

Process Description

In a thermally driven CVD process, component elements of the film to be deposited are introduced into the reaction chamber via gaseous precursor reactants. The reactants are mass-transported to the surface of the hot substrate, where they are adsorbed. If the substrate is heated to an appropriate temperature for the desired chemical reaction to take place, films of the material to be deposited form on the substrate surface while the reaction byproducts are pumped out of the system. Thus the quality and the rate of film deposition are a function of, among other things, reactor geometry, partial pressures of the reactants, and the substrate temperature. Although the thermally driven CVD process is thermodynamically quite well understood and is widely used for the deposition of some films (e.g., undoped

polycrystalline silicon), high deposition temperatures could be quite prohibitive for other applications (e.g., deposition of intermetallic dielectrics).

In the PECVD process, the gaseous precursors are most commonly subjected to time-varying electric fields of frequencies in the range of 50 kHz to 13.5 MHz. In some designs, microwave frequencies are also used. The electric field initially reacts primarily with the free electrons present in the gas. Although the electric field also reacts with the ions, these species remain initially unaffected because of their higher mass. The electrons undergo elastic and inelastic collisions with the gas molecules, but the electrons do not lose much energy during the elastic collisions because they are much lighter than the gas molecules. Loss of electronic energy during inelastic collisions with the gas molecules occurs only if the electrons, accelerated by the electric field, acquire energy that is higher than the threshold energies for excitation and ionization for a particular gas species (e.g., 11.56 eV for excitation and 15.8 eV for ionization of argon) (Ref 10). The inelastic collisions between these energetic electrons and gas molecules generate highly reactive species such as excited neutrals, free radicals, and ions, as well as more electrons. By this mechanism, the energy of the electrons is used to create reactive and charged species, while the gas temperature does not increase substantially.

In the PECVD environment, only a fraction of the precursor species in the gas phase undergo electron impact ionization and excitation, thereby generating the reactive species. The latter have a lower energy barrier to physical and chemical reactions than the parent species and consequently react at lower temperatures. Thus in the PECVD process, these reactive species lead to lower deposition temperatures and higher deposition rates than are possible with only thermally driven CVD. In film growth with the PECVD process, in addition to the unchanged parent species, these highly reactive species also diffuse to the surface of the substrate, where they are adsorbed and undergo a sequence of processes similar to that of thermal CVD. But these reactive species follow an alternate deposition pathway that proceeds parallel to the thermal pathway, because:

- The reactive species created during the inelastic collisions of gas molecules with energetic electrons have a sticking coefficient closer to unity (Ref 10); that is, once they reach the surface of the substrate, they tend not to escape.
- The activation energy for chemical dissociation is typically lower for these plasma-enhanced reactions (Fig. 1).

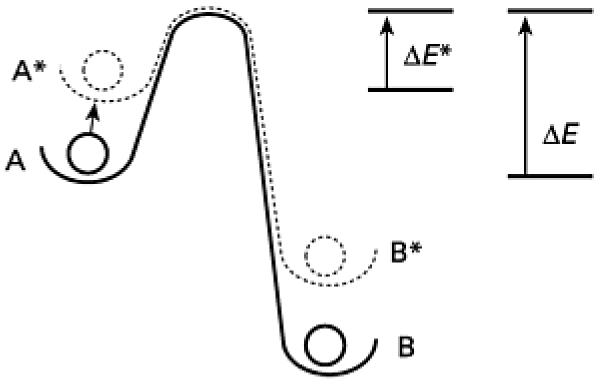

Fig. 1 Activation energy diagram for thermally driven (solid line) and plasma-enhanced (dashed line) chemical vapor deposition reactions. A and B, initial and final energy states, respectively, for the thermally driven reaction; ΔE, activation energy; A*, B*, ΔE*, corresponding parameters for the plasma-enhanced reaction. Source: Ref 11

Some heat is needed to drive the reaction over E*, but as shown in Fig. 1, this energy is typically lower than the energy needed for a purely thermally driven reaction to proceed at a reasonable rate. If the substrate is kept at a temperature such that the deposition proceeds at a very slow rate without the plasma but at a reasonable rate once the plasma is switched on, a plasma can be used as a "switch" to turn the deposition reaction on and off (Ref 12). Switching the plasma on and off can be used to start and stop the deposition process. Extremely abrupt layers can be grown by this technique, because the time required for the plasma to switch is equivalent to that between gas molecule collisions (e.g., 1 ms at 1 torr) (Ref 13). The thermal energy in a PECVD process, in addition to driving the surface reaction, is also needed for desorption of

the reaction byproducts, minimizing adsorption and the inclusion of undesired gases in the deposited film, thereby lowering film contamination.

Typically, radio-frequency (rf) glow discharges used for the deposition of thin films operate at frequencies between 50 kHz to 13.56 MHz and at pressures of 0.1 to 2.0 torr. The plasma density (i.e., the density of ions and free electrons) is in the range of 10^8 to 10^{12} cm^{-3}. The degree of ionization is 10^{-4}. Typical average electron energies are in the range of 1 to 3 eV, but the fastest electrons may reach energies as high as 10 to 30 eV (Ref 14).

In a PECVD deposition system, many factors can affect the growth, composition, and the properties of deposited films, in addition to conditions such as the substrate temperature, reactor geometry, and reactant partial pressures, which are important in thermally driven CVD film growth. Some of these factors are plasma power, frequency, electrode spacing, and substrate positioning. In these plasma glow discharges, the PECVD environment is not in thermal equilibrium because the average electron energies are much higher than the ion energies. Consequently, thermodynamic calculations cannot reliably predict the product of a PECVD reaction (Ref 13).

Types of PECVD Systems

As with thermal CVD reactors, PECVD systems can be either the hot-wall type, in which the reactor walls, the substrate, and the reactant gases are all at the same temperature, or the cold-wall type, in which only the substrate is heated to the desired temperature. In addition, PECVD reactors can be of direct or remote plasma type, where consideration is given to the plasma generation and what is coupled to this plasma. Numerous articles in the published literature (Ref 15, 16, 17, 18, 19, 20, 21) describe in detail the different geometries of commercial PECVD reactors and their use in the deposition of specific films.

In a direct PECVD system, all the reactant gases as well as the substrate are exposed to the rf plasma glow. A schematic of a direct plasma cold-wall reactor is shown in Fig. 2. The upper electrode is connected to the high-frequency rf power generator through an impedance-matching network. The reactants are introduced through the upper electrode, which is perforated, and directly enter the plasma region. The gases are pumped out at the bottom of the chamber. The lower electrode is a continuous plate and has a resistive heating element to heat the substrates. Substrates (wafers) are placed on the lower electrode and are thus immersed in the plasma as well as heated to the desired temperature of deposition.

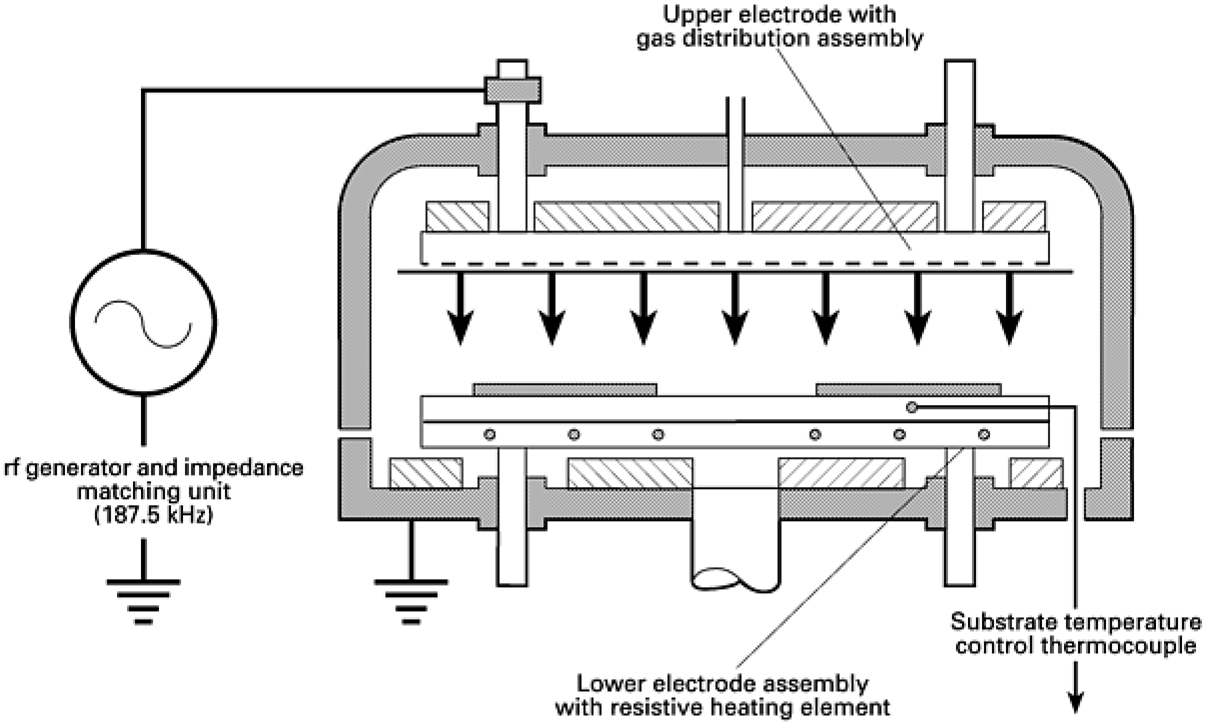

Fig. 2 Schematic of a direct plasma cold-wall reactor. Source: Ref 17, 22

Remote PECVD Systems. In a direct PECVD system, the substrate is exposed to the plasma discharge environment, which may cause radiation damage in the film being deposited. In a remote PECVD system, the substrate is removed from the plasma glow, and the reactant gases may be selectively excited by the plasma. The excited species are then carried to the substrate surface, where they react with other adsorbed gaseous reactants and the desired chemical reaction for deposition takes place. Keeping the substrate out of the plasma glow eliminates the deleterious effects of radiation. Moreover, this technique allows independent optimization of plasma, reactant gas chemistries, and wafer parameters.

One example of a remote PECVD system is shown in Fig. 3. This reactor was designed and built at the Massachusetts Institute of Technology (Ref 23) for metallo-organic CVD (i.e., CVD where some of the source gases are metallo-organic compounds) of gallium arsenide. The reactor consists of three vertically aligned concentric regions. The group III source gases enter through the center tube, the group V source gases enter between the inner and center tubes, and the reaction byproducts are exhausted between the inner and outer tubes. The substrate rests horizontally on a SiC-coated graphite disk, which is heated from below by a 750 W quartz halogen lamp with an elliptical reflector. The reactor can be equipped with internal electrodes fabricated of either aluminum or tantalum that can be connected via feedthroughs to an external power source to generate the plasma. The electrode configuration consists of an aluminum cylinder, 5 cm (2 in.) in diameter and 4 cm (1.6 in.) long, placed parallel to the gas stream. The distance between the wafer and the plasma can be varied by moving the electrode up or down in the inner quartz tube. In this design, the substrate receives a uniform distribution of plasma species and uniform infrared heat.

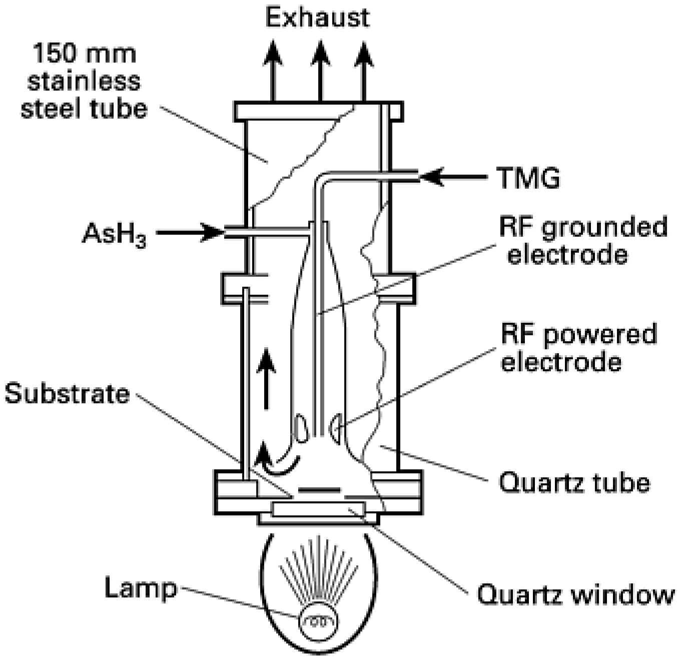

Fig. 3 Schematic of a remote plasma-enhanced chemical vapor deposition reactor for depositing compound semiconductor films. TMG, trimethylgallium. Source: Ref 23

Hybrid PECVD systems are a combination of the direct and remote PECVD systems. One example of such a system is a reactor designed for the deposition of amorphous hydrogenated silicon (Ref 24). In this reactor, one of the electrodes is replaced by a grid and the substrate is positioned directly under it. The substrate is thus shielded from the direct plasma glow while the reactant gases are subjected to the plasma discharge.

In some PECVD systems, microwave power is used to generate plasma. The plasma is excited by the resonance of microwaves and electrons through a microwave discharge across a magnetic field of 800 to 1200 G. This process, called electron cyclotron resonance, allows the film to grow at high rates of deposition at very low gas pressures (!10^{-4} torr) and at very low temperatures (<275 °C, or 525 °F) (Ref 25). The plasma is contained magnetically in the system and the deposition occurs outside the glow region, while all the gases are subject to plasma excitation.

PECVD of Dielectric Films

One of the most important uses of PECVD is in the deposition of dielectric films used in microelectronic device fabrication. The ability to deposit films of a dielectric such as silicon nitride, silicon oxide, or silicon oxynitride at lower temperatures is critical in the manufacture of modern very-large-scale integration (VLSI) chips. Fabrication of devices with smaller dimensions requires precise control of dopant movement during the multistep processing sequences. In addition, deposition of dielectrics used in intermetallic layers and/or chip encapsulations also requires low-temperature depositions.

Silicon nitride films provide an excellent barrier against alkali ions and moisture and are thus the material of choice as a final passivation and coating layer for ICs. The PECVD technique makes it possible to deposit silicon nitride films at temperatures in the range of 250 to 400 °C (480 to 750 °F), which is low enough to be deposited over device wafers with aluminum metallization and interconnects. Silicon nitride films deposited by the PECVD process are generally represented as $Si_xN_yH_z$ because they are not stoichiometric and contain bonded hydrogen. The films can be deposited by using silane (SiH_4) and ammonia (NH_3) as source gases for silicon and nitrogen, respectively. The depositions are normally carried out at pressures of 0.2 to 3 torr, and film growth rates at these pressures are about 200 to 500 Å/min. These films contain 15 to 30 at.% H bonded to either silicon or nitrogen (Ref 9, 26, 27).

Another choice of reactant gases can be silane and nitrogen (N_2). In this case, the deposition rates are low and the films tend to be silicon-rich. The SiH_4-N_2 chemistry tends to yield films that have less hydrogen and an excess of nitrogen, and that have poorer step coverage of the underlying metal.

Film properties such as refractive index, stress, and optical absorption edge are greatly affected by the concentration and chemical bonding of the hydrogen in the film. Other film properties (e.g., electric breakdown strength, etch rates in hydrofluoric acid, diffusion barrier to alkali ions and moisture, and stress) are also functions of the film composition and are very sensitive to the reactor geometry and deposition conditions.

Both bonded hydrogen and a high level of stress are harmful to the chips on which the films are deposited. Hydrogen tends to escape from the films when further processing is done at temperatures higher than the deposition temperature, and this can change the electrical properties of underlying devices (Ref 28). Stress in the PECVD nitride films can vary from 10^{10} dyn/cm^2, compressive, to 10^{10} dyn/cm^2, tensile. Excessive stress can cause the films to crack and peel (Ref 29). It is possible to choose the stress type and control the stress level by selecting the right deposition conditions (Ref 21).

Silicon oxide films are used as intermetallic dielectric layers in microelectronic circuits. Some of the important advantages that PECVD silicon oxide films offer are that:

- The deposition temperatures are low (200 to 300 °C, or 390 to 570 °F), so that PECVD silicon oxide films can be deposited over low-melting-point metals such as aluminum.
- The dielectric constant of PECVD oxide is relatively low (4 to 6, versus 6 to 9 for silicon nitride films) (Ref 30).
- The dry etch rate of PECVD oxide films is much higher than that of thermal CVD films.

The last factor is used to advantage in the process called planarization. During IC device fabrication, the surface needs to be planarized at some point before the next processing step. One method involves depositing the PECVD oxide film over the processed wafer, followed by deposition and flow of photoresist. The photoresist and the oxide films are then dry etched. The etch rate of the PECVD oxide may be 20 to 40% higher than that of thermal oxide. This high etch rate allows the planarization process to succeed, because the latter depends on having equal etch rates of photoresist and oxide (Ref 31).

Properties of PECVD silicon oxide films are a function of deposition conditions, reactor geometry, and the reaction chemistry (but to a lesser degree than in PECVD silicon nitride films) (Ref 13). Some of the source gas combinations that can be used for the deposition of PECVD silicon oxide films are (Ref 1, 32):

- SiH_4, used as the silicon source, and nitrous oxide (N_2O), used as the source of nitrogen. SiH_4 is usually diluted with argon.
- SiH_4 diluted with oxygen (alone or in combination with N_2O)
- Tetraethylorthosilicate (TEOS) as the source of silicon in an O_2-N_2 ambient

The SiH_4-N_2O process tends to yield films with better uniformity and less particle contamination. Hydrogen occurs in PECVD silicon oxide films in the bonded form as Si-H, Si-O-H, or H-O-H in concentrations ranging from 2 to 9 wt% (Ref 30). The hydrogen in oxide films is less of a problem than in PECVD nitride films. If the films are heated substantially beyond their deposition temperatures, the hydrogen in the films escapes by outdiffusion, whereas the PECVD silicon nitride films may be destroyed by blistering because they are relatively impermeable.

Some of the properties of silicon oxide films deposited by PECVD process are:

- Compressive stress, 0.07 to 2.4×10^9 dyn/cm^2
- Breakdown strength, 2 to 6×10^6 V/cm
- Resistivity, 10^{13} to 10^{17} $\Omega \cdot$ cm

Effects of deposition variables on the properties of PECVD silicon oxide films are reported in Ref 33, 34, 35, 36.

Silicon oxynitride films combine some of the best properties of PECVD silicon nitride and oxide films. Deposition of silicon oxynitride film is based on SiH_4 (diluted with helium), NH_3, and N_2O as reactants in various ratios at 300 °C (570 °F) (Ref 37). Properties such as stress, dielectric constant, and resistance to the diffusion of sodium ions and moisture can be modified by changing the gas flow ratios during film growth. The presence of oxygen in these films lowers the values of properties such as stress and dielectric constant, whereas the presence of nitrogen increases the impermeability to sodium ions and moisture (Ref 13). PECVD oxynitride films are also used in the planarization process, where the difference in etch rates of oxynitrides, photoresist, and nitride films is used advantageously (Ref 1).

PECVD of Amorphous and Polycrystalline Silicon Films

Amorphous Silicon Films. The PECVD process is extensively used to deposit amorphous silicon films. Amorphous hydrogenated silicon (a-Si:H) films are deposited by the PECVD process by the decomposition of monosilane, disilane, or chlorosilane in a glow discharge plasma at temperatures in the range of 200 to 300 °C (390 to 570 °F) (Ref 38). The amorphous-to-polycrystalline transition temperature is sensitive to reactor design and deposition conditions and has to be controlled carefully. The a-Si:H films have important applications in the fabrication of solar cells (Ref 39), as photoreceptors in photolithography, and in Vidicon-type photoconductive image tubes (Ref 40).

Polycrystalline Silicon Films. Polycrystalline silicon is used as the gate electrode in metal-oxide semiconductor devices and as the emitter in bipolar devices. It is also used as interconnect material in ICs. In commercial manufacturing of ICs, polycrystalline silicon is deposited by thermally driven LPCVD at 625 °C (1150 °F). The PECVD process is rarely used for polycrystalline silicon film deposition, because deposited polycrystalline silicon films are intrinsic and have very high resistivity. Most applications in the microelectronic industry require the polycrystalline films to be highly conductive, which is achieved by doping the films after deposition. The number of processing steps can be reduced if the films are doped in situ. Application of PECVD for in-situ doping of polycrystalline silicon films is being explored. Thickness, uniformity, and deposition rates are very much affected when relatively high concentrations of dopant species are introduced in the LPCVD reactor during film growth. When PECVD is used to dope the polycrystalline silicon films in situ, the conductivity of these films can be modulated by six orders of magnitude for both p-type (by adding diborane) and n-type (by adding arsine) (Ref 41).

In other applications of polycrystalline silicon films, for example in the fabrication of thin-film transistors, PECVD is very desirable. Thin-film transistors are being explored for use in flat-panel displays and require much lower deposition temperatures, which can be achieved by PECVD. In addition, the growth rate of PECVD polycrystalline silicon films is less sensitive to the deposition temperature (Ref 4), as shown in Fig. 4, and so uniform film deposition requires less stringent control of the wafer temperature.

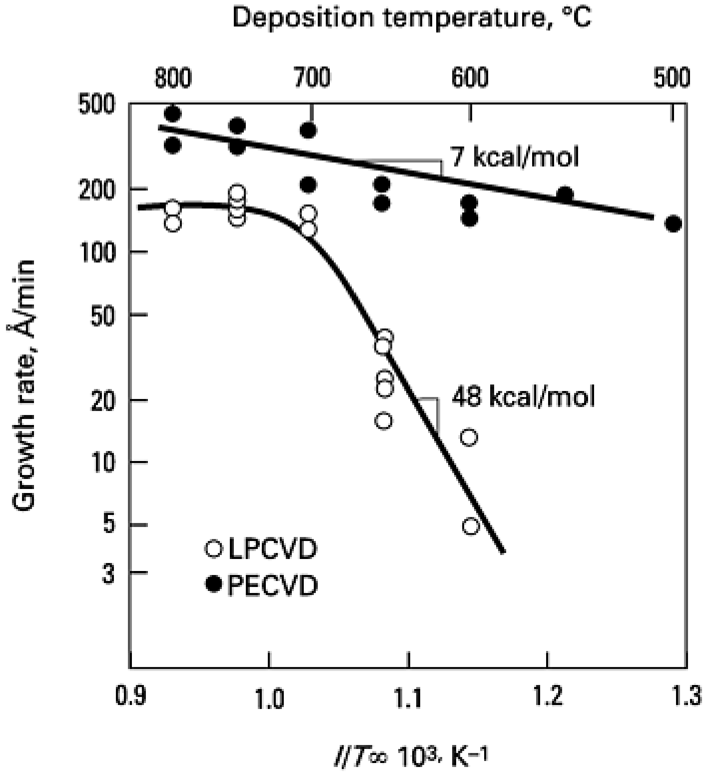

Fig. 4 Arrhenius plots of growth rates of polycrystalline silicon films deposited on oxidized silicon wafers with and without plasma enhancement. LPCVD, low-pressure chemical deposition; PECVD, plasma-enhanced chemical vapor deposition. Source: Ref 41

Epitaxial Films. In microelectronic devices, epitaxial films have extensive applications in both bipolar technology (as subcollector) and complementary metal-oxide semiconductor technology (to prevent latch-up). They are commercially deposited by APCVD at 1050 to 1200 °C (1920 to 2190 ° F) (Ref 42). Other deposition techniques can be used to deposit epitaxial silicon films at temperatures lower than in LPCVD, namely, molecular beam epitaxy (Ref 43), ion beam epitaxy (Ref 44), ultrahigh-vacuum CVD (Ref 45), and photo-enhanced CVD (Ref 46). The PECVD process is another exciting option for depositing homoepitaxial or heteroepitaxial films at lower temperatures. PECVD offers other potential advantages, such as flexibility in the deposition of in-situ doped films (Ref 47).

Deposition of silicon epitaxial films with and without plasma enhancement has been reported (Ref 48). The films were deposited in a very-low-pressure CVD system at temperatures as low as 650 °C (1200 °F) with SiH_4 as the source gas. A schematic of this reactor, which was designed and built at the Massachusetts Institute of Technology, is shown in Fig. 5. The substrate or wafer sits vertically on a graphite susceptor and faces a bank of infrared lamps, which heat both the wafer and the susceptor to the desired deposition temperature. The reactant gases can be pure SiH_4 for intrinsic deposition or SiH_4 mixed with other reactants (e.g., arsine or diborane) for epitaxial deposition of doped silicon. The gases enter the reactor from the top and are pumped out at the bottom. The reactor could be evacuated to a hydrocarbon-free base pressure about 10^{-8} torr, and epitaxial films are deposited at operating pressures of 1 to 100 mtorr. Plasma powers from 2.5 to 100 W could be used at a frequency of 13.56 MHz. In this reactor, a direct-current power supply was also used to bias the susceptor relative to ground and to decouple the substrate biasing from rf plasma power or electrode self-bias. At low plasma power (2.5 W) and in the temperature range of 750 to 800 °C (1380 to 1470 °F), the plasma-enhanced depositions were 20% faster, and at higher power (20 W), an additional 10% increase in the growth rate was observed.

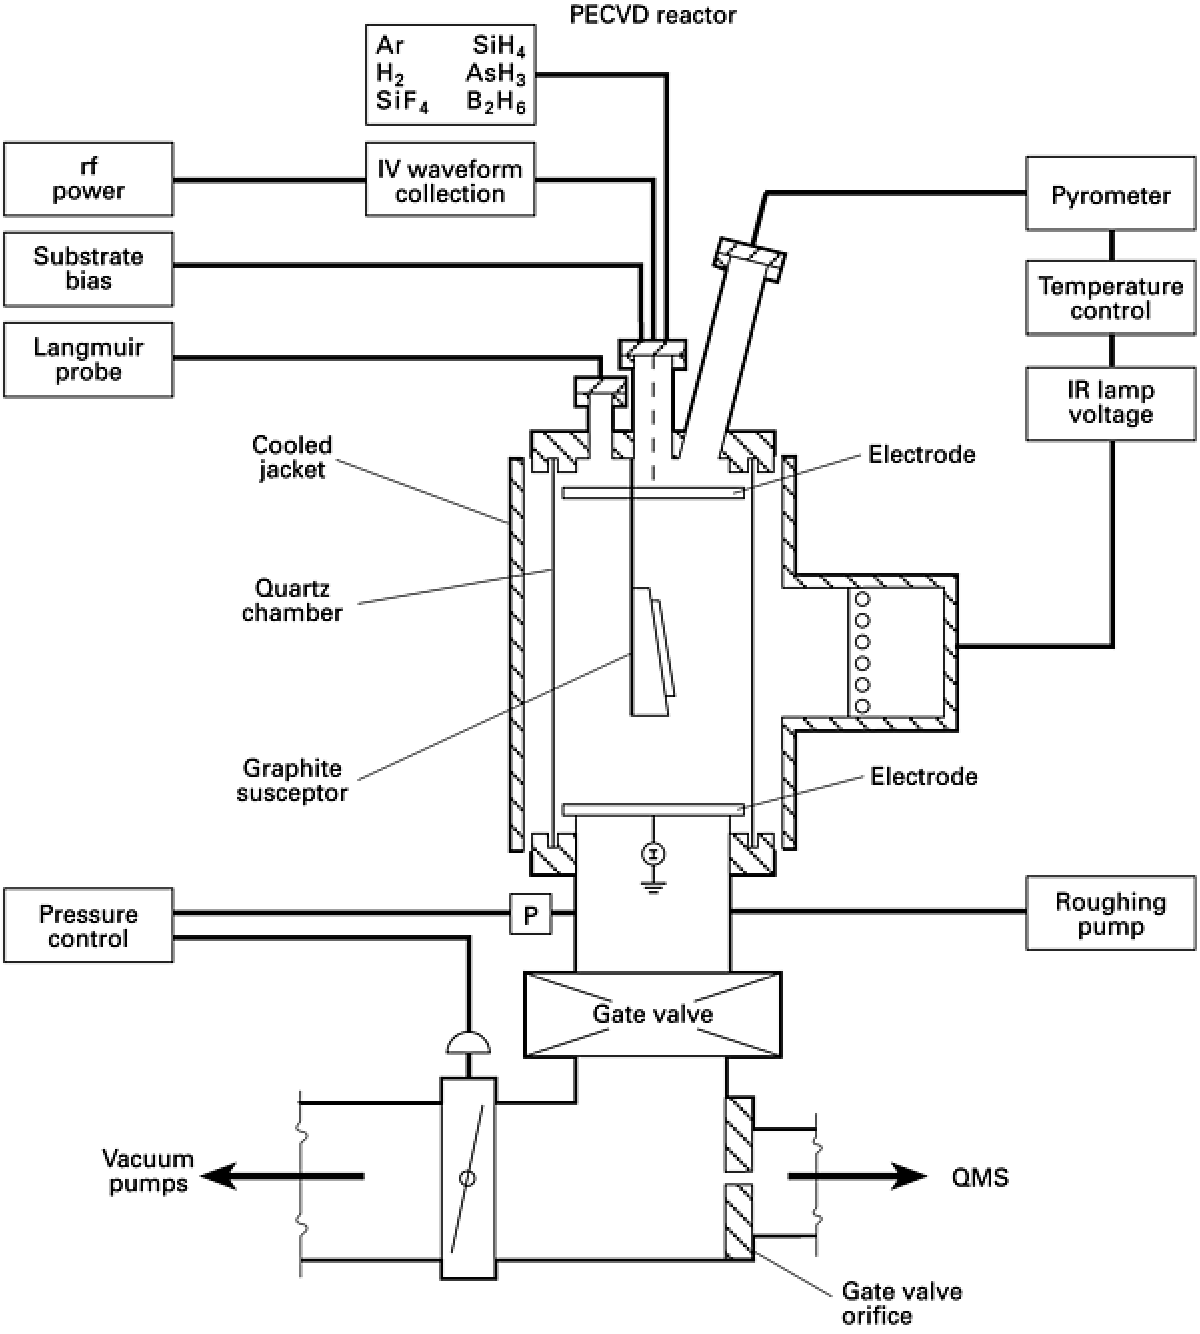

Fig. 5 Reactor for plasma-enhanced chemical vapor deposition of epitaxial silicon films. QMS, quadruple mass spectrometer. Source: Ref 48

Conductive Films. The deposition of refractory metals and their silicides with the PECVD process has been a subject of investigation by many researchers (Ref 49, 50, 51, 52). Refractory metals such as tungsten and molybdenum and their silicides--for example, tungsten silicide (WSi_2), molybdenum silicide ($MoSi_2$), and titanium silicide ($TiSi_2$)--have resistivities greater than that of aluminum but much less than that of doped polycrystalline silicon. Typical resistivities of the refractory metals are !15 μΩ· cm, while those of the refractory metal silicides have a range of 16 to 40 μΩ· cm (as compared to aluminum, which has a resistivity of 2.6 μΩ· cm, and doped polycrystalline silicon, which has a resistivity of about 500 μΩ· cm). When aluminum is used as the interconnect material in ICs, all the postaluminum processing steps have to be kept below about 450 °C (840 °F) (aluminum melts at about 600 °C, or 1220 °F). The refractory metals and their silicides are compatible with higher-temperature processing steps and can be used as interconnects or gates (in conjunction with polycrystalline silicon or alone). They are most commonly deposited by thermally driven CVD (Ref 13).

The resistivities of both the refractory metals and their silicides are very sensitive to factors such as impurities, which can be trapped in the film during the PECVD process, and grain size. When the PECVD process is used to deposit films of refractory metals or their silicides, even though the actual deposition temperatures can be as low as 400 °C (750 °F), a high-temperature postdeposition anneal is always necessary to bring down the resistivity. This high-temperature annealing step also presumably helps in the outdiffusion of impurities, in increasing the grain size, and in the annealing-out of radiation-induced defects in the films created during the PECVD process.

Refractory metal films are usually deposited at 400 °C (750 °F) with metal halides as the source gases (Ref 49, 50), for example, tungsten hexafluoride (WF_6) for tungsten deposition, and molybdenum pentachloride ($MoCl_5$) and H_2 for molybdenum deposition. Deposition of refractory metal silicides is carried out by introducing a silicon source (e.g., SiH_4) along with the metal halides into the reaction chamber. Usually an inert gas is also used to dilute the mixture. Table 1 gives a description of source gases, deposition temperatures, and the required postdeposition anneals when various refractory metal films and their silicides are deposited by the PECVD process.

Table 1 Plasma-enhanced chemical vapor deposition of refractory metal films

Material	Reactant gases	Deposition temperature		Post-deposition anneal	References
		°C	°F		
W	WF_6, H_2	350-400	660-750	1000 °C (1830 °F) for 30 min	49, 50
WSi	WF_6 + SiH_4 diluted with He	230	450	1000 °C (1830 °F) for 60 min in N_2	52
Mo	$MoCl_5$, H_2	170-430	340-800	800 °C (1470 °F) for 30 min in N_2	53
$MoSi_2$	$MoCl_5$, SiH_4 + Ar	400	750	1000 °C (1830 °F) for 20 min in N_2	51
$TaSi_2$	$TaCl_5$, SiH_2Cl_2 + H_2	580	1080	900 °C (1650 °F) for 60 min in Ar	54

Growth and Growth-Related Properties of Films Formed by Physical Vapor Deposition

Donald M. Mattox, IP Industries

Introduction

THE PROPERTIES of atomistically deposited films depend strongly on the material being deposited, the substrate surface chemistry and morphology, the surface preparation process, and the details of the deposition process and the deposition parameters. The origin of the unique properties of physical vapor deposition (PVD) film can be understood by understanding the film formation process.

The formation of a useful and commercially attractive engineered surface using any PVD process (vacuum deposition, sputter deposition, or ion plating) involves several stages:

1. Choice of the substrate ("real surface") and development of an appropriate surface preparation process
2. Selection of the film material(s) to produce the surface properties required
3. Choice of the PVD process to provide reproducible properties, compatibility with subsequent processing, and long-term stability
4. Development of the fabrication process parameters, parameter limits, and the monitoring/control techniques
5. Development of appropriate characterization techniques to determine the film properties and stability of the product
6. Creation of written specifications and manufacturing processing instructions to cover the substrate material, surface preparation, deposition process, and characterization procedures

The properties of a film of a material formed by any PVD process depends on four factors:

- *Substrate surface condition*--e.g., surface morphology (roughness, inclusions, particulate contamination), surface chemistry (surface composition, contaminants), mechanical properties, surface flaws, outgassing, preferential nucleation sites, and the stability of the surface
- *Details of the deposition process and system geometry*--e.g., angle-of-incidence distribution of the depositing adatom flux, substrate temperature, deposition rate, gaseous contamination, and concurrent energetic particle bombardment (flux, particle mass, energy)
- *Details of film growth on the substrate surface*--e.g., substrate temperature, nucleation, interface

formation, interfacial flaw generation, energy input to the growing film, surface mobility of the depositing adatoms, growth morphology of the film, gas entrapment, reaction with deposition ambient (including reactive deposition processes), and changes in the film properties during deposition
- *Postdeposition processing and reactions*--e.g., reaction of film surface with the ambient, thermal or mechanical cycling, corrosion, interfacial degradation, burnishing of soft surfaces, shot peening, and overcoating ("topcoat")

In order for the film to have reproducible properties, each of these factors must be reproducible.

Technological (Real) Surfaces

Technological surfaces or *engineering surfaces* are terms that are used to describe the real surfaces of engineering materials. These layers, along with the underlying bulk material, are the real substrate that must be altered to produce the desired surface properties. Invariably the real surface differs chemically from the bulk material by having surface layers of reacted and adsorbed material such as oxides and hydrocarbons. The surface chemistry, morphology, and mechanical properties of the real surface can be very important to the adhesion and film formation process. The underlying bulk material can be important to the performance of the surface. For example, a wear coating on a soft substrate will not function well if, under load, it is fractured by the deformation of the underlying substrate. Also, good film adhesion cannot be obtained when the substrate surface is mechanically weak, because failure can occur in the near-surface material. The bulk material can influence the surface preparation and the deposition process by continual outgassing and outdiffusion of internal constituents.

Some of the surface properties that affect the formation and properties of the deposited film are:

- *Surface chemistry*--affects the adatom-surface reaction and nucleation density. Chemistry can affect the stability of the interface formed by the deposition.
- *Contamination* (particulate and film, local or uniform)--affects surface chemistry and nucleation of the adatoms on the surface. Particulate contamination generates pinholes in the deposited film.
- *Surface morphology*--affects the angle-of-incidence of the depositing atoms and thus the film growth. Geometrical shadowing of the surface from the depositing adatom flux reduces surface coverage. Surface morphology can affect the film properties and stability.
- *Mechanical properties*--affects film adhesion and deformation under load
- *Outgassing and outdiffusion*--affects nucleation and film contamination
- *Homogeneity of the surface*--affects uniformity of film properties over the surface

In particular, the surface morphology can have an important effect on the film properties. Figure 1 shows the effect of surface morphology and particulate contamination on surface coverage and pinhole formation. Also, the surface morphology can affect the average angle-of-incidence of the adatom flux, which has a large effect on the development of the columnar morphology in atomistically deposited films.

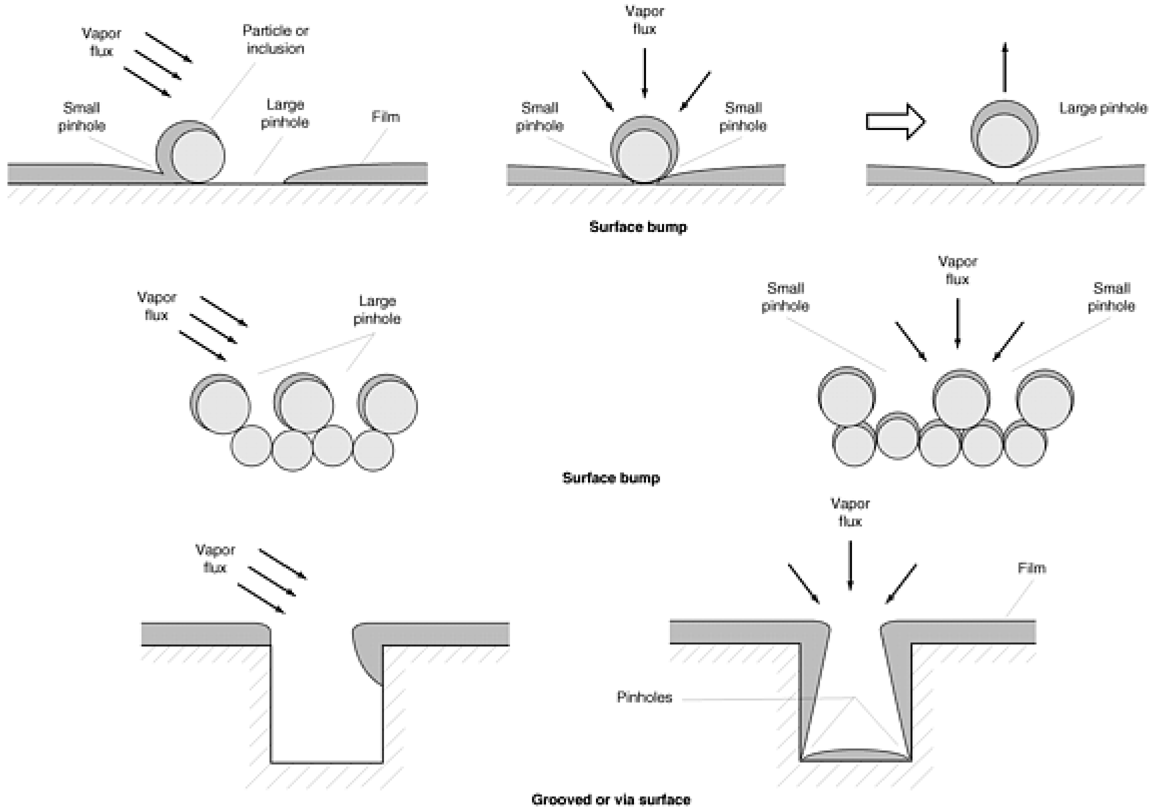

Fig. 1 Surface morphology effects on pinhole formation

The nature of the real surface depends on its formation, handling, and storage history. In order to have reproducible film properties, the substrate surface must be reproducible. This reproducibility is attained by careful specification of the substrate material, careful incoming inspection procedures, careful surface preparation, and appropriate handling and storage of the material.

Surface preparation is the process of preparing a surface for the film/coating deposition process (Ref 1). Surface preparation may mean cleaning (removal of contaminants), but it can also include surface treatments to change the properties of the surface in a desirable way, such as roughening or smoothing the surface, making a harder surface by plasma treatment (i.e., plasma nitriding) or shot peening, or "activating" the surface, such as the oxygen plasma treatment of a polymer surface. Often surface preparation consists of two distinct stages. The first is "external cleaning," which takes place outside the deposition system in a controlled environment. This processing environment is designed to control recontamination after cleaning. For example, to control recontamination by particulates, a filtered air "cleanroom" is used. External cleaning can consist of both "gross cleaning," which removes a portion of the substrate surface material, and "specific cleaning," which removes specific contaminants such as hydrocarbons or salts. The second stage of surface preparation is "in situ cleaning," which is performed in the deposition system. For example, hydrocarbon contamination can be removed from some surfaces by exposing them to an oxygen plasma in the deposition system.

Care must be taken to ensure that the surface preparation process does not change the surface in an undesirable or uncontrolled manner, such as selective leaching of one phase of a two-phase surface. One objective of any surface preparation procedure is to produce as homogeneous a surface as possible. Reproducible surface preparation, as well as associated handling and storage techniques, are obtained by having appropriate specifications for the process, handling, and storage procedures used. In addition, recontamination of the prepared surface in the deposition chamber and by the deposition process is a major consideration.

Processes for Films and Coating, 2nd ed., R. Bunshah, Ed., Noyes Publications, 1994

Atomistic Film Growth

Atomistic film growth occurs as a result of the condensation of atoms ("adatoms") on a surface. The stages of film formation are:

1. Vaporization of the material (adatoms) to be deposited
2. Transport of the material to the substrate
3. Condensation and nucleation of the adatoms
4. Nuclei growth
5. Interface formation
6. Film growth--nucleation and reaction with previously deposited material
7. Changes in structure during the deposition process--interface and film
8. Postdeposition changes due to postdeposition treatments, exposure to the ambient, subsequent processing steps, in-storage changes, or in-service changes

All of these stages are important in determining the properties of the deposited film material (Ref 2, 3, 4, 5).

Vaporization

In physical vapor deposition, vapors can be formed by thermal and nonthermal techniques. Thermal techniques require heating, such as vacuum evaporation and sublimation (see the article "Vacuum Deposition, Reactive Evaporation, and Gas Evaporation" in this Volume). Nonthermal vaporization includes sputtering (see the article "Sputter Deposition" in this Volume), arc vaporization, laser ablation, and others.

Transport

The vaporized material can be transported through a vacuum, gas, or plasma. The vacuum environment allows control of the contamination in the ambient environment to any desired level. The gaseous environment may thermalize energetic particles and cause vapor phase nucleation, depending on the gas density (see the article "Vacuum Deposition, Reactive Evaporation, and Gas Evaporation" in this Volume). The plasma environment "activates" reactive species, making them more chemically reactive.

Condensation and Nucleation

Atoms that impinge on a surface in a vacuum environment either are reflected immediately, reevaporate after a residence time, or condense on the surface. The ratio of the condensing atoms to the impinging atoms is called the *sticking coefficient*. If the atoms do not immediately react with the surface, they will have some degree of surface mobility over the surface before they condense. Re-evaporation is a function of the bonding energy between the adatom and the surface, the surface temperature, and the flux of mobile adatoms. For example, the deposition of cadmium on a steel surface having a temperature greater than about 200 °C (390 °F) will result in total re-evaporation of the cadmium.

Surface Mobility. The mobility of an atom on a surface will depend on the energy of the atom, atom-surface interactions (chemical bonding), and the temperature of the surface. The mobility on a surface can vary due to changes in chemistry or crystallography. The different crystallographic planes of a surface have different surface free energies that affect the surface diffusion. For example, for face-centered cubic metals the surface free energy of the (111) surface is less than that of the (100) surface, and the surface mobility of an adatom is generally higher on the (111) surface than on the (100) surface. This means that different crystallographic planes will grow at different rates during adatom condensation. Various techniques have been developed to study surface mobility and the surface diffusion rate of adatoms on a surface (Ref 6, 7).

The surface mobility of adatoms can be an important factor in surface coverage. For example, the surface coverage of a silicon device is improved by depositing an Al/Cu metallization on a TiN barrier layer at 500 °C (930 °F). The Al/Cu has a higher surface mobility on the TiN surface than on the silicon surface and is able to completely fill a 0.5 μm diameter

by 0.8 μm deep "via" holes. Also, by direct current magnetron sputter-depositing the Al-5Ga eutectic alloy at 300 °C (570 °F), "via" holes with aspect ratios of up to 4:1 have been successfully filled.

Nucleation. Atoms condense on a surface by losing energy. They lose energy by:

- Making and breaking chemical bonds with the substrate surface atoms
- Finding preferential nucleation sites (e.g., lattice defects, atomic steps, impurities)
- Colliding with other diffusing surface atoms (same species)
- Colliding or reacting with adsorbed surfacespecies

Nucleation by Surface Reaction. The condensing atoms react with the surface to form atom-to-atom chemical bonds. The chemical bonding may be by metallic (homopolar) bonding where the atoms share orbital electrons, by electrostatic (coulombic, heteropolar) bonding where ions are formed due to electron loss/gain, or by electrostatic attraction (van der Waals forces) due to polarization of molecules. If the atom-atom interaction is strong, surface mobility is low and each surface atom can act as a nucleation site. If the reaction is strong, the atom is said to be *chemisorbed*. In some cases the chemisorbed adatom displaces the surface atoms, giving rise to a "pseudomorphic" surface structure.

The bonding energy of atoms to surfaces can be studied by thermal desorption techniques. The chemisorption energy for some materials on clean surfaces are:

Material	Energy, eV
Rb on W	2.6
Cs on W	2.8
B on W	6.1
N_2 on Fe	3.0
Ni on Mo	2.1
Ag on Mo	1.5
Au on W	3.0
O_2 on Mo	7.5

Note: 1 eV/atom = 23 kcal/mole.

Source: Ref 8

The bonding between a metal atom and an oxide surface is proportional to the metal-oxygen free energy of formation, with the best adhesion produced by the formation of an intermediate oxide interfacial layer. In many instances the surface composition can differ significantly from that of the bulk of the material, and/or the surface can have an nonhomogeneous

composition. Examples are the glass-bonded (Si-O) sintered, alumina ceramics shown in Fig. 2. Film atoms prefer to nucleate and react with the glassy Si-O phase, and if this material is leached from the surface during surface preparation, the film adhesion suffers (Ref 9). Preferential sputtering of a compound or alloy substrate surface can change the surface chemistry. For instance, preferential sputtering of an Al_2O_3 surface removes oxygen, leaving an aluminum-rich surface (Ref 10). Surface contamination can greatly influence the nucleation density, interfacial reactions, and nuclei orientation. When a two-phase binary alloy is deposited, the two materials may react differently with the surface, resulting in segregation on the surface.

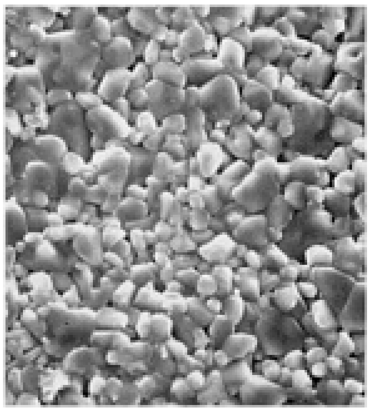

Fig. 2 Surface morphology of an as-sintered 96% alumina ceramic such as is used in hybrid circuitry. 1000×

Nucleation at Preferential Nucleation Sites. If the adatom-surface interaction is weak, the adatom will have a high surface mobility and will condense at preferential nucleation sites where there is stronger bonding due either to a change in chemistry (element or electronic) or an increase in coordination number (e.g., at a step). Preferential nucleation sites can be:

- Morphological surface discontinuities such as steps or scratches
- Lattice defects in the surface such as point defects or grain boundaries
- Foreign atoms in the surface
- Charge sites in insulator surfaces
- Surface areas that have a different chemistry or crystallographic orientation

Steps on a surface can act as preferential nucleation sites. For example, gold deposited on cleaved single-crystal NaCl or KCl shows preferential nucleation on cleavage steps. Steps on Si (100) and GaAs (100) surfaces can be produced by polishing at an angle of several degrees to a crystal plane. This procedure produces an "off-cut" or "vicinal" surface (Ref 11) comprised of a series of closely spaced steps. These steps aid in dense nucleation for epitaxial growth of GaAs on Si and Al_xGa_{1-x} As on GaAs. Scratches on the substrate surface provide nucleation sites in the deposition of diamond films.

Lattice defects can act as preferential nucleation sites. For example, amorphous carbon films have a high density of defects that act as nucleation sites for gold deposition. When depositing adatoms on electrically insulating substrates, charge sites on the surface can act as preferential nucleation sites. Electron irradiation, ultraviolet radiation (UV), and ion bombardment can be used to create charge sites.

Nucleation by Collision. Mobile surface adatoms can nucleate by collision with other mobile surface species to form stable nuclei. Thus the nucleation density can depend on the deposition (arrival) rate. For example, in the deposition of silver on lead it has been shown that at a deposition rate of 0.1 nm/min, the silver is completely re-evaporated, while at 10 nm/min, the atoms are completely condensed. When depositing silver on glass, improved adhesion can be obtained by a rapid initial deposition rate, followed by a lower rate to build up the thickness.

Nucleation by Reaction with Adsorbed Atoms. Mobile surface species can react with adsorbed surface species such as oxygen. For example, chromium deposition after oxygen plasma cleaning of glass generally results in improved

adhesion compared to a glass surface that has not been oxygen-plasma cleaned. This is probably due to the adsorption of oxygen on glass, which increases the nucleation density of deposited gold (Ref 12). The adsorption of reactive species can also have an important effect in reactive deposition processes (Ref 13).

Nucleation of Unstable Surfaces. Some surfaces are unstable and change their nature when atoms are added to the surface. For example, the adatom may interact with the surface lattice and cause atomic rearrangement such that a pseudomorphic surface is formed that presents a different surface to atoms subsequently deposited (Ref 8). Some polymers, particularly glassy polymers (i.e., those above their glass transition temperatures), have surfaces that are unstable and into which the depositing adatom will sink and possibly even nucleate below the polymer surface (Ref 14). Polyethylene and polypropylene are examples of polymers that are glassy at room temperature.

Nucleation Density. In general, the number of nuclei per unit area, or "nucleation density," should be high in order to form a dense film and obtain complete surface coverage at low film thickness. The nucleation density and growth behavior can vary with different substrate locations due to phase distribution, surface morphology, or crystallographic orientation of the substrate surface. The variation of nucleation density and subsequent film growth can result in film property variations over the surface.

Characterization of Nucleation Density. The relative and absolute nucleation density can be determined by a number of techniques (Ref 15), including:

- Optical density of the deposited film as a function of mass deposited
- Behavior of the thermal coefficient of resistivity (TCR) as a function of mass deposited
- Transmission electron microscopy (TEM) and ultrahigh vacuum TEM
- Auger electron spectroscopy (AES)
- Low-energy electron diffraction (LEED)
- Reflection high-energy electron diffraction (RHEED)
- Work function change as a function of mass deposited
- Scanning electron microscopy (SEM)
- Scanning tunneling microscopy (STM) (Ref 16)
- Atomic force microscopy (AFM)
- Photon tunneling microscopy (PTM) (Ref 17)

Optical Adsorption. On transparent substrate materials, the optical density of a film formed by depositing a given amount of material can be used to measure the comparative nucleation density. The optical density (OD) is defined as: OD = log [(% visual light transmitted through the substrate)/(% visual light transmitted through a metallized substrate)]. A good electrical conductor having a high nucleation density is optically opaque to the human eye when the film thickness is about 1000 Å (100 nm). A comparison of optical densities is often a good "quick check" on process reproducibility.

The temperature coefficient of resistance (TCR) of very thin metal films on electrically insulating substrates depends on the growth of the nuclei. Isolated nuclei result in a negative TCR (increasing temperature/decreasing resistance) due to thermally activated tunneling conduction between nuclei. Connected nuclei, which form a continuous film, have a positive TCR as would be expected in a metal. Thus TCR measurements can be used to provide an indication of nucleation density and growth mode by determining the nature of the TCR as a function of mass deposited.

Surface Analytical Techniques. Using low-energy electron diffraction (LEED) it has been shown that very low coverages of contamination can inhibit interfacial reaction and epitaxial growth. The field ion microscope has been used to field-evaporate deposited material and observe the "recovered" substrate surface. Using this technique to study the deposition of copper on tungsten, it was shown that electroplating results in interfacial mixing similar to that produced by high-temperature vacuum deposition processing.

Modification of Nucleation Density. There are a number of ways to modify the nucleation of depositing atoms on substrate surfaces, including:

- Change deposition temperature (increasing temperature can increase reaction with surface and increases

surface mobility; decreasing temperature can decrease surface mobility)

- Increase deposition rate to increase collision probability of diffusing species
- Change surface chemistry to make the surface more reactive
- "Sensitizing" the surface by the addition of "nucleating agents"
- Generate nucleation sites on the surface (lattice defects, charge sites on insulators) by mechanically disrupting the surface to produce defects and disturb contaminant layers ("mechanical activation"), using ion bombardment to produce lattice defects (Ref 18), incorporating species by ion implantation or chemical substitution, or using electron bombardment or photon bombardment (Ref 19) to charge centers on insulator surfaces
- Produce codeposition or absorption of reactive species
- Change surface roughness
- Create a new surface--"basecoat" or "glue layer"

Adsorption and Codeposition or Reactive Species. Adsorbed or codeposited reactive species can affect the surface chemistry and thus the nucleation of the deposited species. The presence of adsorbed oxygen or oxygen in a plasma or bombarding oxygen ion beam during deposition has been shown to aid in the adhesion of gold (Ref 20) and oxygen-active film materials (Ref 21) to oxide substrates. The increased adhesion is attributed to the increased nucleation density. In the case of a plasma system such as plasma-enhanced chemical vapor deposition (PECVD), the radicals, unique species, and excited species formed in the plasma may play an important role in adsorption and deposition from a gaseous precursor. For example, in the deposition of silicon from silane by PECVD, it has been proposed that the formation of disilane and trisilane in the plasma and its adsorption on the surface, along with low-energy particle bombardment, is important to the low-temperature, high-rate deposition of amorphous silicon (Ref 22).

Surface roughness can also play an important role in nucleation. The typical 94% alumina used in microelectronics has a surface roughness that looks like a field of boulders several microns in diameter (see Fig. 2). Deposition on such a surface results in a high nucleation density on the tops of the "boulders" and a lower nucleation density on the sides and in the pores. Flowed glass surfaces, on the other hand, are smooth and the nucleation density can be uniform over the surface.

Establishing a New Surface. In the extreme case, a new surface layer ("glue layer," basecoat) can be used to provide a better surface for the deposition of the desired material. This is often done in the metallization systems used in micro-electronics and for interconnects in integrated circuit technology. In these cases a material is deposited on the oxide/semiconductor surface that forms a desirable oxide interface (e.g., titanium or chromium). Then a surface layer is deposited that alloys with the first layer and provides the desired property (e.g., gold, copper, silver). The new surface can also be used to smooth or "planarize" the initial surface (e.g., a "flowed" basecoat layer).

Growth of Nuclei

When atoms condense they form nuclei. If the surface is of the same material as the depositing atoms, the process is called *homogeneous nucleation*; if they are of different materials, the process is call *heterogeneous nucleation*. In semiconductor terminology, heterogeneous nucleation forms *heterojunctions*. Three types of nucleation mechanisms have been identified; they differ according to nature of interaction between the deposited atoms and the substrate material (Ref 23): (a) the van der Merwe mechanism leading to a monolayer-;by-monolayer growth; (b) the Volmer-;Weber (V-;W) mechanism, characterized by a three-dimensional nucleation and growth; and (c) the Stranski-Krastanov (S-K) mechanism, where an altered surface layer is formed by reaction with the deposited material to generate a strained or pseudomorphic structure, followed by nucleation on this altered layer. The S-K nucleation is common with metal-on-metal deposition and at low temperatures where the surface mobility is low. The conditions for these types of growth is generally given in terms of thermodynamics and surface energy considerations.

Often the adsorption is accompanied by surface reconstruction, surface lattice strain, or surface lattice relaxation, which change the lattice atom spacing or the surface crystallography to give a pseudomorphic structure. The interaction of the depositing material with the surface can form a structure on which subsequent depositing atoms nucleate and grow in a manner different from that of the initially depositing material. This may alter the subsequent film structure. For example, the unique beta-tantalum structured films are stabilized by deposition on an as-grown tantalum silicide interfacial material.

Nuclei Coalescence and Agglomeration. The nuclei grow by collecting atoms that diffuse over the surface. Isolated nuclei grow laterally and vertically on the surface to form a continuous film (Ref 24). The higher the nucleation density, the less the amount of material needed to form a continuous film. The principal growth mode of the nuclei may be laterally over the substrate surface ("wetting growth"), or the nuclei may prefer to grow in a vertical mode ("dewetting growth"). Examples of wetting growth are: gold on copper and chromium, iron on W-O surfaces, and titanium on SiO_2. Examples of dewetting growth are nickel and copper on W-O surfaces, and gold on carbon, Al_2O_3, and SiO_2. Growth and coalescence of the nuclei can leave interfacial voids or structural discontinuities at the interface, particularly if there is no chemical interaction between the nuclei and the substrate material and dewetting growth occurs.

In cases where there is little chemical interaction between the nucleating atoms and the substrate, the isolated nuclei grow together, giving the so-called island-channel-continuous film growth stages. Before coalescence the nuclei can have a "liquid-like" behavior that allows them to rotate and align themselves crystallographically with each other, giving an oriented (epitaxial) overgrowth.

Agglomeration of nuclei occurs when the temperature of the nuclei is high enough to allow atomic diffusion and rearrangement such that the nuclei "ball-up" to minimize the surface area. Agglomeration of evaporated gold films is increased at high deposition rates, at high substrate temperatures, and in high-rate electron beam evaporation. Gold is often used for replication in electron microscopy, and agglomeration of pure gold can be a problem; therefore, gold alloys such as 60Au:40Pd are used to reduce the agglomeration tendencies and provide better replication. Agglomeration can occur after deposition if there is appreciable columnar growth (high surface area) in the film and the film is heated.

Where there is strong interaction between the adatoms and the substrate but little diffusion or compound formation with the substrate, the crystal orientation of the deposited material can be influenced by the substrate crystallographic orientation, producing a preferential crystallographic orientation in the nuclei. This type of oriented overgrowth is called *epitaxial growth.* Lattice mismatch between the nuclei and the substrate at the interface can be accommodated by lattice strain or by the formation of "misfit" dislocation networks, and under proper conditions a single crystal epitaxial film can be grown. This is often the goal in molecular beam epitaxy (MBE) and chemical vapor deposition (CVD) of semiconductor thin films. In the growth of semiconductor materials it is desirable to form an interface that is defect-free so that electronically active sites are not generated. Such an interface can be formed if there is lattice parameter matching between the deposited material and the substrate, or if the deposited material is thin enough to allow lattice strains to accommodate the lattice mismatch without producing dislocation networks. This latter condition produces a "strained layer superlattice" structure (Ref 25).

At the other extreme of growth are amorphous materials where rapid quenching, bond saturation, limited surface diffusion, and the lack of substrate influence results in a highly disordered material. Comparison between amorphous materials formed by coevaporation and those formed by rapid quenching show some indication of a lower degree of short range ordering in the codeposited material, as indicated by the lower crystallization temperature and lower activation energy for crystallization than in the low-temperature deposited films. Amorphous conductive materials, such as $W_{75}Si_{25}$, have been proposed as a diffusion barrier film in semiconductor metallization. Because amorphous films have no grain boundaries, they are expected to show lower diffusion rates than films that have grain boundaries, in that grain boundary diffusion rates are generally higher than bulk diffusion rates.

Heating by Condensation. At high deposition rates, the condensation energy can produce appreciable substrate heating. When a thermally vaporized atom condenses on a surface it releases energy from several sources, including:

- *Heat of vaporization or sublimation* (enthalpy of vaporization)--a few electron volts per atom
- *Energy to cool to ambient*--depends on heat capacity and temperature change
- *Energy associated with reaction*, which may be exothermic, where heat is released, or endothermic, where heat is adsorbed--heat of reaction (Table 1)
- *Energy released on solution*--heat of solution

Table 1 Heats of reaction

Material	Heat, kcal/mole

Ni_2Si	-11
NiSi	-18
Pt_2Si	-11
PtSi	-15
$ZrSi_2$	-35
Ta_2O_5	-500
Al_2O_3	-399
V_2O_3	-290
Cr_2O_3	-270
TiO_2	-218
WO_3	-200
MoO_3	-180
Cu_2O	-40
SiC	-15
Au in Si	-2.3[(a)]
Ni_3C	+16
Au_2O_3	+19

(a) Heat of solution

The thermal vaporization energy for gold from tungsten is about 3 eV per atom, and the kinetic energy of the vaporized atom is about 0.3 eV per atom. Thus the kinetic energy is only a small part of the energy being released during deposition. However, it has been shown, using mechanical velocity filters, that the kinetic energy of the depositing gold particles is important to the film structure, properties, and annealing behavior.

If the depositing atom has greater than thermal energy, due either to being vaporized by sputtering (and not "thermalized" during transport from source to substrate), or to being accelerated as an ion (film ion), the kinetic energy that it releases will be greater than thermal. If the depositing species is excited or ionized, it also releases the excitation energy or the ionization energy. In these situations the energy released also includes excess kinetic energy, excitation energy (if an excited species), or ionization energy (if an ionized species).

Interface Formation

The depositing film material can diffuse and react with the substrate to form an "interfacial region." The material in the interfacial region has been called the "interphase material," and its properties are important to the adhesion, electrical, and electronic properties of film-;substrate systems. The type and extent of the interfacial region can change as the deposition process proceeds or be modified by postdeposition treatments. Interfacial regions are categorized as (Ref 26):

- Abrupt
- Mechanical (specific type of the abrupt interface)
- Diffusion
- Compound (also requires diffusion)
- Pseudodiffusion (physical mixing, ion implantation, recoil implantation)
- Reactively graded
- Combinations of the above

Figure 3 schematically shows the types of interfacial regions.

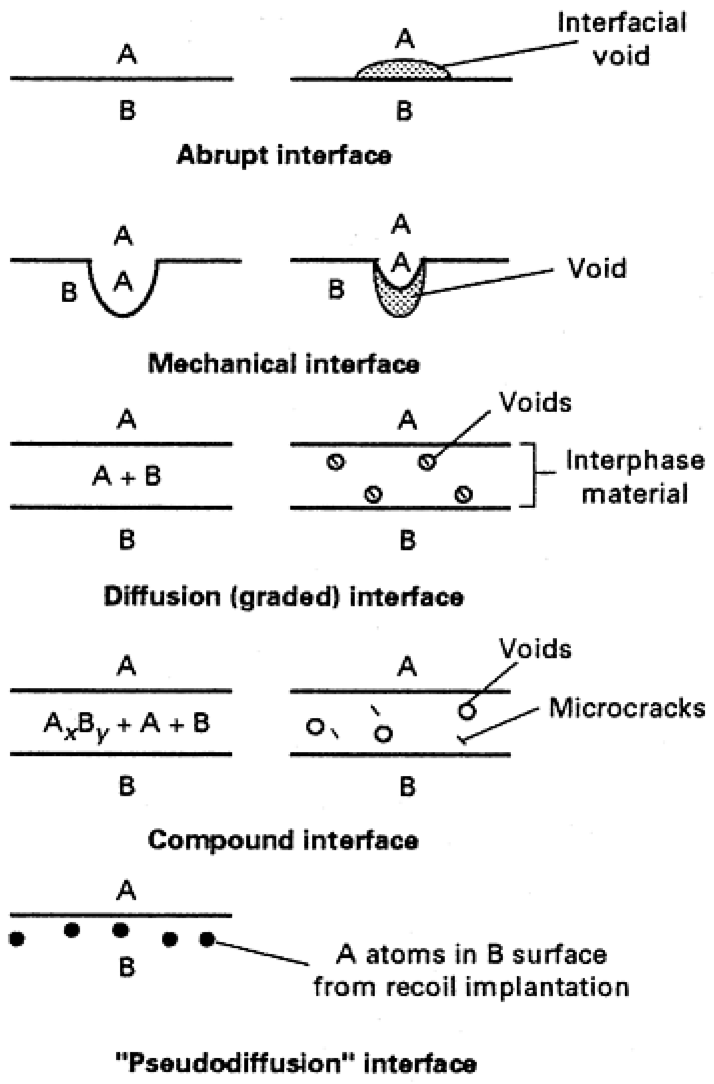

Fig. 3 Types of interfacial regions

The abrupt interface is characterized by an abrupt change from the film material to the substrate material in a distance of the order of the atomic spacing (i.e., 0.2 to 0.5 nm), with concurrent abrupt changes in material properties. This type of interface is formed when there is no bulk diffusion, and it generally signifies weak chemical reaction between the depositing atoms and the substrate, a low deposition temperature, surface contamination, or no solubility between film and substrate materials. The formation of this type of interfacial region generally means that the nucleation density is low and that the film will have to grow to appreciable thickness before it becomes continuous. This results in the formation of interfacial voids along the interface. Typically the adhesion in this system is low because of interfacial voids and an easy fracture path.

Mechanical Interlocking Abrupt Interface. The mechanical interface is an abrupt interface on a rough surface where the deposited material forms a conformal surface to the roughness and the rough surface is "filled in" to give mechanical interlocking. The strength of the interface depends on the mechanical properties of the materials. To fracture along the interface requires following a tortuous path with changing stress tensors, and the adhesion of the film to the surface can be high. Surfaces can be made rough or porous to increase the degree of mechanical interlocking. The adhesion of this couple is limited by the deformation and/or fracture properties of the materials involved. If the roughness is not filled in, the adhesion will be low due to the lack of contact and interfacial voids. The filling in of the roughness can be aided by having a dispersed adatom flux distribution, concurrent energetic particle bombardment, or high surface mobility of the deposited material.

The diffusion interface is characterized by a gradual change or gradation in composition across the interfacial region with no compound formation. The diffusion interface is formed when there is mutual solid solubility between the film and substrate material and the temperature and time are sufficient to allow diffusion to occur. This type of interfacial system is often found in metallic systems. Some systems, such as silver on iron and indium, or gallium on GaAs, have no solubility and an abrupt interface is formed. If contamination is present on the surface, diffusion can be suppressed.

The extent of diffusion in the interface depends on time and temperature. Differing diffusion rates of the film and substrate materials can create porosity in the interfacial material. Porosity formed by this mechanism is called *Kirkendall porosity*. This porosity can weaken the interfacial material and provide an easy fracture path for adhesion failure.

In some cases, diffusion barriers are used at the interface to reduce diffusion. For example, tungsten plus titanium or the electrically conductive nitride, TiN, is used as a diffusion barrier in silicon metallization to inhibit aluminum diffusion into the silicon during high-temperature processing. The presence of compound-forming species in the depositing material reduces the diffusion rate. Alternatively, the depositing material can be alloyed with substrate material to reduce diffusion rates.

In high-temperature processing the substrate material near the interface can be weakened by the diffusion of a constituent of the substrate into the depositing film material. For example, the diffusion of carbon from cemented carbide tools during CVD deposition of coating forms a weak eta phase at the interface. Conversely the diffusion from the substrate can result in increased adhesion. For example, it has been shown that in the deposition of carbides on oxide surfaces the oxygen intermixes and reacts with the carbide material, producing a "keying" action.

Compound Interface. Diffusion, along with chemical reaction, forms a compound interfacial region. The compounds formed are often brittle, and high stresses are often introduced due to the volumetric changes involved in forming the new phase(s). Sometimes these stresses are relieved by microcracking in the interfacial region, thus weakening the interphase material. The compound interface is generally conducive to good adhesion, but if the reaction region is too thick, the development of porosity and the formation of microcracked brittle compounds can lead to poor adhesion.

The compound interface is the type of interface found in reactive systems, such as oxygen-active metal films on oxide substrates (Ref 27), or in intermetallic-forming metal-on-metal systems such as Au-Al and Al-U. In the case of Au-Al, the interdiffusion and reaction forms both Kirkendall voids and a brittle intermetallic phase termed "purple plague" that causes easy bond failure (Ref 28).

Table 1 lists heats of reactions of various materials in forming compounds. An exothermic reaction is one in which heat is released and is indicated by a negative heat of formation. An endothermic reaction is one in which heat is taken up and is indicated by a positive heat of reaction. In some layered film systems there can be an exothermic reaction such that large amounts of heat are generated after the reaction has been "triggered." Such systems are Pd-Sn, Al-Pd, and Al-Zr, which have increasingly higher "triggering" temperatures. Multilayer composite structures of these materials can be used to rapidly release heat (Ref 29).

Interfacial Boundary. It should be remembered that diffusion and reaction can continue during the deposition process, particularly if an elevated deposition temperature and long times are used. For example, with aluminum on platinum an Al-Pt intermetallic is formed, and as the intermetallic layer thickness increases it removes the aluminum preferentially from grain boundaries at the Al/Al-Pt interface. This leads to void formation at the grain boundaries and the formation of "capillary voids."

As diffusion proceeds, the interfacial boundary becomes "rough." Rapid diffusion can occur at grain boundaries and dislocations, giving a "spiked" interfacial surface that aids in the bonding of some coatings to surfaces but can cause shorting in semiconductor junctions ("pipe diffusion"). Rapid heating and cooling can also limit diffusion and in ion plating, where heat is introduced directly into the surface, a cold substrate can be used. As a postdeposition process, heating by rapid thermal processing can be used to limit preferential diffusion along lattice defects.

The interphase material formed by diffusion and reaction often contains a graded composition with properties that vary throughout the layer. If the material becomes thick, it can develop high residual stress, voids, and microcracks that weaken the material and result in poor adhesion. The interphase material is important in film adhesion, contact resistance, and the electronic "interfacial states" of metal-semiconductor contacts.

In the extreme the film material can completely react with the substrate, thus forming a film of the interphase material. This is usually an effect of high substrate temperature during deposition or postdeposition processing. For example, it has been reported that sputter-deposited tungsten on silicon forms a silicide film that has the same properties as 900 °C (1650 °F) furnace-diffused tungsten-on-silicon silicide films. Platinum on silicon can also be completely reacted to form silicide electrodes on the silicon.

Metal-Polymer Interfaces. In the case of polymer surfaces, particularly glassy polymers, the depositing atoms can diffuse into the surface, then nucleate, forming nuclei of the material in the subsurface region. For example, in the deposition of copper on polyimide at low deposition rates (1 monolayer/min), copper nuclei are formed beneath the surface while chromium, which forms a chemical bond with the polymer chain, does not diffuse into the surface. The nucleation and chemical bonding of the adatoms to the polymer surface determine the adhesion strength (Ref 30).

Pseudodiffusion Interfaces. In deposition processes, an interface with a graded composition and materials properties can be formed by "grading" the deposition from one deposited material to the other. For example, in depositing Ti-Au or Ti-Cu metallization, the gold or copper deposition can begin before the titanium deposition has ended. This produces a graded interface similar to the diffusion interface, called a *pseudodiffusion interface*. This can be formed between insoluble materials, such as silver and iron, and at low temperatures where the phases do not segregate. This method of grading the interface also avoids the potential problem of oxidation of the titanium film before the gold or copper is deposited. If oxidation occurs, the adhesion between the titanium and the gold or copper layers will be poor. The pseudodiffusion type of interface can also be formed by "recoil implantation" during concurrent or subsequent ion bombardment.

Reactively Graded Interface. A compound-containing interfacial region that consists of a graded compound-matrix material can be formed by controlling the availability of reactive gases during reactive deposition. For example, a TiN hard coating can be deposited with a graded interfacial layer of Ti to TiN_x, to improve adhesion, by controlling the availability of the reactive nitrogen.

Characterization of Interfaces. Generally the interphase material is difficult to characterize because it usually consists of a small amount of material buried under a relatively thick film. In 1988 the National Science Foundation conducted a workshop on adhesion, and one of the principal determinations was that the properties of the interphase material were poorly characterized and understood (Ref 31).

In some cases the compositional profile of the interfacial region can be determined using Auger electron spectroscopy in combination with sputter etching or Rutherford backscatter spectrometry (Ref 15). Cross section TEM can be used with proper care not to introduce artifacts due to sample preparation.

Modification of Interfacial Regions. Interface composition, structure, and extent can be modified by:

- Substrate surface cleaning and surface preparation
- Changing the substrate temperature and deposition time
- Introducing energy into the surface region during deposition by concurrent ion bombardment, laser heating, and so on

Surface preparation is an important factor in interface formation in that the interface reactions can be drastically modified by the presence of strongly bound contaminants such as oxygen, carbon, and nitrogen, whereas weakly bound contaminants such as H_2O, CO, and hydrogen, can be displaced from the surface during deposition.

Ion bombardment, before and during deposition, can introduce defects into the surface region, and diffusion can be enhanced by mechanisms similar to those found in "radiation enhanced diffusion." For example, in the aluminum metallization of silicon it has been shown that there is little diffusion of aluminum into silicon during high-temperature processing if the silicon surface is undamaged. However, extensive diffusion occurs if the surface is damaged by ion bombardment.

Film Growth

Films grow by the continuous nucleation of depositing atoms on previously deposited material. The film growth, as well as the nucleation mode, determines many film properties, such as density, surface area, surface morphology, and grain size. Important aspects of film growth are:

- Continual burial of the surface under newly depositing material
- Substrate surface roughness--initially, and as the film develops
- Surface temperature--initially, and as the film develops
- Adatom surface mobility
- Geometrical shadowing effects (angle-of-incidence effects)
- Reaction and mass transport during deposition, such as segregation effects and void agglomeration

Developing Surface Roughness. On an atomistic scale, surface morphology can vary from very smooth, such as that of a flowed glass surface, to very rough, such as is found with sintered materials (see Fig. 2). Generally, as the film grows the surface roughness increases because some features or crystallographic planes grow faster than others. The roughness may not be uniform over the surface, or there can be local areas of roughness due to scratches, vias, embedded particles, particulate contamination, and so on that lead to variations of the film properties in these areas.

Structure-Zone Model (SZM). Typically the film near the interface is influenced by the substrate and/or interface material, and it takes an appreciable thickness before the film establishes a particular growth mode. After a growth mode has been established, the film morphology can be described by a structure zone model (SZM). The SZM was first applied to vacuum-deposited coatings by Movchan and Demchishin in 1969 (Ref 32). Later the SZM was extended to sputter-deposited films by Thornton (Ref 33), as shown in Fig. 4, and was later modified by Meissier (Ref 34) to include point defect agglomeration and void coarsening with thickness. The details of the condensation processes that determine the film morphology at low temperatures where atom mobility is low are not well understood, although there are a number of factors involved, including:

In vacuum:

- Angle-of-incidence of the adatom flux effects (i.e., geometrical shadowing)
- Ratio of the deposition temperature (in K) to the melting temperature (in K) of the film material
- Energy released on condensation
- Adatom surface mobility on surfaces and crystallographic planes
- Surface roughness
- Deposition rate
- Void coalescence
- Mass transport and grain growth during deposition

In sputter deposition and ion plating (Ref 13):

- Adsorption of inert and/or reactive gaseous species on the surface
- Gas scattering of vaporized particles
- Concurrent bombardment by high-energy particles, which can be from reflected high-energy neutrals from the sputtering target that are not thermalized by collisions in the gas phase, accelerated negative ions from the sputtering target, accelerated positive ions from a plasma, or energetic neutrals formed by charge exchange processes

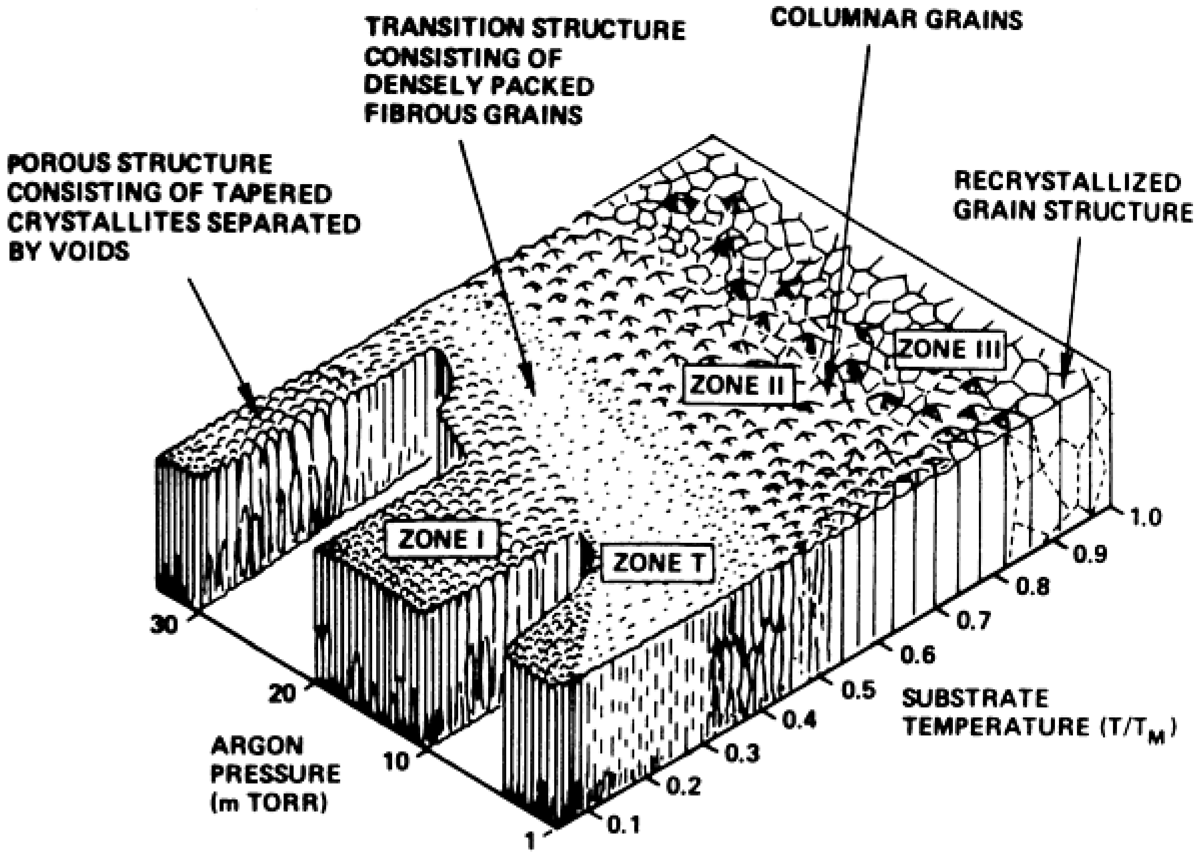

Fig. 4 Structure-zone model for sputter-deposited films (Ref 33)

The morphology of the depositing film is determined by the surface roughness and the surface mobility of the depositing atoms, with geometrical shadowing and surface diffusion competing to determine the morphology of the depositing material. When the surface is rough, the peaks receive the adatom flux from all directions, and if the surface mobility of the adatoms is low, the peaks grow faster than the valleys due to geometrical shadowing. This shadowing effect is exacerbated if the adatom flux is off-normal so that the valleys are in "deeper shadows" than when the flux is normal to the surface. Adsorbed gaseous species decrease the adatom surface mobility, while concurrent energetic particle bombardment can increase or decrease the surface mobility.

SZM Zone 1. In Zone 1 of the Movchan and Demchishin model and in the Thornton model, the adatom surface diffusion is insufficient to overcome the geometrical shadowing by the surface features. This results in open boundaries between the columns that are formed. This morphology produces a film with a high surface area and a film surface that has a "mossy" appearance. Higher gas pressures extend this zone to higher temperatures due to gas scattering, and surface mobilities decrease due to gas adsorption and collisions on the surface. The columnar morphology that develops has been computer modeled for depositing spheres (Ref 35). The columns can have different shapes such as round columns for aluminum (as shown in Fig. 5) and platelets for beryllium. The columns are not single grains. The columns can be microns in size, but the grain size can be less than 1000 Å (100 nm) or even amorphous within the columns. Because the columnar growth is strictly a function of surface geometry and adatom surface mobility, amorphous as well as crystalline materials show the columnar growth mode.

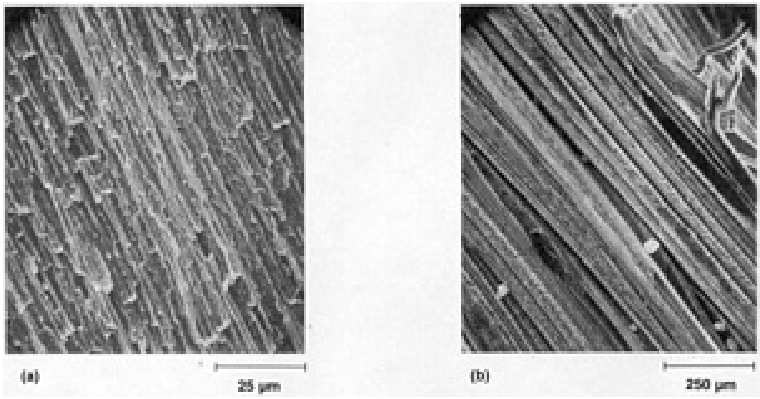

Fig. 5 Columnar morphologies of (a) sputter-deposited stainless steel and (b) vacuum-deposited aluminum films

The development of the columnar morphology begins very early in the film growth stage and generally becomes prominent after about 100 nm of thickness. For example, in the sputter deposition of MoS_2 solid film lubricants, the growth is such that, irrespective of the thickness of the deposited film, during wear, all the columns shear off at their base, leaving a surface layer of about 200 nm thickness. Another example is the vacuum deposition or sputter deposition of CoCr, a magnetic recording material that is very sensitive to film growth. The film consists of columnar grains with the hexagonal close-packed (hcp) *c*-axis, which is the easy magnetization direction, perpendicular to the substrate surface. TEM studies of the growth of sputter-deposited CoCr on NaCl at 100 °C (212 °F) show the following stages of columnar morphology development as a function of film thickness (Ref 36):

- Less than 5 nm: Poor crystal quality--substrate effects
- 10 nm: Good hcp with clear grain boundaries--grain size 2 to 8 nm, various crystallographic orientations
- 80 nm: Well-developed columnar grain orientation
- 100 nm: *c*-axis becomes perpendicular to growth direction, grain size 15 to 25 nm

Angle-of Incidence Effects. The columnar growth is exacerbated by oblique deposition flux orientations because now the valleys get no flux. The oblique angle of incidence can be due to a rough surface, a surface with features such as steps, scratches, or vias, or an off-normal deposition on a relatively smooth surface. For an off-normal incident flux, the columns do not grow normal to the surface but grow toward the adatom source with a change in column shape. The off-normal growth gives an even more open morphology with a lower density than that of the normal-deposited columnar morphology. The off-normal incidence can vary over the surface due to local surface morphologies such as that of a sintered material (see Fig. 2), scratches, via sidewalls, particulates, steps (Ref 37), etc. Figure 6 shows a "nodule" in a sputter-deposited chromium film that developed on particulate contamination on the substrate surface.

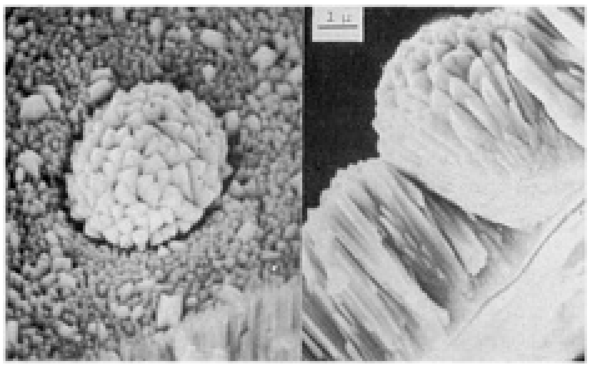

Fig. 6 Picture of a "nodule" in a thick sputter-deposited chromium film

Angle-of-incidence effects can be apparent when the substrate is moved in front of the vaporization source, as in the case of the use of a pallet fixture. In this case the angle of incidence starts very low, goes through normal incidence, then exits at a low angle of incidence. The initial growth at high angle can influence the growth at normal incidence.

SZM Zone T. In the zone model for sputter-deposited films, Thornton introduced the zone T. In zone T the coating has a fibrous morphology and is considered to be a transition from zone 1 to zone 2. The formation of the zone T material is due to the energetic bombardment from reflected high-energy neutrals from the sputtering target at low gas pressures. These energetic high-energy neutrals erode the peaks and fill in the valleys to some extent.

SZM Zone 2. In zone 2 the growth process is dominated by adatom surface diffusion. In this region, surface diffusion during deposition allows the densification of the intercolumnar boundaries. However, the basic columnar morphology remains. The grain size increases and the surface features tend to be faceted.

SZM Zone 3. In zone 3, bulk diffusion allows recrystallization, grain growth, and densification. Often the highly modified columnar morphology is detectable, with the columns being single crystals of material.

Surface Morphology Effects on Film Morphology. A columnar morphology will develop on a smooth substrate surface as it roughens with film thickness during growth. If the surface is not smooth, the variation in the angle of incidence and the general roughness will produce a more complex morphology and generally a less dense film than on a smooth surface. For example, a film grown on the surface shown in Fig. 2 will consist of a "microcolumnar" morphology of columns grown in films on each of the individual "boulders" and a "macrocolumnar morphology" resulting from shadowing effects by the boulders. The result will be a very complicated morphology that will depend on the surface morphology. If the surface has some morphology pattern, such as the patterned metallization on a smooth silicon wafer, the angle of incidence will vary with position on the surface, and differing film properties with position can be expected over the surface. For example, the film on the sidewall of a via can be expected to be less dense than the surface facing the vapor source directly (Ref 37). This effect is easily demonstrated using chemical etch rate tests. It is important to remember that the film growth can vary over the surface due to surface inhomogeneities, angle-of-incidence variation, and variations in the process variables.

Particulates on the surface present very local changes in surface morphology, and local features develop such as those shown in Fig. 6. These features are poorly bonded to the film and the surface and easily come out, leaving a pinhole in the film. The resulting pinhole will be larger than the initiating particulate. This "pinhole flaking" from film deposited on surfaces and fixtures in the deposition system can be a major source of particulate contamination in the deposition system. It is particularly evident when the surfaces and fixtures have been cleaned by glass bead blasting and glass chards have been embedded in the surfaces.

Residual Gas Effects on Film Growth. Residual gases in the deposition system can influence the growth, structure, morphology, and properties of the deposited films. The origins of these effects are poorly understood, but some portion can be attributed to changing the surface mobility of the adatom. In the case of reactive deposition, the residual gas partial pressure is high and has a major effect on the surface mobility and the development of columnar morphologies at high deposition temperatures.

Changes in Microstructure and Morphology during Deposition

Film microstructure, morphology, and properties can be influenced by processes that occur after adatom condensation but during film growth. The processes that change the film properties include:

- Mass transport, such as growth of the interfacial region and crystal defect formation and void coalescence
- Recrystallization and grain growth
- Phase precipitation and growth
- Chemical reaction of codeposited species

- Stress annealing

Many of these changes are time- and temperature-dependent and therefore depend on the thermal history of the film during deposition. This thermal history depends on the deposition temperature, condensation energy release, deposition rate, deposition time, thermal conductivity of the film and substrate materials, heat removal mechanisms, and so on.

Modification of Film Morphology. The film morphology and microstructure can be modified during growth. Methods of modifying the columnar growth include continuous or periodic:

- Bulk or surface heating by laser or radiant heating
- Codeposition of alloying species
- Reaction with ambient gaseous species
- Changing angle of incidence of adatom flux
- Mechanical disruption of the growth
- Changing deposition rate
- Changing gas pressure
- Bombardment by massive energetic particles

Heating. Increasing the deposition (substrate) temperature changes the film morphology, as shown in Fig. 4. Surface heating by a laser or by a radiant heat source can change the surface mobility of the adatom, thereby changing the growth mode of the deposited material.

Codeposition of Alloying, Impurity, or Dopant Species. Codeposition of alloying species can change the surface mobility and thus the film morphology. Alloying species that lower the melting point of the deposited material are particularly effective.

Impurities are small amounts of material incorporated into the structure unintentionally. The addition of small amounts of an impurity can have a significant influence on the microstructure and properties of the growing film. Small amounts of nitrogen in aluminum films change the electromigration properties. Residual gases present during deposition can affect film stress.

Dopants are small amounts of materials that are deliberately incorporated into the structure to affect microstructure or film properties. For example, the inclusion of gold, nickel, or cobalt (5 wt%) in sputter-deposited MoS_2 films for solid film lubricants produces "compact" films that are physically stronger to greater thicknesses than MoS_2 films sputtered without the additions.

Periodic Injection of Reactive Gas. Periodic reaction of the surface of the growing film with ambient species generates a new surface chemistry. This can force the adatoms to renucleate on the "foreign" surface, thereby changing the film morphology. For example, the periodic injection of oxygen during aluminum deposition suppresses the columnar growth morphology (Ref 38). The same effect is seen for nitrogen on beryllium films. The effect is similar to the "brightening agents" used in electrodeposition.

The angle of incidence of the adatom flux is important to the growth of the columnar morphology. The angle of incidence can be modified by proper fixturing and position control. Generally it is not possible to optimize the angle of incidence for all surface features.

Mechanical Disruption during Deposition. Mechanical disruption of the growing surface can be used to change the columnar morphology. Periodic mechanical brushing of a surface during deposition has been used to densify and eliminate porosity in sputter-deposited aluminum films and in CVD-tungsten deposits.

Changing Gas Pressure during Deposition. For gaseous environments, where vapor phase collision processes are important, changes in the ambient pressure change the scattering and thermalization of the adatom flux, and, in the case of sputter deposition, the flux and energy of reflected high-energy neutrals. These factors are important in determining the film morphology, stress (Ref 39), and other properties.

Concurrent Massive Energetic Particle Bombardment. In ion plating, the growing film is subjected to continuous or periodic energetic particle bombardment during deposition. When massive energetic particles bombard a surface, they release their energy rapidly by physical collisions with the near-surface atoms. These physical collisions cause a number of effects, some of which modify the columnar morphology of the growing film. These effects include:

- Sputtering and redeposition
- Input of "heat" into the surface and the near-surface region
- Increased or decreased surface mobility of the depositing atoms
- Generation of point defects that act as nucleation sites

Typically, a film sputtering rate of 20 to 40% of the deposition rate or an energy input of about 20 eV per depositing atom is necessary to completely disrupt the columnar growth process.

Reactive Deposition

Reactive deposition is the formation of a film of a compound, either by codeposition and reaction of the constituents or by the reaction of a deposited species with the ambient gaseous environment. If the reacting species form a volatile compound, etching results. If the reaction results in a nonvolatile species, a compound film is formed (Ref 40).

Codeposition of reactive species does not necessarily mean that they will chemically react to form a compound. For example, a mixture of titanium and carbon may not have any TiC, or it may be partially TiC and the rest an unreacted mixture of titanium and carbon, substoichiometric TiC_{1-x}, or TiC with excess titanium or carbon, each of which will have different properties. Generally, for low-temperature deposition, the best situation for reactive deposition is where one of the reacting species is condensable and the other is gaseous (e.g., titanium plus nitrogen). If both are condensable (e.g., titanium plus carbon), the best deposition condition is to have a high substrate temperature to promote reaction or use postdeposition heat treatment to promote reaction. Reactively deposited films of oxides and nitrides are commonly used in the optics, electronics, decorative, and mechanical applications, with TiN being one of the more common film materials.

There are a number of techniques for performing reactive atomistic film deposition. The simplest way is to thermally evaporate the material in a partial pressure of a reactive gas in the process called *reactive evaporation* (see the article "Vacuum Deposition, Reactive Evaporation, and Gas Evaporation" in this Volume). This generally gives poor-quality films because the materials are not completely reacted and the high gas pressures necessary for reaction result in gas phase collision and vapor phase nucleation, giving a low-density deposit. Better-quality films are obtained by promoting the chemical reaction by some means, such as activating the reactive gas or using concurrent energetic particle bombardment to promote the chemical reaction (Ref 13).

Reactive Species

Molecular Species. Typically gaseous reactive species are in the molecular form (i.e., N_2, O_2, H_2, etc.). The molecular species is less chemically reactive than the atomic species of the gas.

Activated Reactive Species. The gaseous reactive species can be "activated" to make them more chemically reactive and/or more readily adsorbed on surfaces (Ref 13). The reactivity of the species can be increased by adding internal energy to form "excited species," by fragmenting the species to form uncharged "radicals," such as O, N, or F, by forming ions, which are charged species such as O^+, N_2^+, or N^+, or by forming a new volatile reactive species, such as ozone (O_3) from O_2 + O or Si_2H_6 from SiH_4. Activation is most often done in a direct current, radio frequency, or microwave plasma, in a plasma arc, or by radiation adsorption (e.g., "photoexcitation") from a source such as a mercury vapor lamp or an excimer laser. Such activation is done in reactive sputter deposition, reactive ion plating, PECVD, and activated reactive evaporation. Activation of the gaseous species can also be done using other means, such as the hot filament decomposition of NH_4, F_2, and H_2.

A plasma provides a very complicated chemical environment that can give reactive deposition processes that are not normally expected. For example, the sputter deposition of gold on oxide surfaces in an oxygen-containing plasma gives rise to very adherent gold films. It has been shown that the deposition of gold in an oxygen plasma gives rise to Au-O bonding. This may be due to the formation of activated oxygen species in the plasma or the formation of a more readily adsorbed reactive species (i.e., O_3) (Ref 41, 42).

Reaction Probability

In reactive deposition, the depositing material is continually being buried and the time available for reaction is limited. The probability of chemical reaction of the growing film surface depends on a number of factors, including:

- Temperature of the surface
- Chemical reactivity of the species
- Extent of prior reaction on the surface (e.g., whether the surface composition is $TiN_{0.1}$ or $TiN_{0.95}$)
- Relative fluxes of condensing species and incident gaseous species (i.e., the "availability" of the reactive species)
- Residence time (adsorption) of reactive species on the surface
- Radiation by electrons capable of stimulating chemical reactions on the surface
- Radiation by photons capable of stimulating photochemical reactions
- Energy of the incident reactive species
- Concurrent bombardment by energetic species not involved in the reaction (e.g., concurrent argon ion bombardment during titanium plus nitrogen deposition)

In many cases, surface reaction occurs first at active sites on a surface providing a nonhomogeneous growth mode. The extent to which this occurs in reactive deposition is not known.

Adsorption on a Surface. For an ambient pressure of 10^{-3} torr (0.13 Pa) and 25 °C (77 °F), gaseous particles will impinge on a surface at about 10^3 monolayers/s, compared to a typical atomistic deposition rate of 10 or so monolayers per second. The impinging species may be reflected with little residence time, or they may be adsorbed with an appreciable residence time (Ref 42). Adsorbed species will be available for reaction for a longer period of time than the reflected species. The adsorption probability and adsorbed film thickness will depend on a number of factors, such as the impinging species, nature of the surface, adsorption sites, and so on. For instance, it has been shown that atomic oxygen on silicon will adsorb with a higher probability and to a greater thickness than molecular oxygen and that ozone (O_3) is strongly adsorbed on Al_2O_3, whereas O_2 is not (Ref 41). It has also been shown that the surface stoichiometry affects the adsorption. For example, stoichiometric TiO_2 surfaces do not adsorb oxygen but substoichiometric surfaces do, with the amount depending on the degree of substoichiometry. In plasma CVD of silicon from silane (SiH_4), it has been shown that the disilane species formed in a plasma has a high adsorption probability and is important in the deposition of the silicon at low temperatures (Ref 22). Oxygen molecules will react with a pure aluminum film, but nitrogen molecules will not react. The probability that the oxygen molecules will react with the aluminum decreases as the aluminum reacts with the oxygen molecules and the oxygen coverage increases.

Reaction Extent. The extent of the reaction before the surface is buried also depends on the factors listed above. For example, in the case of atomic oxygen on silicon surfaces, the reaction probability will decrease monotonically with coverage through several monolayer coverages. If the material can form a series of compounds (e.g., TiN, T_2N) the probability of reaction is further decreased as the extent of reaction increases, making it more difficult to form the higher compound (i.e., TiN will be more difficult to form than the Ti_2N).

Reactant Availability. The degree of reaction of codepositing species depends on the availability of the reactive species; therefore, the relative fluxes of the reactants are important. This gives rise to the "loading factor," which means that there is a relationship between the surface area for reaction (deposited film area) and the amount of reaction gas available.

Stoichiometry. Many materials form a series of stable compounds that have different crystal structures. For example, titanium and oxygen form TiO, Ti_2O_3, TiO_2 (brookite), TiO_2 (anatase), and TiO_2 (rutile). By controlling the availability of the reactive gas, the stoichiometry of the resulting film material can be controlled. The stoichiometry of the material can be changed during the deposition by changing the reactant gas availability.

Reactively Graded Interface. The composition of the reactively deposited material can be controlled by controlling the availability of the reactive species. This allows the gradation of composition from an elemental phase to the compound phase. For example, in the deposition of titanium nitride TiN, the deposition may start by having no nitrogen available, so as to deposit pure titanium, and then increase the nitrogen availability so as to grade the composition to TiN. This technique is often helpful in obtaining good adhesion of compound films to surfaces. Another example is the deposition of a nitride on an oxide where the deposited material is graded from an oxide through an oxynitride composition to the nitride by controlling the availability of both oxygen and nitrogen.

Free electrons can enhance chemical reactions in the vapor phase and on a surface. Electron energies of about 50 eV are the most effective. The effect of electrons on reactive deposition is relatively unknown.

Photon radiation can enhance chemical reactions by exciting the reacting species (photoexcitation), thereby providing internal energy to aid in chemical reactions (Ref 18).

Energetic Inert Particle Bombardment Effects. The reactivity between codeposited or adsorbed species can be increased by using concurrent energetic particle bombardment by a reactive species or with an inert species that does not enter into the reaction. Concurrent energetic particle bombardment during reactive film deposition has been shown to have a substantial effect on the composition, structure, and properties of compound films (Ref 43, 44). In general, the bombardment:

- Introduces heat into the surface
- Generates defects that can act as adsorption and reaction sites
- Dissociates adsorbed molecular species
- Produces secondary electrons that can assist chemical reactions

- Selectively desorbs or sputters unreacted or weakly bound species

This process has been termed "bombardment-enhanced chemical reaction" (Ref 44). It is of interest to note that Coburn and Winters attribute the major portion of bombardment-enhanced etching of silicon with fluorine to the development of the volatile high-fluoride compound (SiF_4) (i.e., more complete reaction) under bombardment conditions. Periodic bombardment of a depositing species by energetic reactive species can accomplish many of the same effects (Ref 45). For example, oxide films can be formed by depositing several monolayers of aluminum, then alternately bombarding the film with energetic oxygen ions and depositing more aluminum to form an aluminum oxide film.

Beam Deposition Using Activated Species. Ions of an activated species can be produced in a separate source, accelerated, and then used to bombard the depositing material in a vacuum environment to give "reactive ion beam" deposition. For particle energies greater than a few tens of electron volts, the energetic particle will physically penetrate into the surface, thereby increasing its "residence time." For example, it has been shown that for N_2^+, ions having an energy of 500 eV impinging on a depositing aluminum film, all of the nitrogen will react with the aluminum up to a N:Al deposition ratio of 1:1 (Ref 46).

Deposition of Composite Materials

Composite materials are materials that consist of several phases in the form of either layers or phases dispersed in a matrix.

Layered Composites. In many applications, multilayer film structures are used. One of the most common uses is to produce an adhesion layer next to the substrate with the functional layer(s) on top, such as the Ti-Au metallization on oxides. In some cases several layers are used. Examples are Ti-Pd-Au (Ref 47, 48), where the palladium inhibits corrosion, and the Ti-Pd-Cu-Au metallization, where the copper acts as an economical electrical conductor and the gold is present to prevent surface reaction.

Dispersed Phase Composites. Dispersed phase materials can be formed by codepositing insoluble materials. If the temperature is high enough for mass transport, the phases will separate, resulting in a two-phase material. Composite materials can also be formed by codepositing materials where the phase formed by reaction is dispersed in a matrix of the unreacted material (Ref 49). For example, a reactive material such as titanium can be codeposited with a less reactive material such as nickel in a reactive environment of oxygen or carbon to give dispersed phases of oxides (TiO_2) or carbides (TiC) in nickel. Composite films can be formed by a minor constituent reacting with the major constituent to form an intermetallic phase that is dispersed in the major phase. For example, in the Al-2Cu metallization, on heating, the Al_2Cu phase will precipitate to form a dispersion in the aluminum. This precipitate phase then acts as segregation sites for voids formed due to film stress. In cases where two or more materials are depositing at the same time on nonreactive surfaces, there may be changes in composition in the early stages of nucleation due to differing segregation effects.

The presence of second-phase materials in a film can lead to galvanic corrosion problems when an electrolyte is present. For example, Al-Al_2Cu composite films have been found to be more susceptible to intergranular and pitting corrosion than pure aluminum films (Ref 50). The Al_2Cu acts as a cathode (-0.73 volts) while the aluminum acts as the anode (-0.85 volts). The corrosion effects become more important with increasing copper concentration, so the copper in the Al-Cu metallization is limited to 2 to 4% when a homogeneous distribution of the Al-Cu particles is desirable.

Composite materials of metal particles in a polymer matrix can be formed by deposition of the metallic phase during plasma polymerization. Such a composite film has been shown to have a better wear durability than the polymer film alone (Ref 51) and to have interesting optical properties.

Deposition of Intermetallic Materials

Intermetallic compounds are formed from relatively electropositive and electronegative metals that chemically bond to form compounds with a specific composition and crystalline structure. Intermetallic films are often formed by depositing the film material on a hot surface so that the adatoms diffuse and react with the surface material, converting it into a silicide, aluminide, or whatever. Very corrosion-resistant intermetallic materials can be formed by codeposition processes at high temperatures. These include the very chemically stable compounds Mo_5Ru_3 and W_3Ru_2 (Ref 52) and $ZrPt_3$ and $ZrIr_3$, which are d-orbital bonded intermetallic compounds (Ref 53).

"Amphoteric" metals are those that may gain or lose electrons, that is, act as either an acid (electron donor) or a base (electron acceptor) in chemical reactions.

Postdeposition Processing

Postdeposition heating of films can be done in a furnace, by flash lamp heating such as is used in RTP techniques, or by laser irradiation. In the extreme, the heating can be used to melt and "reflow" the film to planarize the surface.

Postdeposition heating can create film stresses due to differences in the coefficient of thermal expansion between the film and substrate and between different phases in the film. These stresses can result in plastic deformation of the film or substrate material, create stress-related changes in the film properties such as voids (Ref 54), or create interfacial fractures.

Diffusion. Heating is used to promote mass transport so as to anneal the residual stress and defect structure in deposited films. For example, it has been shown that glass films exhibit strain points far lower than those of the bulk material (Ref 55), that grain growth can take place in sputter-deposited copper films at very low temperatures (Ref 56), and that stress relief in TiB_2 films occurs far below the annealing temperature of the bulk material. Postdeposition heating has been shown to modify the structure and electrical properties of deposited SiO_2 films. These effects are probably due to the residual film stress and high defect concentrations in the deposited films.

Postdeposition heat treatments can be used to induce grain growth or phase changes, but care must be taken because the changes can result in increased film stress or fracture. The substrate material and structure can influence the kinetics of the phase change by influencing the nucleation of the new phase. Postdeposition heating rarely allows densification of columnar films, because the surfaces of the columnar structure react with the ambient and the surface layers that are formed prevent the diffusion needed for densification. Typically, heating during deposition or in situ heating in the deposition chamber is more effective in densifying deposits than ex situ heating.

Agglomeration. Postdeposition heating can cause the film structure to agglomerate into islands generating porosity and changing the optical and electrical properties of the films (Ref 57). Agglomeration also occurs by grain boundary grooving of the film material (Ref 58).

Heating with Reaction and Diffusion. Postdeposition heat treatments are used to promote reaction between unreacted codeposited materials and to promote reaction of the deposited material with an ambient gas. For instance, it is common practice to heat deposited high-temperature oxide superconductor films in an oxygen atmosphere to improve their performance, and transparent, electrically conductive indium-tin-oxide films are heated in "forming gas" to increase their electrical conductivity. Heating can also cause the formation of internal dispersed phases (e.g., Ni-B, Cu-Al) to give dispersion strengthening.

Heating is used to alloy the deposited material with the substrate surface. Postdeposition diffusion and reaction can form a more extensive interfacial region and induce compound formation in semiconductor metallization. Postdeposition heating and diffusion can be used to completely convert the deposited material to interfacial material. For example, a platinum film on silicon can be heated to form a platinum silicide layer. Postdeposition interdiffusion can result in the failure of metallized semiconductor devices by diffusion and shorting of the junctions.

Alloying and reaction between films and substrates can be limited by:

- Deposition of refractory metal diffusion barriers such as tungsten or W-Ti alloy
- Deposition of electrically conductive diffusion barrier layers of compounds such as carbide (e.g., TiC), nitrides (e.g., TiN), or silicides (Ref 59)
- Formation of compounds that act as diffusion barriers when the film and substrate materials react
- Doping of the film or substrate materials with a material that retards mass-transport (e.g., rare earth metals in aluminum)
- Rapidly heating and cooling the surface region

Melting. The XeCl (308 nm) excimer laser has been used to melt and planarize thin films of gold, copper, and aluminum on silicon devices with submicron features.

Postdeposition ion bombardment using reactive or nonreactive bombarding species can be used to change the composition or properties of the film material or to increase the interfacial adhesion by interfacial mixing or "stitching" (Ref 60).

To "recoil mix" or "stitch" an interface, the films must be rather thin (<100 nm) and the ion energies are selected to give the peak range just beyond the interface. In recoil mixing at an interface, if the materials involved are miscible, the ion mixing results in interfacial reaction and diffusion. If the materials are not miscible, the interfacial region is not mixed but the adhesion is increased. Generally adhesion improvement is dose dependent, with the best result being for doses of 10^{15} to 10^{17} ions/cm^2, while excessive bombardment induces interfacial voids. Part of the observed increase in adhesion may be due to the elimination of interfacial voids by "forward sputtering."

Deformation. In the case of films of soft materials, the film structure can be densified and porosity closed by postdeposition burnishing (Ref 61) or shot peening of the surface. For example, the MCrAl (where M can be a metal of various types) films deposited on turbine blades are routinely shot peened to increase their corrosion resistance.

Chemical and Electrochemical Treatments. Deposited films may be subjected to various chemical and electrochemical treatments to convert all or part of the film to another material. For example, aluminum films can be anodized (Ref 62) or chemically converted by a chromate conversion process for increased corrosion resistance.

Pore Filling. Porosity of the deposited films is often a limiting factor in their use. Various techniques may be used to fill the pores in the film. For example, electrophoretic deposition of polymer particles has been used to selectively fill the pores in a dielectric film on a conductive substrate (Ref 62), and corrosion of the substrate through the pores has been used to plug the pores with corrosion products.

Topcoats are often applied to deposited films to increase abrasion and corrosion resistance. An example of a fluid topcoat is the dip-coated polysiloxane coating used on aluminum-coated polycarbonate automotive headlight reflectors.

Fluid Topcoats. Often deposited coatings are overcoated with a thin (<1μm) protective film of highly cross-linked polymeric material. Many topcoat materials require heat for curing. The heating is necessary to remove the solvents and cross-link the polymeric materials. Due to environmental concerns this type of topcoat material is being modified to give a higher "solids content" (i.e., less solvent will be released into the environment). Another class of polymeric topcoat materials are the organo-siloxanes, which consist of an organic host polymer containing siloxane coupling agents and colloidal silica. The coatings can be applied by spraying, spinning, or dip coating and can be cross-linked by UV radiation or electron irradiation (e.g., UV-curable acrylics).

Plasma-Deposited Topcoats. Some topcoat material can be deposited by plasma polymerization. For example, plasma polymerization of polysiloxane is used to form organo-silicon coatings, which are sometimes heat treated in oxygen to increase the Si-O content of the films. The plasma-polymerized organo-silicon films have excellent surface coverage ability and are hydrophobic, hard, and relatively pinhole-free. The films are being used as clear protective topcoats on optical reflective films. Plasma-deposited organo-carbon films are used as conductive films.

Growth-Related Film Properties

Films deposited by PVD processes invariably have properties that differ from those of the bulk materials (Ref 63). For this reason the specific film properties should be determined for films made with controlled and reproducible materials

and processes. The columnar morphology and the residual film stress developed during film growth are important to a number of the film properties and the stability of the deposited film structure, including:

- *Density*--mechanical deformation, electrical resistivity
- *Porosity*--corrosion rate, etch rate
- *Surface area and morphology*--contaminant adsorption, optical reflectivity, electrical resistivity

Residual Film Stress

Invariably, atomistically deposited films have a residual film stress that can be tensile or compressive and that can approach the yield or fracture strength of the materials involved. Generally, vacuum-deposited films and sputter-deposited films prepared at a high sputtering gas pressure have a tensile stress that can be anisotropic with off-normal angle-of-incidence depositions. Compressive stresses are generally encountered in films deposited under conditions where there is concurrent high-energy particle bombardment, such as in ion plating and in low-pressure sputtering where high-energy reflected neutrals from the target bombard the growing film (Ref 39). Figure 7 shows the residual film stresses generated in one direction in the film during postcathode magnetron sputter deposition of molybdenum. The film stress is anisotropic and is related to the configuration of the sputtering cathode. At low pressures, where there is bombardment by high-energy reflected neutrals, the stress is compressive. At higher pressures the stress is tensile, and at even higher pressures, where the morphology is more columnar and the film density is lower, the stress decreases. The origin of these stresses is poorly understood, though several phenomenological models have been proposed (Ref 64).

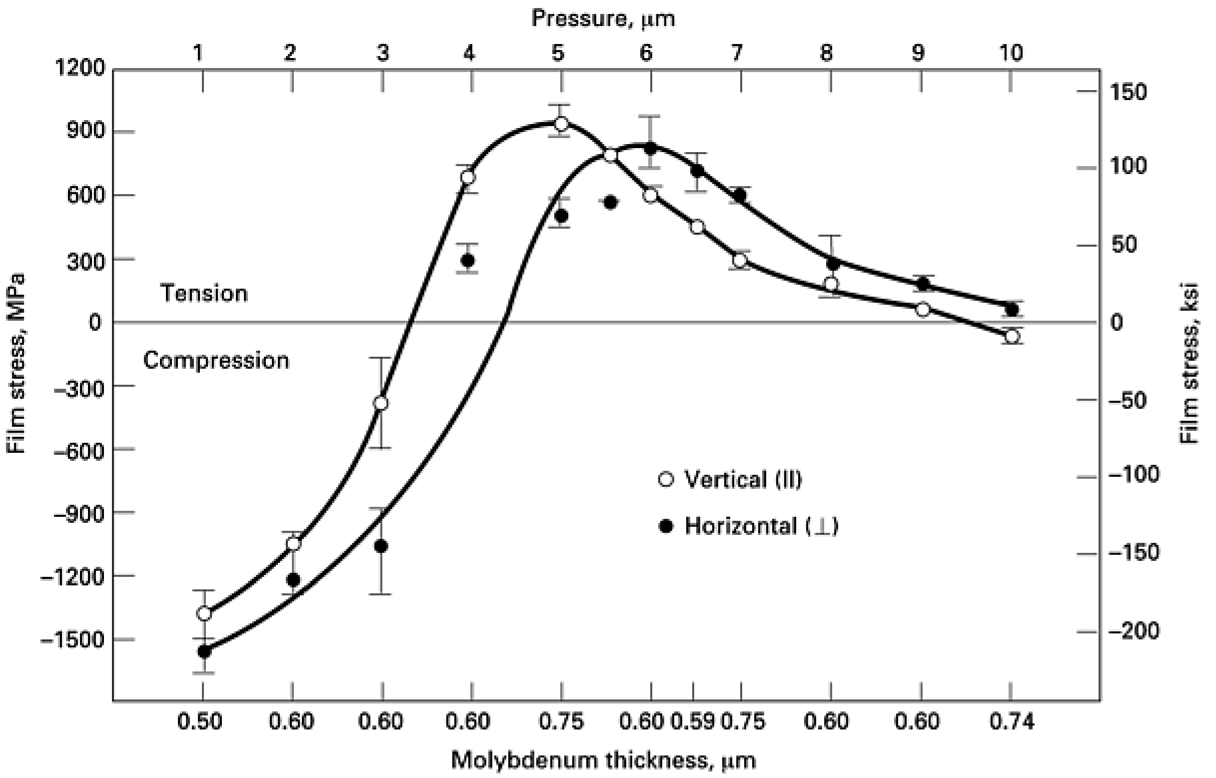

Fig. 7 Film stress as a function of gas pressure in postcathode magnetron sputter-deposited molybdenum films (Ref 39)

Tensile stresses can be developed when the growth mechanism does not allow the depositing atoms to attain their lowest energy positions. The Klockholm-Berry model is based on a constrained shrinkage of deposited material resulting in lattice parameters greater than normal. The grain boundary model attributes the stress to the development of grain boundary material. It has been proposed that the coalescence of lattice defects into "microvoids" causes the tensile stresses. It has been shown that the mechanical properties of the grain material are important to the resulting stresses and that impurity incorporation and reaction with the depositing film material can also be important factors in the stress

generation. Tensile stresses can also be generated by phase changes and recrystallization, which result in volumetric shrinkage.

For high-temperature deposition conditions, the differences in the coefficients of thermal expansion of the substrate and film material can produce thermal (shrinkage) stresses that put the film in tension or in compression, depending on which material has the greater thermal expansion.

Film stress can change with film thickness. Stress gradients can exist in the deposited film due to the growth mode and differing thermal histories of the various layers of the film. These stresses can give the outermost layer of the film a tensile stress compared to the rest of the film. This film stress profile leads to "curling" of a film when it is detached from the substrate. If the adhesion failure is such that some of the substrate material remains attached to the film, the film can curl because of the constrained surface. Local stresses can be found in films where there is nonhomogeneous growth, such as over steps and defects in the substrate.

On a thin substrate that is in the form of a thin, long beam, the sum of all these stresses in the film causes the "beam" to bend. From the degree of bending and the material properties, the film stress can be calculated. The force on a substrate due to the film stress is a function of the film thickness. Film stress can also be determined by x-ray diffraction measurements of lattice strain, but this does not fully take into account boundary effects. The film morphology affects the stress buildup with a columnar morphology resulting in a low total stress.

Film stress and the resulting force and shear stresses are important factors in the adhesion and stability of films. High isotropic compressive film stresses produce "blistering" of the film from the surface in "worm-track" patterns. High isotropic tensile film stresses produce microcracking of the film. The cracks tend to meet orthogonally and form polygon "islands" or "chips" such as are seen in dried "mudflats" (Ref 65). Because the interface is constrained, the mudflat islands will tend to curl at the edges. If the compressive stresses are highly anisotropic, the "worm-track" pattern changes to line-shape blisters. If the tensile stresses are highly anisotropic, the "mud-flatting" pattern changes to linear cracks. If the adhesion between the film and the substrate is high, the stress can cause fracture in the film or substrate material. The film buckling or cracking can be time-dependent and can also depend on the moisture available in the ambient environment. This time/environment-related failure is called *static fatigue* (Ref 66). Fractures and fracture patterns in films can be detected by the use of fluorescent tracers. Generally, residual film stress should be minimized to prevent failure.

Modification of Film Stress. There are several methods of modifying the mechanical stresses developed in films during growth:

- Limiting the thickness of the stressed film
- Using concurrent energetic particle bombardment during deposition to maintain a near-zero-stress condition (Ref 67)
- Periodically alternating the concurrent bombardment conditions (Ref 39)
- Periodically adding alloying or reacting materials
- Mixing materials
- Deliberately generating an open columnar morphology that cannot transmit a stress

Limiting the film thickness is generally the most easily accomplished approach. As a "rule-of-thumb," the thickness of high-modulus materials such as chromium and tungsten should be limited to less than 50 nm to avoid excessive residual stress. If the film thickness is to exceed that value, some technique for stress monitoring and control should be developed.

One technique to control film stress is to use concurrent ion bombardment during deposition to create compressive stress to offset the tensile stress (Ref 67). By carefully controlling the bombardment parameters it is possible to find a zero-stress condition. Unfortunately this condition is usually very dependent on the process parameters and the proper conditions are hard to control and maintain. A more flexible technique is to alternately deposit layers having tensile and compressive stresses that offset each other (Ref 39). This can be done by varying the concurrent bombardment from the reflected high-energy neutrals in low-pressure sputter deposition, bombardment from a plasma or bombardment from an ion gun.

Adhesion

Adhesion is a fundamental requirement of almost all film systems. It is determined by the nature of the stresses that appear at the interface and the energy needed to propagate a fracture and/or cause deformation. Film adhesion is intimately connected with the film and substrate properties as well as the properties of the interfacial (interphase) materials (Ref 26). Good adhesion is promoted by high fracture toughness of the interface and the near-surface material, presence of fracture blunting and deflecting features, low stresses and stress gradients, absence of fracture-initiating features, and an absence of operational adhesion-degradation mechanisms.

Poor adhesion can be attributable to low degree of chemical bonding, poor interfacial contact, low fracture toughness (brittle materials, flaws), high residual film stresses, fracture-initiating features, and/or operational adhesion-degradation mechanisms. Poor adhesion may be localized so as to give local failure (i.e., pinholes). In many systems where direct adhesion is difficult to attain, an intermediate material is introduced onto the substrate surface to bond to both the substrate and the film material. Substrate surface roughness can improve or degrade the adhesion, depending on the ability of the deposition technique to fill in the surface roughness and the film morphology generated. The generation of a good interface is also important to other properties such as thermal transport and electrical contact resistance. The lack or loss of adhesion is often called *deadhesion*.

Modeling of Adhesion. The principal models used for explaining adhesion are:

- Surface energy reduction, wettability, and spreading--commonly used with polymer bonding
- Interfacial fracture and deformation--used in inorganic systems (Ref 26)

In the latter case the fracture toughness or fracture energy is the relevant physical parameter. This depends on the stress at the interface and the properties of the interface, the "interphase material," and the nearby material of the film and substrate. The failure modes for ductile materials will be quite different from those of brittle materials.

Causes of Deadhesion. The stresses that appear at the interface and can cause adhesion failure (deadhesion) include:

- *Mechanical*--tensile, shear, compressive, shock, fatigue
- *Chemical and electrochemical*--corrosion, solution
- *Thermal*/*time*--diffusion, reaction

These stresses can cause loss of adhesion at or near the interface by:

- Fracture and deformation at the interface--mechanical
- Generation or propagation of flaws in the interface region--mechanical, static fatigue
- Corrosion at the interface--chemical
- Dissolution of interfacial material--chemical
- Diffusion of material away from the interface--thermal (Ref 21)
- Diffusion of species to the interface--thermal
- Phase change of material at the interface giving flaws and stress--thermal, diffusion

These stresses can originate externally to the film from the environment, subsequent processing, storage, or use, or they can be internal to the film-substrate structure. In addition, residual ionic species in the film can cause interfacial corrosion if exposed to humidity, or dissolved mobile species, such as gases, can migrate to the interface, causing deadhesion.

Deadhesion due to Fracture. The loss of adhesion under mechanical stress (tensile, compressive, shear) occurs by deformation and fracture of material at or near the interface. The fracture mode (brittle or ductile) depends on the properties of the materials. The fracture path depends on the applied tensor stress, the presence of flaws, the interface configuration, "easy fracture paths," and the properties of the materials involved.

The fracture toughness (K_c) of a material is a measure of the energy necessary for fracture propagation and is thus an important adhesion parameter. In fracture, energy is adsorbed in the material and at the propagating crack tip by elastic deformation, plastic deformation, generation of defects, phase changes, and the generation of new surfaces. If this fracture

occurs at an interface or in the nearby material, then loss of adhesion (deadhesion) occurs. Fracture mechanics approaches to measuring, describing, modeling, and/or predicting thin film (or any interface) adhesion are few. Some work has been published on the fracture of thick film and thin film systems. Thouless (Ref 68) has described the problem of critical and subcritical crack growth in thin film systems. Very little has been done to elucidate the effects of environment (subcritical crack growth) and film properties (Ref 69) on fracture and adhesion of thin film systems.

The fracture toughness of a material depends on the material composition, the microstructure, the flaw concentration, and the nature of the applied stresses. If an interphase material has been formed in the interfacial region it will be involved in the fracture process. Such interphase material is formed by diffusion, by diffusion plus compound formation, and by physical processes such as physical mixing and recoil implantation. The interphase material may be weaker or stronger than the nearby film and/or substrate material. For example, carbon lost from high-carbon steel substrates by diffusion into the film material during high-temperature processing can weaken the substrate and strengthen the film material. A National Science Foundation workshop in 1987 determined that the properties of the "interphase" (interfacial) material are some of the critical concerns in quantifying, measuring, and modeling the adhesion failure process (Ref 31). At present there are few if any good characterization techniques for determining the properties of interfacial materials that affect adhesion, such as fracture toughness, deformation properties, interfacial stress, presence of microscopic flaws, or effects of degradation mechanisms.

When a fracture surface (crack) advances, energy is needed for the creation of new crack surfaces and the deformation processes around the crack tip. This energy is supplied by the applied stress and the internal strain energy stored in the film-substrate system (residual film stress). The path of crack propagation is determined by the mechanical properties of the materials and by the resolved tensor stresses (tensile and shear) on the crack tip. The crack may progress along a plane of weakness, through weak material, or it can be diverted into stronger materials by the resolved stress. The fracture path is also determined by the presence of features that can blunt or change the fracture propagation direction.

Interfacial Morphology Effects on Fracture. In atomistic film deposition, the nucleation of depositing atoms on a smooth surface is controlled by various factors such as surface chemistry and nucleation sites. If the film-substrate interface is smooth, then any interfacial growth defects, such as interfacial voids, will lie in a plane that will then be a plane of weakness or "easy fracture path" along which fracture will easily propagate.

If the surface is rough and the deposited film material "fills in" the roughness, the propagating fracture must take a circuitous path with the likelihood that the fracture will be arrested and have to be reinitiated, as in the case of fiber-reinforced composite materials. If the roughness is not "filled in," there will be weakness (voids and low contact area) built into the interfacial region. Therefore the nature of the substrate surface roughness and the ability of the deposition process to fill in this roughness is important to the development of good adhesion.

The energy necessary for fracture propagation (fracture energy) can be lessened by mechanisms that weaken the material at the crack tip or reduce the elastic-plastic deformation in the vicinity of the crack tip. These mechanisms can be dependent on the environment in the case of ionically bonded materials. If time is involved in reducing the strength of the crack tip, the loss of strength is called *static fatigue* (Ref 66). Static fatigue depends strongly on mechanical (stress) and environmental (chemical) effects, particularly moisture and hydrogen (Ref 70).

Brittle surfaces and interfaces can be strengthened by placing them in compressive stress. This can be done by chemically replacing some surface ions with larger ions (chemical strengthening), by ion implantation, by putting the interior of the bulk material into tensile stress, or by placing the film in a state of compressive stress.

Residual Film Stress Effects on Adhesion. Invariably, atomistically deposited films have a residual stress that can be either tensile or compressive and can approach the yield or fracture strength of the materials involved. These stresses can arise from high-temperature deposition when there are differences in the thermal coefficients of expansion between the film and substrate, thermal gradients formed in the depositing film, and/or stresses due to the growth of the film. These stresses can enhance or retard fracture propagation.

In thin-film systems, high residual stress can be relieved by plastic deformation, blistering of the film from the surface in the case of compressive stress, or by microcracking and flaking in the case of high tensile stresses. If the film adhesion is high or the strength of the surface or film is low, the actual fracture path can be in the substrate or film and not at the interface. In many cases, in order to obtain good adhesion the residual film stress must be minimized and controlled. In some cases, film adhesion can increase with time due to the relief of high residual film stress.

Localized regions of high intrinsic stress can be found in films due to growth discontinuities or defects such as pinholes, nodules, or surface features such as edges or inclusions. These stressed areas can lead to localized adhesion failure under applied stress, producing pinholes.

Static fatigue is the slow growth of a crack under ambient stress and environmental conditions (Ref 66). The static fatigue failure mode due to moisture can be accelerated by breathing on the films to condense moisture at the crack tip. This moisture condensation method is an easy method of quickly determining if the residual film stresses are high, if the adhesion is poor, and whether the stresses in a failed film are compressive or tensile.

Corrosion. Interfacial corrosion/dissolution occurs when chemical or electrochemical (galvanic) effects create a solid or soluble corrosion product at the interface. An example of the loss of adhesion due to corrosion effects is the degradation of Ti-Au metallization in an HCl environment. This electrochemical degradation can be prevented by the addition of a thin intermediate layer of palladium between the titanium and the gold. The presence of chloride ions is generally to be avoided; they are often present as residues from cleaning and processing steps. Corrosion products can aggravate failure by a "wedging" action at the crack tip, either by solid corrosion products or by gas accumulation.

The diffusion of material away from the interface can weaken the interface by producing voids or in the extreme the complete removal of a bonding layer. For example, in the case of Cr-Au metallization, heating the system to higher than 200 °C in air will cause the chromium to diffuse from the interface to the surface, where it is tied up as the oxide (Ref 21). If all of the chromium diffuses from the interface, the gold film will not adhere. This "out-diffusion" of the interfacial material is dependent on the gaseous ambient, and a nonoxidizing ambient reduces the diffusion. The incorporation of a small amount of oxygen in the gold during deposition (by deposition in an oxygen plasma) reduces the chromium diffusion rate and gives a more thermally stable metallization.

Diffusion to the Interface. Interfaces generally act as preferential condensation regions for diffusion species. Diffusion of species to the interface can weaken or strengthen the interface. The deposition process may have influence on this effect. For instance, plasma cleaning of glass surfaces prior to silver deposition has been shown to give a time-dependent improvement in the adhesion of the silver films after deposition. Precipitation of gas at the interface to form voids will reduce adhesion. The diffusion of hydrogen through a film to an interface where it precipitates has been used by the electroplating community as an adhesion test. Diffusion and precipitation of vacancies form voids at interfaces that can cause adhesion loss.

Diffusion of water vapor through a polymer film to the interface can lead to the degradation of metal-polymer adhesion (Ref 71). Interfacial mixing can improve the moisture degradation properties of polymer-metal film systems.

Interdiffusion and reaction at the interface can generate an undesirable interphase material that results in a loss of adhesion. For example, in Au-Al metallization, interdiffusion and reaction form both Kirkendall voids and a brittle intermetallic phase ($AuAl_2$), termed "purple plague," that causes loss of adhesion (Ref 28).

Film Morphology Effects on Adhesion. Film properties can influence the apparent adhesion of a film-substrate couple (Ref 72). The mechanical, microstructural, and morphological properties of the film material determine the ability of the material to transmit mechanical stress and to sustain internal stresses. For example, a columnar film morphology can exhibit good adhesion because each column is separately bonded to the substrate and the columns are poorly bonded to each other. The columnar morphology is generally not desirable because of its low density and high surface area.

Deliberate Nonadhering Coatings. In some situations, adhesion is not desirable. For example, one technique to form freestanding films or shapes is to deposit a coating on a mandrel and then separate the coating from the mandrel. The coating can be deposited on a substrate to which it will not adhere, or a "parting layer" (release layer) can be used (Ref 73). In the electrodeposition of freestanding copper or gold structures, stainless steel or carbon is often used as a mandrel, because the chromium oxide and carbon are good electrical conductors but copper and gold will not adhere to the oxide or carbon surface. Easily dissolved materials such as sodium chloride or polymers can be used as parting layer materials. In some cases, particularly for complex shapes, the mandrel must be completely dissolved to release the structure.

Film Density and Surface Area

The presence of porosity in the columnar structure, closed and open voids, and pinholes means that the film density is lower than that of the bulk material and that the surface area exposed to the ambient is much higher than the geometrical

surface area. This low density and high surface area influence many film properties, such as hardness, deformation, chemical etch rate, resistivity, and index of refraction.

Open porosity features pores that connect to the free surface and contribute to the surface area of the film. The coalescence of lattice defects along surfaces such as grain boundaries and the open space between the columns in the columnar microstructure are sources of such porosity. Process parameters that affect the growth of the columnar microstructure affect the film porosity. For example, the porosity of vacuum-deposited films can be varied by controlling the substrate surface roughness, angle of incidence of the adatom flux, or the gas pressure during deposition.

Through porosity is a special case of open porosity where the porosity is aligned in such a manner as to allow an open space to exist between the film surface and the substrate surface. Through porosity develops from the columnar growth, particularly on rough surfaces, and the growth on surface contaminants such as particulates (see Fig. 6). Such porosity causes pinholes in the film and allows corrosion of the substrate through the pinholes, electrical "opens" in patterned electrical circuits, optical transmission, and high surface diffusion rates from the interface to the film surface.

Crystallographic Orientation

The crystallographic orientation of the grains in the film is determined by the preferential growth of certain crystal planes over others. This orientation can be altered by epitaxial growth on a substrate or by concurrent energetic ion bombardment.

Even when single crystal films are not formed, it is often found that a preferential crystallographic orientation or texture develops in deposited films. This texturing can lead to nonisotropic film properties in materials that do not have cubic crystal forms.

Epitaxial Film Growth. *Epitaxy* is defined as the oriented overgrowth of film material and typically refers to the growth of single crystal films (Ref 74). *Homoepitaxy* is the epitaxial growth of a deposit on a substrate of the same material (e.g., doped Si on Si). *Heteroepitaxy* is the epitaxial growth of a deposit on a substrate of a different material (e.g., Au on Ag, GaAs on Si). Epitaxial growth requires some degree of mobility of the atoms and nuclei on the surface. An "epitaxial temperature" necessary for epitaxial growth in specific systems and under specific deposition conditions is sometimes specified.

Single crystal overgrowth can be accomplished with large mismatches in lattice parameters between the film and substrate, either by keeping the thickness of the deposited material small, so that the mismatch can be taken up by straining the film lattice without forming lattice defects ("strained layer superlattice"), or by using a "buffer" layer to grade the strains from the substrate to the film. For example, thick single crystal SiC layers can be grown on silicon by CVD techniques even though the lattice mismatch is large (20%). This is accomplished by forming a buffer layer by first carbonizing the silicon surface and grading the composition from the substrate to the film. However, in general, if the lattice mismatch is large, the interface has a high density of dislocations and the resulting film is polycrystalline.

Oriented growth can be enhanced by "seeding" of the substrate surface with oriented nuclei. Such "seeds" can be formed by depositing a small amount of material, heating the surface to form isolated oriented grains, and then using these grains as seeds for the deposition of an oriented film.

Energetic adatoms and low-energy ion bombardment during deposition can be used as partial substitutes for increased substrate temperature in the epitaxial growth process. Carefully controlled bombardment can lower the temperature at which epitaxy can be obtained. This is probably due to increased surface mobility of the adatoms. Ion beams of the depositing material (film ions) have also been used to deposit epitaxial films.

Lattice Defects and Voids

Lattice defects are point defects in the lattice and the microstructures, such as dislocations, that arise from coalescence of point defects or the relaxation of elastic strains. Voids are internal pores that do not connect to a free surface of the material and thus do not contribute to the surface area but do affect film properties such as density. During film growth, vacancies can agglomerate into "microvoids" in the crystal structure. Defects in the films can be reduced by:

- Increased substrate heating during deposition

- Controlled concurrent ion bombardment during deposition--use of low enough particle energies such that the bombarding species are not incorporated into the growing film

Point defects in the film can affect the electrical conductivity and electromigration in metallic films, and carrier mobility and lifetime in semiconductor materials. Generally, high-defect concentrations result in poor electromigration properties. Lattice defects have been shown to be important to the properties of the high-transition-temperature superconductor films.

Surface Coverage

Surface geometry affects the growth of films by shadowing the surfaces from the depositing flux of atoms. Steps, vias, and grooves are of particular importance, and in order to get conformal coverage over such surfaces, the deposition often must be done at an elevated temperature to increase surface mobility or by using backsputtering/redeposition. Off-normal incidence of the depositing flux makes conformal coverage more difficult. The ability of concurrent ion bombardment to improve step-coverage is of great interest in microelectronic fabrication. The improved coverage by concurrent ion bombardment is due to a number of factors, including:

- Forward sputtering (Ref 75)
- Gas scattering--randomizing of direction of adatom flux
- Backscattering of sputtered material
- Ionization and return of sputtered material

Graded Properties

There are a number of effects that lead to changes of film properties with thickness (graded properties). As previously discussed, the film growth mode is continually changing with thickness in the early stages of growth, particularly on rough surfaces. The initial deposition may have reacted with residual gases, giving a changing composition with thickness. In addition, the initially deposited material is being heated while the film is growing, thus allowing annealing during growth. The degree of this annealing differs with deposition time, deposition rate, thickness, and the thermal transport properties of the film and substrate material.

Postdeposition Changes (Stability) in Film Properties

High surface areas and high residual film stress are major factors in the change of film properties with time. The high surface areas allows corrosion and adsorption to play major roles in the stability of film properties. Residual stress represents stored energy that can give long-term stability problems.

Adhesion. In some cases, film adhesion can increase or decrease with time under ambient conditions. The increase in adhesion can be due to diffusion of reactive species to the interface or the relief of residual stresses. The film adhesion may decrease with time, and it can be due to static fatigue fracture at the interface due to residual stress, promoted by the presence of moisture, or to corrosion of the interface by ambient species.

Microstructure. High residual stress and high point defect concentrations can lead to time-dependent changes in the microstructure of the deposited material. This may lead to low-temperature grain growth and recrystallization in sputter-deposited copper and the generation of voids ("stress voiding") at room temperature.

Electromigration (Ref 76) and stress-induced void formation (Ref 54, 77) in aluminum metallization can be reduced by the addition of a material that will react with the aluminum to form finely dispersed second-phase materials that act as sinks for migrating defects and coalescing voids. Copper is the common material added to aluminum metallization to reduce stress-induced voiding and electromigration (Ref 77). The copper forms the theta Al-Cu phase Al_2Cu.

Residual Stress. A high internal concentration of defects along with high intrinsic stress can lead to time-dependent changes of stress ("stress relaxation") in films.

Electrical Properties. Changes of the electrical resistivity of a film can be due to oxidation of the columnar surfaces. The combination of metallic conduction in the columns and the tunneling conduction through oxide layers on the column surfaces, allows the formation of films that have a low-temperature coefficient of resistivity.

Unique Materials Formed by Atomic Deposition Processes

Amorphous materials are those that have no detectable crystal structure. Materials can be naturally amorphous, such as the nonmetallic glasses. Some normally crystalline materials can be formed in the solid amorphous condition by rapidly cooling ("quenching") from the liquid phase (Ref 78).

Amorphous film materials can be formed by:

- Deposition of a natural "glassy" material such as a glass composition
- Deposition at low temperatures where the adatoms do not have enough mobility to form a crystalline structure
- Ion bombardment of high-modulus materials (Ref 79)
- Deposition of materials some of whose bonds are partially saturated by hydrogen (e.g., a-Si:H, a-C:H, and a-B:H, where "a" stands for *amorphous*)
- Deposition of complex metal alloys

Hydrogen seems to play a very unusual role in the growth of some materials. In the case of depositing silicon from the silane (SiH_4) precursor gas in CVD, the incomplete decomposition of the precursor results in the deposition of a-Si, which can contain 10 to 15 at.% H. The hydrogen prevents Si-Si bonding, thus causing the film material to be amorphous in much the same way as "glass formers" do in forming glasses by melting. The a-Si seems to deposit much like a polymer film, giving very good surface replication and low void density in the early stages of film growth.

The unique applications of amorphous materials arise because of:

- Absence of grain boundaries--no grain boundary diffusion
- Low void/pinhole content
- Considerable compositional latitude
- Unique optical properties
- Unique electronic properties
- Ease of fabrication

Some semiconductor materials grow with some of their bonds unsaturated ("dangling"). This can lead to unacceptable electron trapping. It has been demonstrated that the unsaturated bonds in a-Si can be passivated by hydrogen doping, thus raising the electron mobility in the material. Hydrogen ion bombardment is now used to treat polycrystalline silicon photovoltaic materials to improve photoconversion efficiency.

Metastable or labile phases are unstable phases of materials that are easily changed if energy is available for mass transport processes to occur. Deposition processes allow the development of metastable forms of the material. Metastable crystal structures can be formed by rapid quenching of high-temperature phases of the deposited material, or they can be stabilized by residual stresses or impurities in the film. For example, diamond is a metastable phase of carbon that is formed naturally in a high-pressure and high-temperature environment and changes to graphitic carbon on heating. However, diamond films can be deposited using the proper deposition techniques. Metastable film compositions can also be formed under deposition conditions that do not allow precipitation of material when it is above the solubility limit of the system. For example, concurrent low-energy ion bombardment using "dopant ions" allows doping of semiconductor films to a level greater than that obtainable by diffusion-doping techniques (Ref 80).

Diamond and Diamond-like Carbon (DLC) Films. Recently great progress has been made in the deposition of diamond and diamond-like carbon (DLC) coatings for industrial applications. Natural diamond, with its high hardness, low coefficient of friction, high thermal conductivity (1.5 times that of silver), high packing density, good visible and infrared transparency, and chemical inertness, has long provided a goal for the thin film deposition community.

Diamond is a carbon material with a specific crystallographic structure (diamond structure) and specific chemical bonding (sp^3 bonding). DLC is an amorphous carbon material with mostly sp^3 bonding that exhibits many of the desirable

properties of crystalline diamond. DLC material is sometimes called "amorphous diamond," but that term is an oxymoron and should be avoided.

The property of the carbon sp^3 bonding that allows the deposition of both diamond and DLC coatings is its relative chemical inertness to hydrogen reduction. The sp^3 bonds formed during deposition are stable against hydrogen etching. Any sp^2 (graphite) bond formed, however, is susceptible to hydrogen etching.

Polycrystalline diamond films can be formed if the deposition temperature is high enough (>600 °C, or 1100 °F) to allow atomic rearrangement during deposition. DLC films are formed at lower temperatures (room temperature and even below) where the atoms cannot arrange themselves into the diamond structure, giving an amorphous material. The DLC films have varying amounts of sp^2 bonding and included hydrogen that affect their properties. The sp^3-bonded material can be deposited by a number of techniques, all of which involve "activating" both a hydrocarbon species, to allow carbon deposition, and hydrogen, to provide the etchant species.

Polycrystalline diamond films are most often deposited by the hot filament CVD technique, the combustion flame technique, or PECVD using a microwave plasma. In all cases, the diamond film that is formed is polycrystalline and has a rough surface. This is due to the method of film nucleation on the substrate surface and the nature of the film growth. This rough surface gives a high coefficient of friction, and a great deal of work is being done to try to improve this surface morphology for wear and friction applications. Other properties can approach those of natural diamond.

DLC films are made primarily using PECVD or ion beam techniques with low substrate temperatures (Ref 81). The DLC films are smooth with properties approaching those of natural diamond, except that thermal conductivity is much lower. DLC films can also be deposited by ion bombardment processes that do not involve hydrogen. These films are sometimes called "i-C" films (Ref 79). DLC films are being used as coatings on optical products such as eyeglasses, sunglasses and IR optics, and as wear-resistant coatings on storage media and cutting surfaces.

Vacuum Deposition, Reactive Evaporation, and Gas Evaporation

Donald M. Mattox, IP Industries

Introduction

VACUUM DEPOSITION, or vacuum evaporation, is a physical vapor deposition process in which the atoms or molecules from a vaporization source reach the substrate without colliding with residual gas molecules. Generally, the vaporization source is one that vaporizes materials by thermal means (that is, evaporation or sublimation), but other vapor sources can be used. The advantage of vacuum evaporation is that films of a variety of materials can be deposited at high rates over large areas in a very pure form. Limitations of vacuum evaporation are that often the films do not have optimum properties and that there are relatively few deposition parameters that can be modified to improve the film properties.

Vacuum deposition requires a vacuum of better than 13 mPa (0.1 mtorr). At this pressure, there is still a large amount of concurrent bombardment of the substrate by potentially undesirable residual gases that can contaminate the film. If film

contamination is a problem, a high (13 μPa, or 10^{-7} torr) or ultrahigh (0.13 μPa, or 10^{-9} torr) vacuum environment can be used to produce a film with the desired purity, depending on the deposition rate, reactivities of the residual gases and depositing species, and the tolerable impurity level in the deposit.

Vacuum deposition of a film was first reported by Faraday in 1857 using exploding wires. Nahrwold was the first to use thermal evaporation in a vacuum to produce a thin film, in 1887. Vacuum deposition was not routinely used until about 1929, when it was first used for optical coatings (Ref 1). Strong, for example, metallized the 100 in. mirror for the Mount Wilson Observatory in 1935. The subject of vacuum deposition was thoroughly investigated by Glang in 1970 (Ref 2), and most review articles and book chapters on the subject since that time have drawn heavily on his work.

In reactive evaporation, a partial pressure of reactive gas is used to deposit compounds of the vaporized material by the reaction of deposited atoms with ambient gases. Reactive evaporation was first reported by Auwarter in 1952 and Brinsmaid et al. in 1953. In 1971, Heitmann used reactive evaporation to deposit oxide films by evaporating the film material through a plasma of the reactive gas, and this technique is now generally called activated reactive evaporation. With this method, either a gas, such as oxygen or nitrogen, or a hydrocarbon is metered into the vacuum chamber, where it reacts with the vapor from a metallic evaporant to form a metal oxide, nitride, or carbide coating.

In gas evaporation, a high residual gas pressure causes the formation of ultrafine (100 nm, or 1000 Å) particles by gas phase collision and nucleation. Gas evaporation is a term given to the deposition of ultrafine particles ("smokes"), which are formed by gas phase nucleation due to collision of the evaporated atoms with residual gas molecules. This typically requires an ambient gas pressure greater than about 1.3 mPa (10 torr). The formation of useful films of ultrafine particles formed by gas evaporation was reported by Pfund, who produced "zinc black" infrared absorbing films in 1933.

Vacuum Deposition

In the vacuum deposition process, elements, alloys, or compounds are vaporized and deposited in a vacuum. The process is carried out at pressures of less than 0.1 Pa (1 mtorr) and usually in vacuum levels of 10 to 0.1 mPa (100 to 1 μtorr). The substrate temperature typically ranges from ambient to 500 °C (930 °F). Figure 1 shows a typical batch vacuum deposition system. Vacuum deposition is commonly used to deposit pure metals (for example, aluminum, silver, gold, nickel, chromium, titanium, molybdenum, and tungsten), some alloys (for example, stainless steel, nickel-chromium, lead-tin, and M-Cr-Al-Y), and selected compounds (for example, Al_2O_3, TiC, and TiB_2).

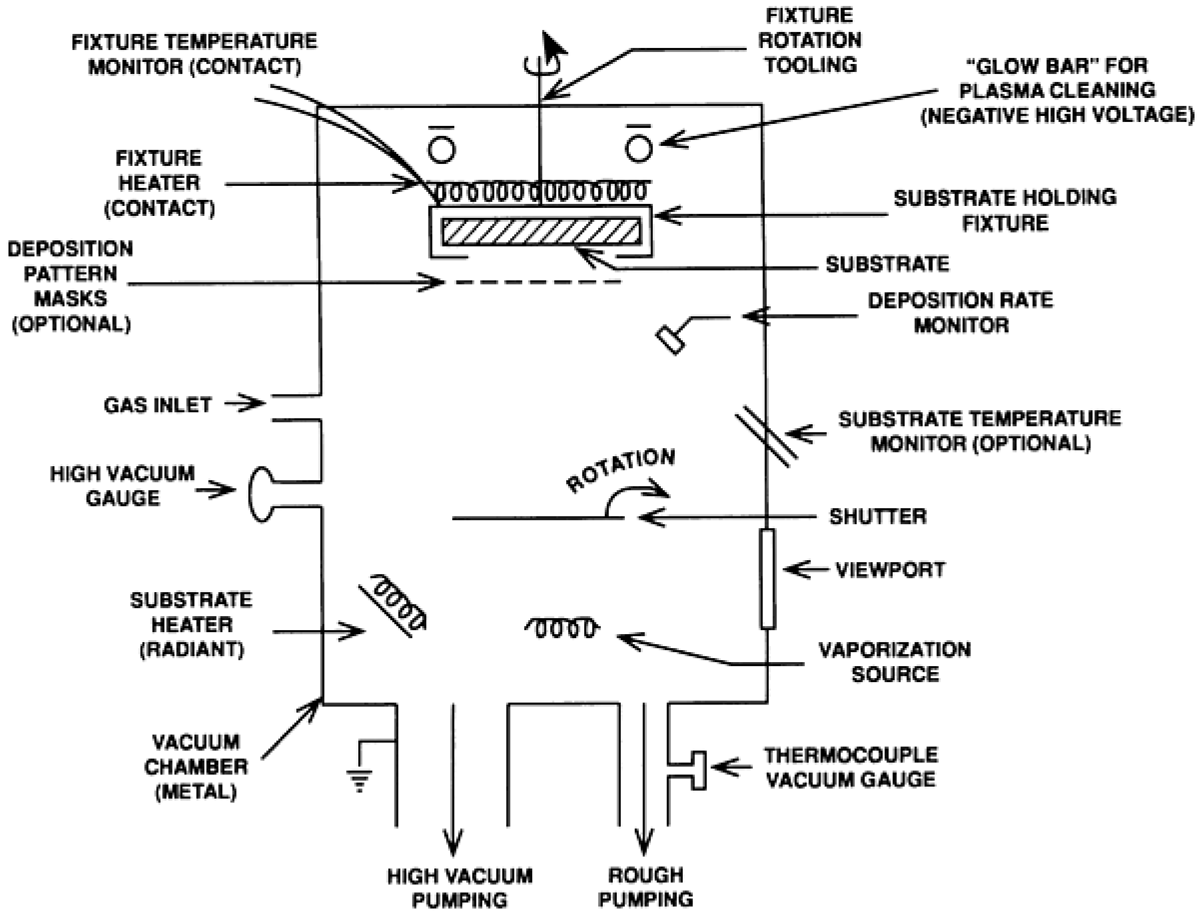

Fig. 1 Schematic diagram of a typical vacuum deposition chamber

Fundamentals of Thermal Vaporization

Equilibrium Vapor Pressure. The saturation or equilibrium vapor pressure of a material is defined as the vapor pressure of the material in equilibrium with the solid or liquid surface. At equilibrium, as many atoms return to the surface as leave the surface. The vapor pressure is measured by the use of a Knudsen cell, which consists of a closed volume with a small orifice of known conductance. When the container is held at a constant temperature the material that escapes through the hole depends on the pressure differential. In a vacuum environment and knowing the rate of material escaping, the equilibrium vapor pressure in the container can be calculated. The vapor pressures of the elements have been presented in tabular and graphical form (Ref 3). The Knudsen cell is often used as a source for molecular beam epitaxy, where the deposition rate can be carefully controlled by controlling the temperature of the source (Ref 4) or by mechanically interrupting the beam (Ref 5).

Figure 2(a) and 2(b) shows the vapor pressure of selected materials as a function of temperature. Note that the slopes of the vapor pressure curves are strongly temperature dependent (about 13 mPa/100 °C for cadmium and 13 mPa/250 °C for tungsten). The vapor pressures of different materials at a given temperature can differ by many orders of magnitude. For vacuum deposition, a reasonable deposition rate can be obtained only if the vaporization rate is fairly high. A vapor pressure of 1.3 Pa (10^{-2} torr) is typically considered the value necessary to give a useful deposition rate. Materials with that vapor pressure above the solid are described as subliming materials, and materials with that vapor pressure above the liquid are described as evaporating materials. Figure 3 shows the equilibrium vapor pressure curves of lithium and silver in detail and shows that at 800 K (527 °C) the vapor pressures differ by a factor of 10^7.

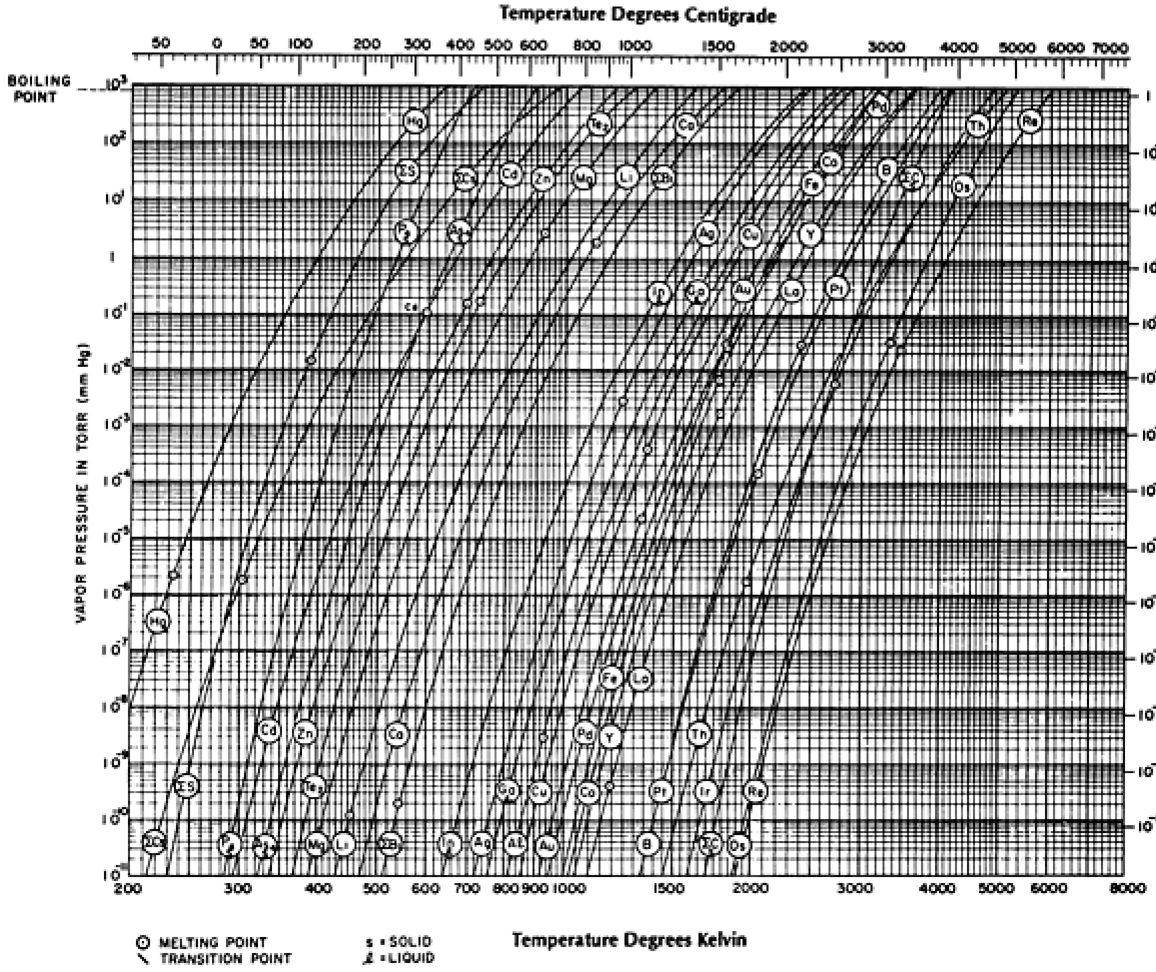

Fig. 2(a) Vapor pressure curves of the elements

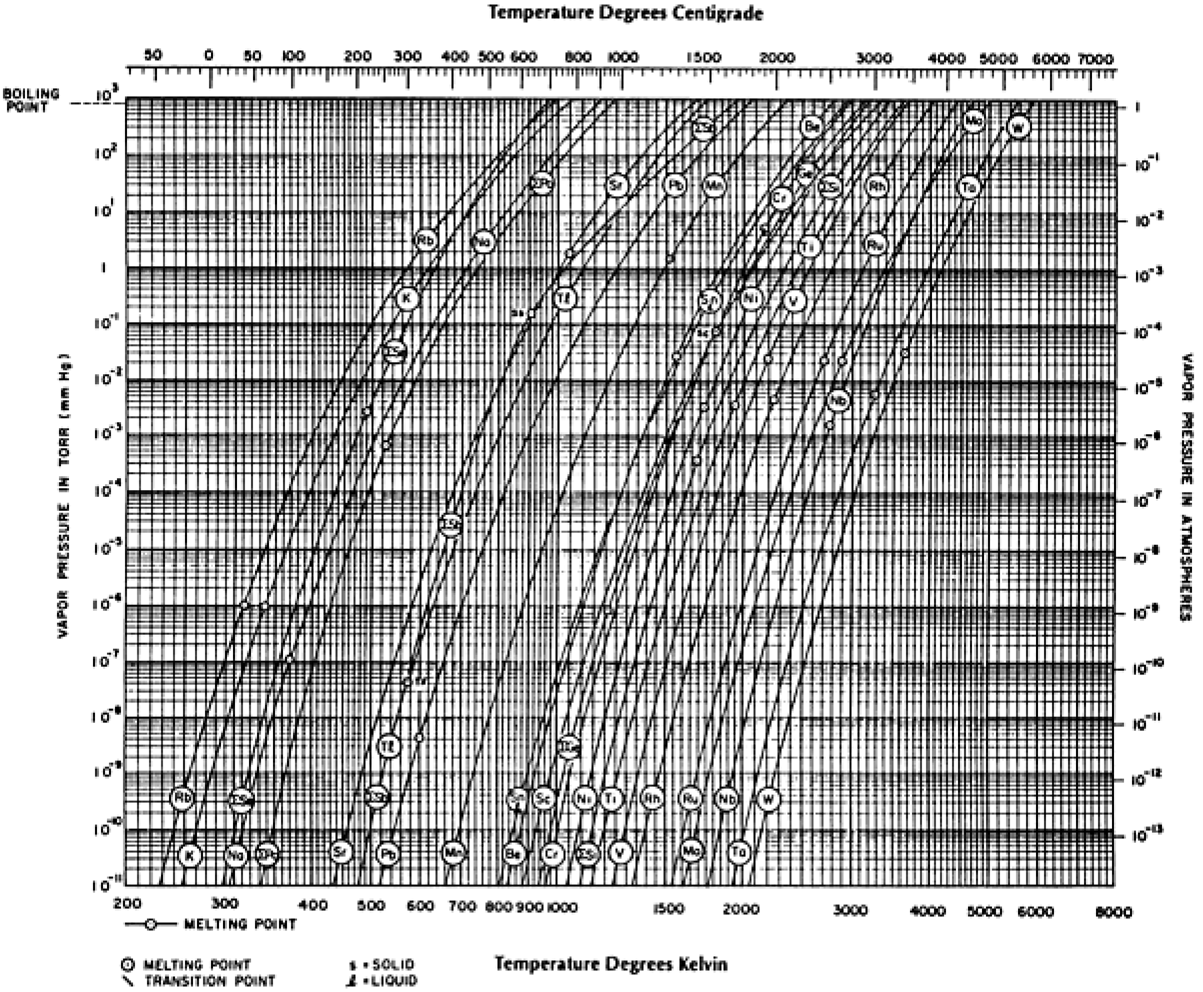

Fig. 2(b) Vapor pressure curves of the elements

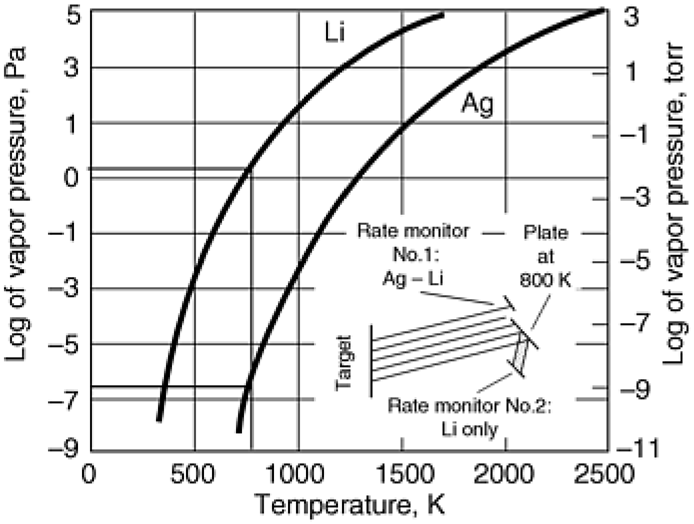

Fig. 3 Plot of equilibrium vapor pressure vs. temperature for lithium and silver

Vaporization Rate. A material vaporizes freely from a surface when the vaporized material leaves the surface with no collisions above the surface. The free surface vaporization rate, dN/dt (in s^{-1}) is proportional to the vapor pressure and is given by the Hertz-Knudsen vaporization equation (Ref 2, 6):

$$dN/dt = C\,(2\pi mkT)^{-1/2}\,(p^* - p) \qquad \textbf{(Eq 1)}$$

where dN/dt is the number of evaporating atoms per cm^2 of surface area per second, C is a constant that depends on the rotational degrees of freedom in the liquid and the vapor, p^* is the vapor pressure of the material at temperature T, p is the hydrostatic pressure of the vapor above the surface, k is Boltzmann's constant, T is the absolute temperature, and m is the mass of the vaporized species. The maximum vaporization rate is when $p = 0$ and $C = 1$. The actual vaporization rate will be one-third to one-tenth of this maximum rate because of collisions in the vapor above the surface (that is, $p > 0$ and $C \neq 1$), surface contamination, and other effects (Ref 7). Figure 4 shows some calculated maximum vaporization rates.

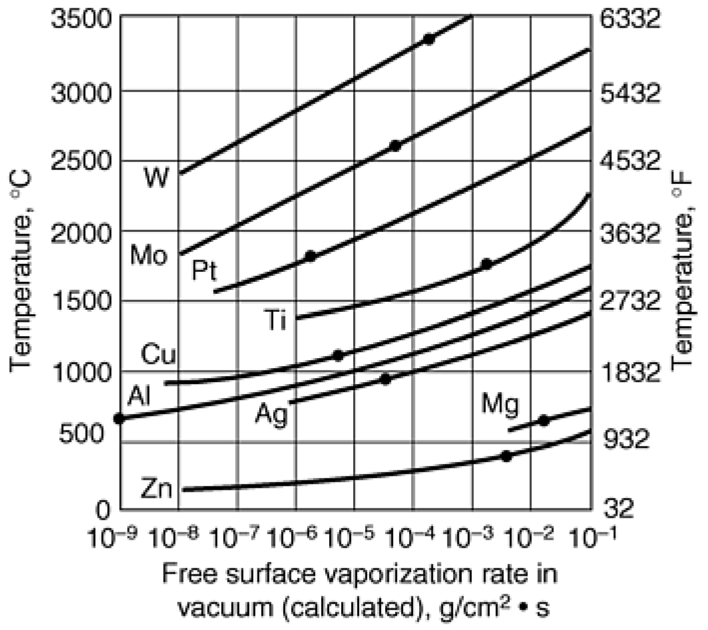

Fig. 4 Plot of temperature vs. free surface vaporization rate in a vacuum for selected elements. The symbol • indicates the melting point.

Vapor Flux Distribution on Vaporization. For low vaporization rates, the flux distribution can be described by a cosine distribution (Ref 2, 6). With no collisions in the gas phase, the material travels in a straight line between the source and the substrate (that is, line-of-sight deposition). The material from a point deposits on a surface with a distance and substrate orientation dependence given by the cosine deposition distribution equation:

$$dm/dA = (E/\pi r^2)\cos\theta\cos j \qquad \textbf{(Eq 2)}$$

where dm/dA is the mass per unit area, E is the total mass evaporated, r is the distance from the source to the substrate, θ is the angle from the normal to the vaporizing surface, and j is the angle from the source-substrate line.

Figure 5 shows the distribution of atoms vaporized from a point source and the thickness distribution of the film formed on a planar surface above the source based on Eq 2.

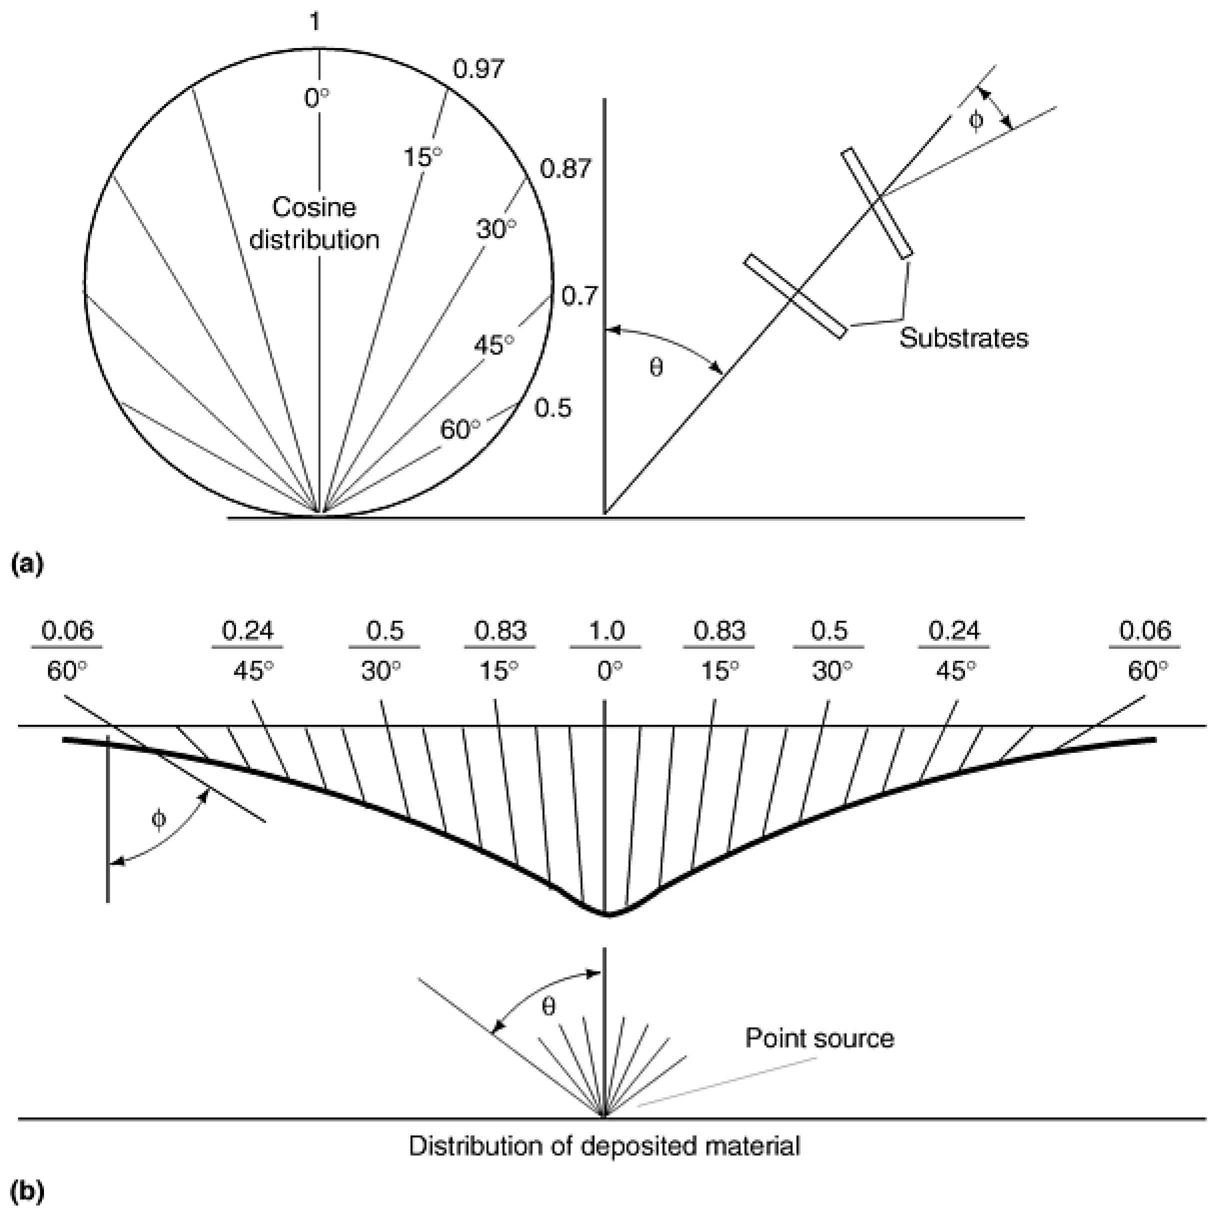

Fig. 5 Flux distribution above a point source, based on cosine deposition distribution equation. (a) Distribution of atoms vaporized from a point source. (b) Thickness distribution of film formed on planar surface above source

In actuality the flux distribution from a free surface may not be cosine but can be modified by source geometry, collisions associated with a high vaporization rate, level of evaporant in the source, and so on. In such cases, the flux distribution must be measured directly (Ref 8). A more complete model for the flux distribution from a Knudsen (orifice) source is given by the Knudsen effusion model proposed by Ruth and Hirth (Ref 9).

Particle Energies. Atoms leave a hot surface with thermal energies given by 3/2 kT, where k is Boltzmann's constant and T is the absolute temperature (Ref 2, 6). The atoms have a Maxwell-Boltzmann distribution in velocities. For example, for a 1500 °C evaporation temperature for copper, the mean energy of the vaporized copper atoms is 0.2 eV, and the mean atom velocity is about 1 km/s.

Shutters. Because the particles from a vaporizing source travel in straight lines in a vacuum, a shutter can be used to intercept vaporized material and prevent it from reaching the substrate. By opening and closing the shutter the deposition time can be precisely controlled.

Vaporization of Materials

Elements. Many elements evaporate, but many (for example, chromium, cadmium, magnesium, arsenic, and carbon) sublime, and many others (for example, antimony, selenium, and titanium) are on the borderline between evaporation and sublimation. Chromium has a vapor pressure of 1.3 Pa (10^{-2} torr) at 600 °C (1080 °F) below its melting point, and carbon cannot be melted except under high hydrostatic pressure. Materials such as aluminum, tin, gallium, and lead have very low vapor pressures above the just-molten material. Tin, for example, has a vapor pressure of 1.3 Pa (10^{-2} torr) at 1000 °C (1800 °F) above its melting point. Aluminum and lead have vapor pressures of about 1.3 Pa (10^{-2} torr) at 500 °C (900 °F) above their melting points.

Most elements vaporize as atoms, but some (for example, antimony, tin, carbon, and selenium) have a significant portion of the vaporized species as clusters of atoms. For materials that evaporate as clusters, special vaporization sources called *baffle sources* can be used to ensure that the depositing vapor is in the form of atoms. It should be noted that as a material is heated, the first materials that are volatilized are high-vapor-pressure surface contaminants, absorbed gases, and high-vapor-pressure impurities.

Alloys vaporize in a ratio that is the same as their vapor pressures (that is, the high vapor pressure constituent vaporizes more rapidly than the low vapor pressure material). This relationship is called Raoult's Law, and the effect can be used to purify materials by selective vaporization/condensation. When an alloy is evaporated from a molten pool, the higher-vapor-pressure material steadily decreases in proportion to the lower-vapor-pressure material in the melt. For example, when an Al:Mg (6.27 at.%) alloy is evaporated at 1919 K, the magnesium is totally vaporized in about 3% of the total vaporization time (Ref 10). Vaporization of alloys produces a gradation of film composition as the evaporant is selectively vaporized. This can be desirable or undesirable. For example, when copper-gold is deposited on polymers by evaporation of a copper-gold alloy, copper, which has a higher vapor pressure than gold, is deposited at a higher initial rate than the gold. This results in copper enrichment at the interface, which is conducive to better adhesion between the deposited film and the polymer.

In some cases, the nature of vaporization of an element can be changed by alloying it with another material. For example, chromium (melting point of 1863 °C, or 3385 °F), which normally sublimes, can be alloyed with zirconium (melting point of 1855 °C, or 3371 °F) to give a liquid melt from which the chromium evaporates. The eutectic alloy of zirconium-chromium (14 wt%) melts at 1332 °C (2430 °F), at which temperature chromium has a vapor pressure of approximately 1.3 Pa (10^{-2} torr) and zirconium has a vapor pressure of approximately 0.13 μPa (10^{-9} torr). Another eutectic alloy of zirconium-chromium (72 wt%) has a melting point of 1592 °C (2898 °F).

Compounds. Many compounds (for example, SiO, MgF_2, Si_3N_4, HfC, SnO_2, BN, PbS, and VO_2) sublime. Compounds often vaporize with a range of species, from clusters of molecules to dissociated or partially dissociated molecules (Ref 2). The degree of dissociation is strongly dependent on the temperature and composition of the compound (Ref 11). For example, in the thermal vaporization of SiO_2, a number of species are formed in addition to SiO_2, including $(SiO_2)_x$, SiO_{2-x}, SiO, Si, and O.

Evaporation from a very hot surface or by electron beams can give ionization of some of the molecular fragments. These charged species can be detrimental to the electrical properties of the deposited material. The ionized species can be deflected from the vapor flux using electrically charged plates above the source.

Fundamentals of Condensation

Thermally vaporized atoms may not condense when they impinge on a surface, but may rather be reflected or re-evaporate. Re-evaporation is a function of the surface temperature and the flux of depositing atoms. A hot surface can act as a mirror for atoms. For example, the deposition of cadmium on a steel surface having a temperature greater than 200 °C (390 °F) results in total re-evaporation of the cadmium. Figure 3 shows how this "hot mirror effect" can be used to monitor the deposition of the separate constituents of a depositing Ag-50Li alloy. The lithium is re-evaporated from the hot collector surface to deposit on the cold collector surface, while the silver remains on the hot surface. Hot surfaces can be used to reflect the evaporant flux of some materials, such as cadmium or zinc, into non-line-of-sight locations on a substrate to improve surface coverage and uniformity.

Nucleation and Nucleation Density. When adatoms (atoms adsorbed on a surface so that they migrate over the surface) move over a surface, they lose energy by making and breaking chemical bonds formed with the surface atoms, by colliding with other atoms, or by chemically reacting with an adsorbed species. If there is little chemical interaction between the surface atoms and the adatoms, the surface mobility will be high and the adatoms will nucleate on preferential nucleation sites such as steps, charge centers, impurities, grain boundaries, and so on. If the chemical reaction

is strong, the adatoms will have low surface mobility and the nucleation density will be high. The nucleation density plays an important role in determining film properties.

Condensation Energy. When a thermally vaporized atom condenses on a surface, it gives up energy, including:

- Heat of vaporization or sublimation (enthalpy change on vaporization): a few eV per atom, including the kinetic energy of the particle, which is typically 0.3 eV or less
- Energy to cool to ambient temperature: depends on heat capacity and temperature change
- Energy associated with chemical reaction (heat of reaction), which can be exothermic (when heat is released) or endothermic (when heat is adsorbed)
- Energy released on solution (alloying): heat of solution

The heat of vaporization for gold is about 3 eV/atom, and the mean kinetic energy of the vaporized gold atom is about 0.3 eV. This means that the kinetic energy is only a small part of the energy released at the substrate during deposition. However, it has been shown, using mechanical velocity filters, that the kinetic energy of the depositing gold atoms is important to the film structure, properties, and annealing behavior (Ref 12). At high deposition rates, the condensation energy can produce appreciable substrate heating (Ref 13).

Deposition rates for vacuum deposition processes vary greatly. They range from less than one monolayer per second (MLS) (<0.3 nm/s, or 3 Å/s) to more than 10^4 MLS (>3 μm/s, or 3×10^4 Å/s). The rate depends on the thermal power input to the source, the system geometry, and the material. Generally, the power input to the source is controlled by monitoring the deposition rate.

Deposition Uniformity. As shown in Fig. 5, the deposition thickness uniformity from a vaporizing point onto a plane is poor. A more uniform deposit over a planar surface can be obtained by using multiple sources with overlapping patterns. However, this produces source control and flux distribution problems (Ref 8). By moving the substrate farther away, the uniformity over a given area can be improved; however, the deposition rate is decreased. The most common technique to improve uniformity is to move the substrate in a random manner over the vapor source(s). Because the vaporization rate can change during the deposition process, the movement should sample each position a number of times during deposition. Often the substrates are rotated on a hemispherical fixture (calotte) with the evaporant source at the center of the sphere to give a constant r (see Eq 2). Specially designed movable masks can be used to provide specific thickness distributions over a surface (Ref 14, 15, 16), or the substrate movement can be controlled to give a specific film thickness distribution.

Surface Coverage. Because the deposition is line-of-sight, deposition on a rough or nonplanar surface can give geometrical shadowing effects resulting in nonuniform film thickness and variable film morphology. This is particularly a problem at sharp steps and at oblique angles of deposition. Figure 6 shows the effect of the angle of incidence in covering a surface having a particle on the surface. These geometrical problems can be alleviated by extended vaporization sources, multiple sources, or substrate movement.

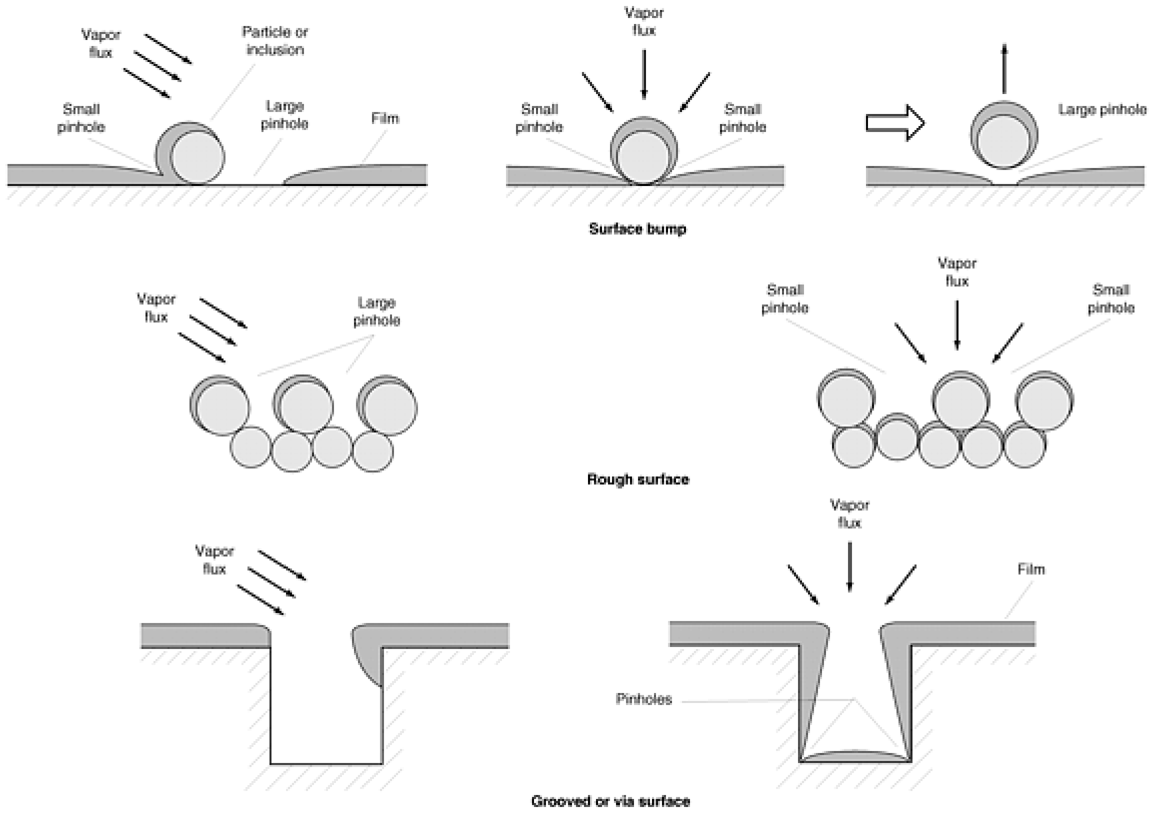

Fig. 6 Geometrical shadowing of the deposition flux by a particle on the surface relative to the angle of incidence and the surface morphology

Attempts to use gas scattering (that is, scatter plating, pressure plating, or gas plating) to randomize the flux distribution and improve the surface covering ability of evaporated films (Ref 17) have been singularly unsuccessful because of the poor density of the deposited material.

Additional information on condensation and growth is available in the article "Growth and Growth-Related Properties of Films Formed by Physical Vapor Deposition Processes" in this Volume.

Deposition of Materials

Deposition of Elements. Elements are typically deposited by vaporization of the elemental material directly. The purity of the deposited film depends on the purity of the starting material and contaminant gases in the ambient.

Deposition of Alloys. Alloys can be deposited directly by the vaporization of the alloy material if the vapor pressures of the constituent are comparable. However, if the vapor pressures differ, the composition of the film will change as the deposition proceeds and the composition of the melt changes.

Rod-Fed Source. One technique for depositing a constant composition alloy film is to use a rod-fed electron beam evaporation source and to keep the temperature and volume of the molten pool constant. After an equilibration time, the composition of the vapor flux is the same as the composition of the material being melted, even though the composition of the molten pool is not the same as that of the bulk material (Ref 18, 19). Using this technique, alloys whose constituents vary in vapor pressure by as much as 10^3 are being deposited on aircraft engine turbine blades.

Sequential Layers. Alloy films can be formed by depositing alternating layers of the different materials from different sources. The layers are then diffused to form the alloy film. The alloy composition then depends on the relative amounts of materials in the films.

Multiple Sources. Alloy films can be deposited using multiple separate vaporization sources with individual deposition rate controllers. In this case, the vapor flux distribution from each source must be taken into account. The multiple source technique can also be used to deposit layered composite films (Ref 2, 20). Sources with overlapping flux distributions can be used to form films having a range of compositions over the substrate surface.

Flash Evaporation. A constant-composition alloy film can be deposited using flash evaporation techniques, where a small amount of the alloy material is periodically completely vaporized (Ref 2, 21, 22, 23). Flash evaporation uses a very hot surface and requires dropping a pellet or periodically touching a wire tip to the surface, so that the molten pellet or tip is completely vaporized.

Deposition of Compounds. When compounds are vaporized, some of the lighter fragments, such as oxygen, may be lost by scattering in the gas phase and by not reacting with the deposited material when it reaches the substrate. In the vaporization of SiO_2, this results in an oxygen-deficient SiO_{2-x} film that is yellowish in color. The composition of the deposited material is determined by the degree of dissociation, the loss of materials in the mass transport process, and the reaction coefficient of the reactive species at the film surface. The lost oxygen can be replaced by reactive deposition in an oxygen environment (see the section "Reactive Evaporation" in this article), or postdeposition heat treatments in oxygen (Ref 24).

In some cases, the state of reaction can be increased by concurrent bombardment with a reactive species from a plasma (activated reactive ion plating) (Ref 25) or an ion source (reactive ion beam assisted deposition). For example, SiO, which is easily evaporated, can be bombarded with oxygen ions to give $SiO_{1.8}$, which is of interest as a transparent, insulating, permeation-barrier coating on polymers for the packaging industry.

Graded Interfaces. When layered structures are deposited, the interface between the layers can be graded from one composition to the other by beginning the second deposition before the first is completed. This forms a "pseudo-diffusion" interface between the two layers and prevents possible contamination/reaction of the first layer by the ambient environment before the second layer begins depositing. Grading the interface between deposited films often provides better adhesion than abruptly changing from one material to another.

Vaporization Sources

Common heating techniques for evaporation/sublimation include resistive heating, high-energy electron beams, low-energy electron beams, and inductive (radio frequency) heating. Figures 7, 8(a), and 8(b) show some vaporization source configurations. Resistive heating is the most common technique for vaporizing materialat temperatures below about 1800 °C (3270 °F), while focused electron beams are most commonly used above 1800 °C (3270 °F).

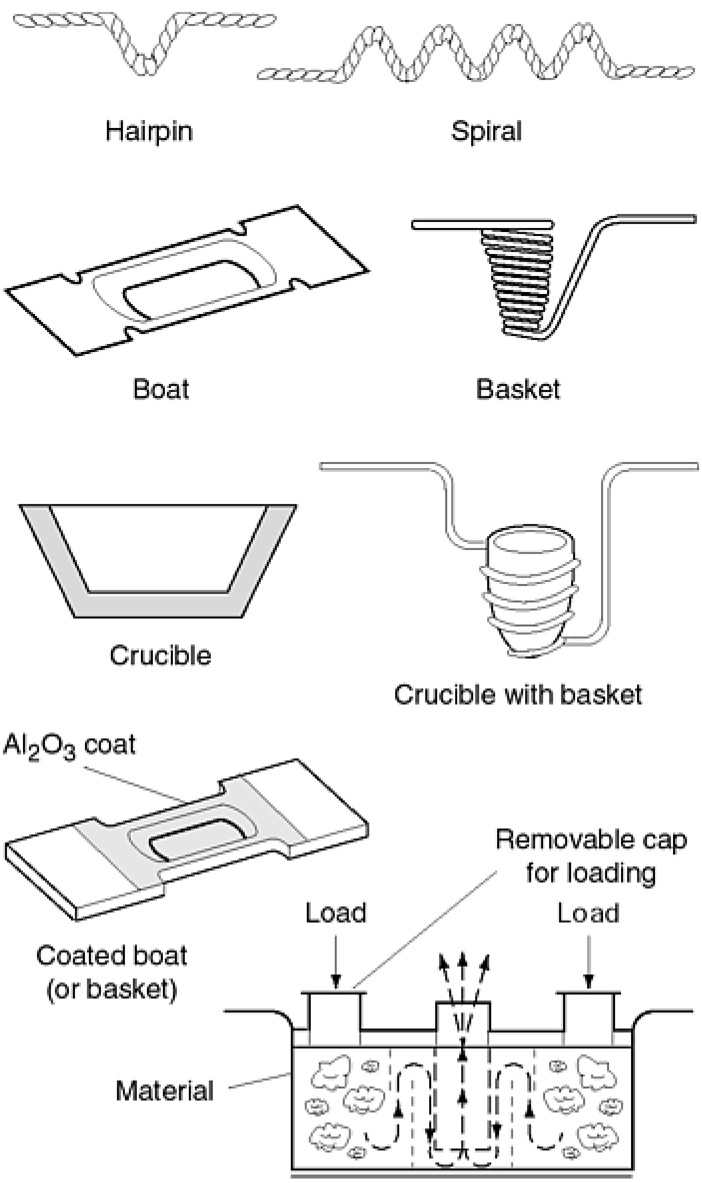

Fig. 7 Sources used for resistive heating of materials in evaporation processing

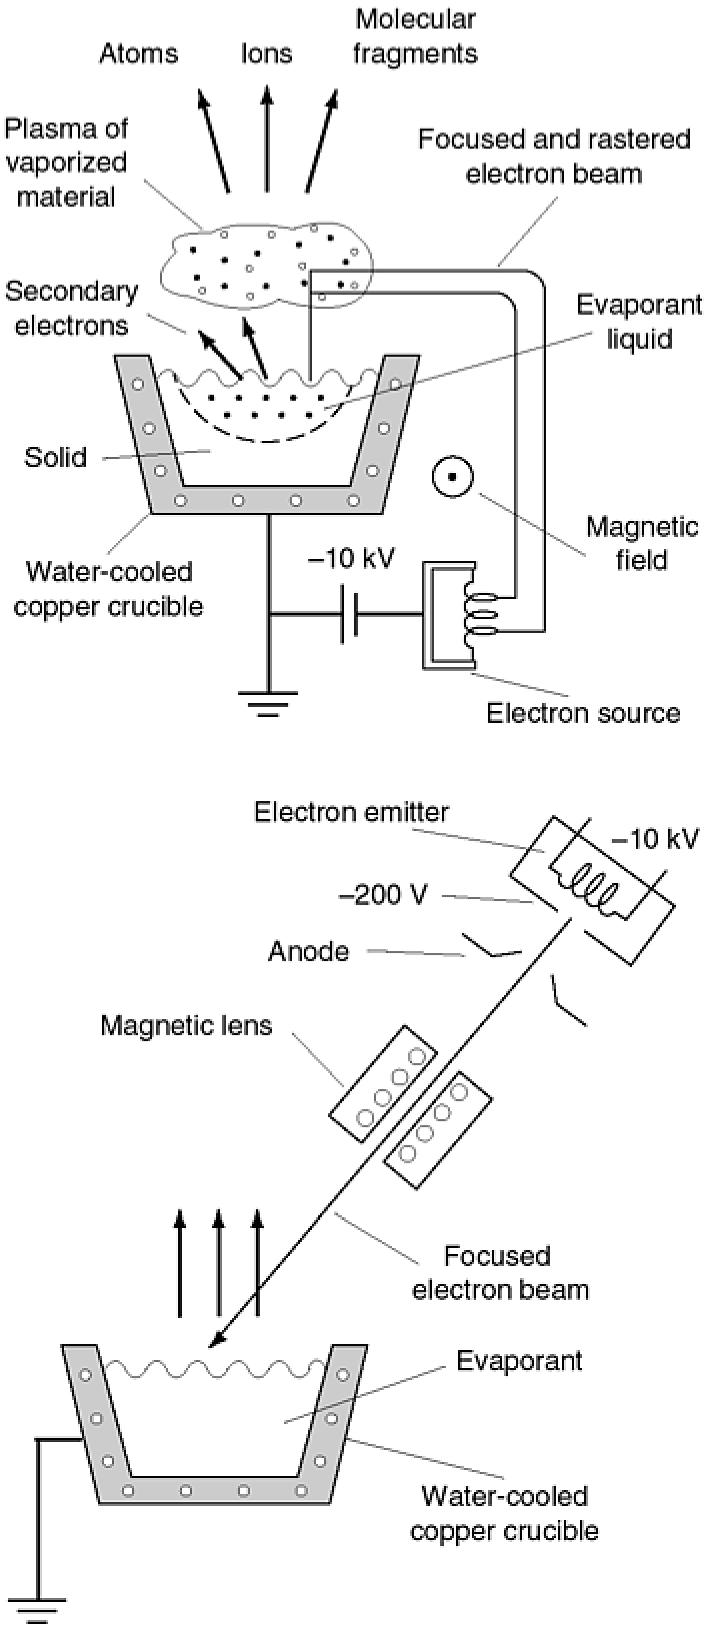

Fig. 8(a) Focused electron-beam sources used for evaporation processing. Bent-beam electron gun (top); long-focus gun (bottom)

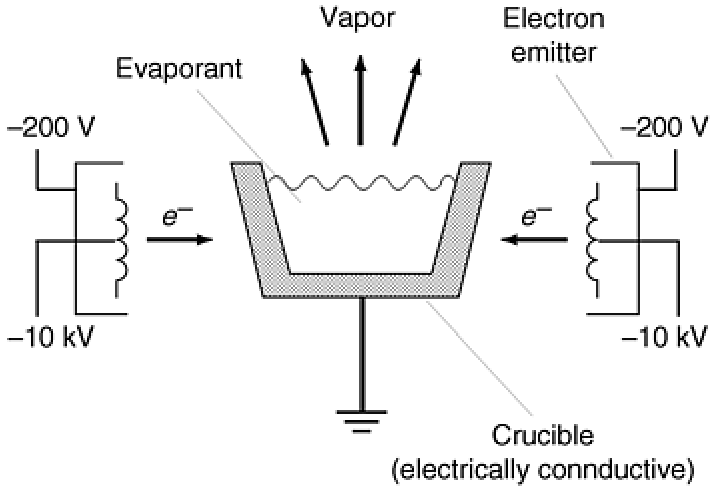

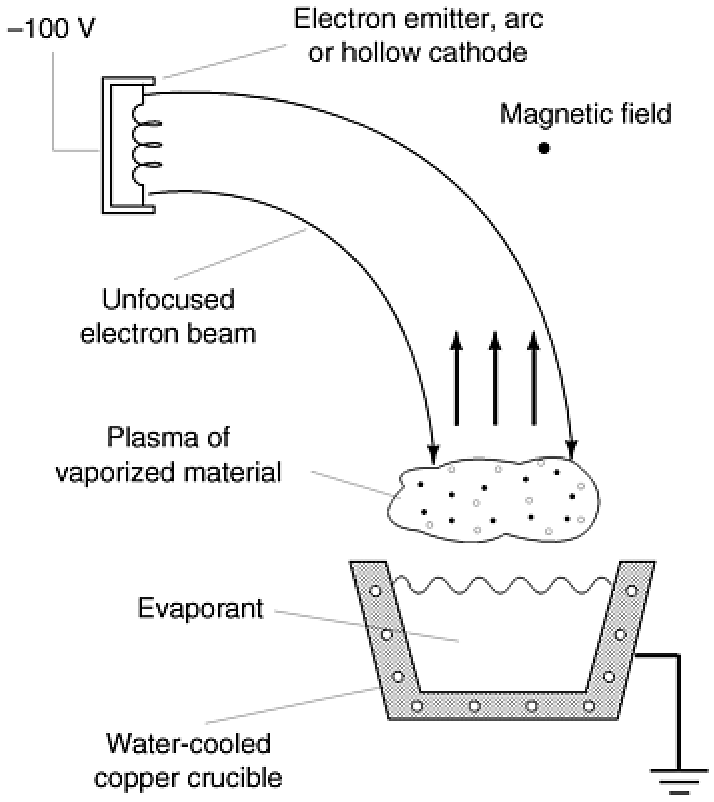

Fig. 8(b) Unfocused electron-beam sources used for evaporation processing. Work-accelerated gun (top); setup with magnetic confinement of electrons (bottom)

Resistive Heating. Resistively heated sources are the most widely used vaporization sources (Ref 26, 27). Typical conductive source materials are tungsten, tantalum, molybdenum, carbon, and BN/TiB_2 composite ceramics. Resistive heating of electrically conductive heater is typically by low voltage (<10 V), very high alternating current (several hundred amperes) transformer supplies. It is generally better to slowly increase the heater current than to suddenly turn on full heater power. Due to the low voltages used in resistive heating, contact resistance is an important factor in source design. As the temperature increases, thermal expansion causes the evaporator parts to move; this movement should be accounted for in the design of the heater fixturing. Because metals expand on heating, the contacting clamps between the fixture and the source may have to be water cooled to provide consistent clamping and contact resistance (Ref 27). Figure 7 shows some typical resistively heated source configurations. The resistively heated vaporization sources are typically operated near ground potential. If the sources are to be operated much above ground, filament isolation transformers must be used.

Electron-beam heating sources can be classified as being either focused or unfocused.

Focused, high-energy electron beams are necessary to provide local high temperatures when required for the evaporation of refractory materials, such as most ceramics, glasses, carbon, and refractory metals. This electron-beam heating is also useful for evaporating large quantities of materials. Graper has tabulated the electron-beam vaporization characteristics of a large number of materials (Ref 28). Figure 8(a) and 8(b) shows two sources that use focused electron-beam heating: the deflected electron gun and the long-focus gun (Fig. 8(a)).

With the deflected or bent-beam electron gun source, the high-energy electron beam is formed using a thermionic-emitting filament to generate the electrons, high voltages (typically 10 to 20 kV) to accelerate the electrons, and electric or magnetic fields to focus and deflect the beam (Ref 29, 30, 31). Electron-beam guns for evaporation typically require 10 to 50 kW of power. Using high power electron-beam sources, deposition rates as high as 50 μm/s (0.002 in./s) have been attained (Ref 32) from sources capable of vaporizing aluminum at rates of up to 10 to 15 kg/h (22 to 33 lb/h). Electron-beam evaporators can be made compatible with ultrahigh vacuum (UHV) processing (Ref 33). Electron-beam evaporators are typically built to deposit material in the vertical direction, but high-rate electron-beam source installations that deposit material in a horizontal direction are being used (Ref 34).

In many applications, the electron beam is magnetically deflected through greater than 180°, to avoid deposition of evaporated material on the filament insulators and to focus the beam onto the source material, which is contained in a water-cooled copper hearth "pocket". The electron beam can be rastered over the surface to produce heating over a large area. The electron bombardment produces secondary electrons that are magnetically deflected to ground. The high-energy electron bombardment also produces soft x-rays that can be detrimental to sensitive semiconductor devices (Ref 35, 36, 37). The electrons ionize a portion of the vaporized materials and these ionscan be used to monitor the evaporation rate. With the electron-beam evaporation of some materials (for example, beryllium), a significant number of ions are produced that can be accelerated to the substrate to modify the film microstructure (Ref 38).

Electron gun sources can have multiple pockets so that several materials can be evaporated. By moving the beam or the crucible, more than one material can be heated with the same electron source.

The long-focus gun uses electron optics to focus the electron beam on a surface that can be an appreciable distance from the electron emitter (Ref 32, 39). The optic axis is often a straight line from the emitter to the evaporant, and therefore the gun must be mounted off-axis from the source-substrate axis.

Unfocused, high-energy electron-beam heating can be accomplished with an electron source by applying a voltage between the electron emitter and the source material or source container, which is usually at ground potential (Fig. 8(b)). Such a source is referred to as a work-accelerated gun (Ref 40, 41). Magnetic confinement of the electrons along the emitter-source axis (Fig. 8(b)) can also be used to increase the electron path length and so increase the ionization probability (Ref 42, 43).

Unfocused, Low-Energy Electron-Beam Heating. High-current, low-energy electron beams can be produced by thermionic-emitting surfaces, plasma arcs (Ref 44), or hollow cathodes (Ref 45, 46, 47, 48, 49). They can be accelerated to several hundred volts and magnetically deflected onto the source, which is at ground potential. Low-energy electron beams are typically not very well focused, but they can have high current densities. The vaporization of a surface by the low-energy electron beam can provide appreciable ionization of the vaporized material because the vaporized atoms pass through a high-density, low-energy electron cloud as they leave the surface.

Electron-Beam Guns in a Plasma Environment. Electron-beam guns are not generally used in a plasma environment because of sputter erosion of the filament by positive ions. There are also problems with the reaction of the hot emitting filaments in reactive gases. In order to use an electron-beam evaporator in a plasma or reactive gas environment, the electron-emitter region can be differentially pumped by being isolated from the deposition environment. This is accomplished by having a septum between the differentially pumped electron-emitter chamber and the deposition chamber. This septum incorporates a small orifice for the electron beam to pass from one chamber to the other (Ref 50).

Inductive Heating. Inductive heating couples radio frequency (rf) energy directly into electrical conductors such as metals or carbon (Ref 51). The rf source can be used either to heat the source material directly or to heat the container ("susceptor") that holds the source material. This technique has been particularly useful in evaporating aluminum from boron nitride and BN/TiB_2 crucibles (Ref 52). When the source material is heated directly, the containing crucible can be cooled.

Evaporation sources must contain molten liquid without extensive reaction and prevent the molten liquid from falling from the heated surface. This is accomplished by having a wetted surface or by using a container (Ref 53). Commercial evaporation source manufacturers provide lists of recommended sources for various materials.

Wetted Sources. Wetting is desirable to obtain good thermal contact between the hot surface and the material being vaporized. Wetted sources are also useful for depositing downward, sideways, or from nonplanar surfaces. Metallic stranded wire, coils, and baskets are relatively cheap and can be used in many applications. Wires for evaporation are typically tungsten (Ref 2, 54, 55) but can be molybdenum or tantalum. Wire meshes and porous metals, through which the molten metals wet and wick by capillary action, can be used for large-area vaporization sources.

Wire and coil filaments have the often-frustrating property that the molten material runs to the low spots, where it can drop off. To help alleviate this problem, stranded wire is used to hold the molten material by capillary action. Bends or kinks can be put in the wire at selected points to collect the molten material, or coils of tantalum wire can be wrapped on the filament to hold the molten material at specific points.

Solid evaporants have poor thermal contact with the heater surface until they melt and wet the surface. To obtain wetting of the evaporant on the heater surface, it is often necessary to have a temperature in excess of that needed for a reasonable evaporation rate. When the material becomes molten and wets the surface, the vaporization rate is very high and can cause "spitting" as the molten evaporant spreads over the superheated surface. Refractory metals used for vaporization are covered with oxides, which volatilize at temperatures lower than the vaporization temperatures of many source materials. If film contamination by these oxides is to be avoided, the heater material should be cleaned before installation, shutters should be used, or the surface should be prewetted by the source material.

Premelting and wetting of the evaporant on the heater surface prior to the beginning of the deposition has several benefits:

- Good thermal contact can be established.
- There is volatilization of volatile impurities and contaminants from the evaporant and from the surface of the heater.
- Overheating of the heater surface is avoided, thereby minimizing spitting and radiant heating from the source.

Premelting can be done external to the deposition system if care is used in handling the source afterwards, to prevent surface contamination. Premelting can be done in the evaporator system by using shutters to prevent the deposition of undesirable material on the substrate before film deposition begins.

Crucible containers can hold large amounts of molten evaporant, but the vapor flux distribution changes as the level of the molten material changes. Electrically conductive crucibles can be heated resistively and are available in the form of boats, canoes, dimpled surfaces, crucibles, and so on (Ref 56). Typical refractory metals used for containers are tungsten, molybdenum, and tantalum, as well as refractory metal alloys such as TZM (titanium and zirconium added to molybdenum for improved high-temperature strength) and tungsten with 5 to 20% rhenium added for improved ductility. Metallic containers are often wetted by the molten material, and the material can spread to areas where it is not desired. This spreading can be prevented by having nonwetting areas on the surface. Such nonwetting areas can be formed by plasma spraying Al_2O_3 on the surface.

Commonly used crucible construction includes water-cooled copper, ceramics (both conductive and insulating), and glasses:

- *Water-cooled copper* is used as a crucible material when the evaporant materials are heated directly, as with electron-beam heating. The design of the coolant flow is important in high-rate evaporation from a copper crucible, because a great deal of heat must be dissipated (Ref 57). The water-cooled copper solidifies the molten material near the interface, forming a "skull" of the evaporant material so that the molten material is actually contained in a like material. This prevents reaction of the evaporant with the crucible material. On cooling, the evaporant "slug" shrinks and can be easily removed from the pocket of the electron-beam evaporator. In some cases, a liner can be used with a water-cooled crucible. Typical liner materials include pyrolytic graphite, pyrolytic boron nitride, BN/TiB_2, BeO, Al_2O_3, and

other such materials. In general, the liner materials have poor thermal conductivity. This property, along with the poor thermal contact that the liner makes with the copper, allows the liner to heat significantly. Liners can be fabricated in special shapes to obtain specific characteristics (Ref 58).

- *Electrically conductive ceramics* can be used as containers. Carbon and glassy carbon are commonly used container materials, and when a carbon-reactive material is evaporated from such a container, a carbide skull forms that limits the reaction with the container. For example, titanium in a carbon crucible forms a titanium carbide skull. An electrically conductive composite ceramic that is used for evaporating aluminum is BN-50TiB_2 composite ceramic (known by the tradename UCAR) (Ref 59). This composite ceramic is stable in contact with molten aluminum, whereas most metals react rapidly with the molten aluminum at vaporization temperature.
- *Glasses and electrically insulating ceramics* can be used as crucibles and are often desirable because of their chemical inertness with many molten materials. Typical crucible ceramics are ThO_2, BeO, stabilized ZrO_2 (additions of HfO_2 and CaO to ZrO_2), Al_2O_3, MgO, BN, and fused silica. Kohl has written an extensive review of the oxide and nitride materials that may be of interest as crucible materials (Ref 60). The ceramics can be heated by conduction or radiation from a hot surface though these are very inefficient methods of heating. For more efficient heating, the material contained in the electrically insulating crucible can be heated directly by electron bombardment of the surface or by rf inductive heating from a surrounding coil. Isotopic boron nitride is a good crucible material for containing molten aluminum for rf heating because most other ceramics are attacked by molten aluminum. Metal sources, such as boats, can be coated with a ceramic (for example, plasma-sprayed Al_2O_3) in order to form a ceramic surface in contact with the molten material.

Feeding sources are sources where additional evaporant material is added to the molten pool without opening the processing chamber. Feeding sources can use pellets (Ref 61), powder, wires, tapes, or rods of the evaporant material. Pellet and powder feeding is often done with vibratory feeders, while wires and tapes are fed by friction and gear drives. Multiple wire-fed electron-beam evaporators are often aligned to give a line source for deposition in a web coater (Ref 62, 63). Rod feeds are often used with electron-beam evaporators where the end of the rod, whose side is cooled by radiation to a cold surface, acts as the crucible to hold the molten material (Ref 18). Feeding sources are used to deposit large amounts of material.

Baffle Sources. Some elements vaporize as clusters of atoms, and some compounds vaporize as clusters of molecules. Baffle sources are designed so that the vaporized material must undergo several evaporations from heated surfaces before it leaves the source, to ensure that the clusters are decomposed. Baffle sources can also be used to allow deposition downward from a molten material. Baffle sources are desirable when evaporating silicon monoxide or magnesium fluoride for optical coatings, to ensure the vaporization of monomolecular SiO or MgF_2. Drumheller made one of the first baffle sources, called a "chimney source," for the vaporization of SiO (Ref 64).

Focused vaporization sources can be used to confine the vapor flux to a beam. Focusing can be done using wetted curved surfaces or by using defining apertures. A beam-type evaporation source that uses apertures has been developed to allow the efficient deposition of gold on a small area (Ref 65). This source forms a $2\frac{1}{2}°$ beam of gold and gives a deposition rate of 4 nm/s (40 Å/s) at 50 mm (2 in.).

Confined vapor sources confine the vapor in a heated cavity and pass the substrate through the vapor. The vapor that is not deposited stays in the cavity. Such a source uses material very efficiently and can produce very high rates of deposition. For example, a wire can be coated by having a heated cavity source such that the wire is passed through a hole in the bottom and out through a hole in the top. By having a raised stem in the bottom of the crucible, the molten material can be confined in a doughnut-shaped melt away from the moving wire. The wire can be heated by passing a current through the wire as it moves through the crucible.

Porous Evaporation Sources. Porous materials and meshes can be used to evaporate materials that wet and wick through the material. Examples of such materials are porous tungsten, tungsten meshes, and porous ceramics. These types of sources are sometimes called *dispenser sources* and are similar to the electron-emitted cathodes in electronic devices (Ref 60).

Radiation shields can be used to surround the hot vaporization source to reduce radiant heat loss (Ref 56). Generally radiation shields consist of several layers of refractory metal sheet separated from each other and from the heated surface. These radiation shields:

- Reduce the power requirements of the source
- Reduce radiant heating from the source
- Allow the source to reach a higher temperature
- Have a more uniform temperature over a larger volume

Source Degradation. Vaporization sources can degrade with time due to reaction of the evaporant material with the heated surface. When there is reaction between the molten source material and the heater material, the vaporization should be done rapidly. For example, palladium, platinum, aluminum, iron, and titanium should be evaporated rapidly from tungsten heaters. When tungsten is used as the heater material, crystallization at high temperatures makes the tungsten brittle and causes microcracks, which create local hot spots that result in burnout. On burnout, the tungsten is vaporized and can contaminate the film. In general, it is better to replace tungsten wire heaters after each deposition if such contamination poses a problem. When large masses of material that have wet the surface are allowed to cool in brittle containers (crucibles or boats), the stresses can crack the container material.

Sublimation Sources. Vaporization from solid sources has the advantage that the vaporizing material does not melt and flow. Vaporization from a solid can be sublimation from a chunk or pellet, or sublimation from a solid composed of a subliming phase and a nonvaporizing phase (for example, Ag-50Li and Ta-25Ti alloy wire, known by the tradename KEMET). Heating can be by resistive heating, direct contact with a hot surface, radiant heating from a hot surface, or bombardment by electrons.

A problem with sublimation of a solid material from a heated surface is the poor thermal contact with the surface. This is particularly true if the evaporant can "jump around" due to system vibration during heating. Changing the source setup can often alleviate the problem (for example, changing from a boat to a basket source, eliminating mechanical vibration, using mesh "caps" on open-top sources, etc.). Direct electron-beam heating of the material is generally more desirable than contact heating for heating a subliming material.

Better thermal contact between the subliming material and the heater can be obtained when forming the material in contact with the heater by pressing powders around the heater or by electroplating the material onto the heater surface. Powder pressing generally produces a porous material that has appreciable outgassing. Chromium is often electrodeposited on a tungsten heater. Electroplated chromium has an appreciable amount of trapped hydrogen, and such a source should be heated slowly to allow outgassing of the material before deposition commences.

Exploding Wires. Flash evaporation can be accomplished by "exploding wire" techniques, where very high currents are pulsed through a small wire by the discharge of a capacitor (Ref 66). The majority of the vaporized material is in the form of molten globules. This technique has the interesting feature that the wire can be placed through a small hole and the vaporized material can be used to coat the inside of the hole.

Radiant Heating from the Source. The radiant energy, E, from a hot surface is given by:

$$E = \varepsilon T^4 A \quad \textbf{(Eq 3)}$$

where ε is the emittance of the surface, T is the absolute temperature, and A is the area of emitting surface. Radiant energy heats all of the surfaces in the deposition chamber, leading to a rise in the substrate temperature, desorption of gases from surfaces, and surface creep of contaminants. Radiant heating of the substrate and interior surfaces can be minimized by:

- Using small heated areas (A)
- Using prewetted evaporant surfaces
- Using radiation shields
- Using shutters over the source until the vaporization rate is established
- Rapid vaporization of the source material onto the substrate

Some materials, such as gold, are good heat reflectors; as soon as a gold film is formed, a high percentage of the incident radiant heat is reflected from the coated surface. Some materials, such as silicon dioxide, do not adsorb infrared radiation very well and are not easily heated by radiation.

Spits and Comets. In the evaporation of materials from heated surfaces, "spits" and "comets" are often encountered. Spits are solidified globules of the source material found on the deposited film. When these poorly bonded globules are disturbed, they fall out, leaving large pinholes in the film. Comets are seen in the system during vaporization as the hot molten globules are ejected from the source.

Molten globules can originate from the molten material by any one of several processes. During heating, particularly rapid heating, gases and vapors in the molten source material agglomerate into bubbles and explode through the surface, giving spits. For example, silver can have a high content of dissolved oxygen and give spitting problems. The source of spits can be continual if new material is continually being added to the melt. Spits can be reduced by using pure vacuum-melted source material, handled and stored in an appropriate way, and by degassing the evaporant charge by premelting with slow heating to melting.

If the molten evaporant is held in a heated crucible, vapor bubbles can form on the crucible surfaces, where they grow and break loose. As the bubbles rise through the molten material, the hydrostatic pressure decreases and the bubbles grow in size. When the bubbles reach the surface they "explode," giving rise to globules of ejected molten material. Materials that have high vapor pressures at their melting points are more likely to give spits than materials that have low vapor pressures at their melting points. Spitting is common in boiling water; in high school chemistry, students are taught to add boiling beads to the water to reduce the violence and splashing. The same approach can be used to prevent spitting from molten material. For example, chunks of tantalum are placed in molten gold to prevent gold spits. The tantalum does not react with the gold and does not vaporize at the gold evaporation temperatures.

Spits from crucibles can be minimized by:

- Using source materials that are free of gases and high-vapor-pressure impurities
- Polishing the crucible surfaces so that bubbles do not stick well and break loose when they are small
- Using "boiling beads" in the molten material to prevent large bubbles from forming
- Using baffle-type sources so that the source material must be vaporized several times before the vapor leaves the source
- Using specially designed crucibles (Ref 58)
- Using electron-beam evaporation where the surface of the evaporant is heated
- Reducing source power if spitting occurs

Spits can also occur during melting and flowing of a material on a hot surface. A solid material placed on a surface has poor thermal contact with the surface, so the tendency is to heat the surface to a very high temperature. When the evaporant melts and spreads over the surface, the very hot surface creates vapor that "explodes" through the spreading molten material. This source of spits can be eliminated by premelting the charge on the surface, to give good thermal contact, and by using shutters in the system, to prevent the substrate from "seeing" the source until the molten charge has wetted the surface and is vaporizing uniformly.

Additional Vaporization Methods

Vaporization can also be produced by vacuum arc, laser, electric field, and polymer evaporation methods.

Vacuum Arc Vaporization. Arc vaporization was first reported by Robert Hare in 1839 and has been used to deposit carbon (Ref 67) and metal (Ref 68) films. Arc vaporization in vacuum occurs when a high-current, low-voltage arc passes between slightly separated electrodes in a vacuum, vaporizing the electrode surfaces and forming a plasma of the vaporized material (Ref 69, 70, 71, 72). In order to initiate the arc, a high voltage "trigger" arc is used. A high percentage of the vaporized material is ionized in the arc, and the ions are often multiply charged. A negative space charge is generated in the plasma, and the ions are accelerated away from the plasma to energies that are much higher than thermal energies. This means that the deposition is accompanied by concurrent bombardment from the high-energy film ions. This concurrent bombardment can have beneficial effects on the film density, as is found in ion plating.

If the arc anode is cooled or has a large area, vaporization primarily occurs from the solid cathode surface by arc erosion. At the present time,the principal arc vapor source in thin-film technology is the solid cathode. Problems with this deposition technique include stabilization and movement of the arc on the solid surface and the formation of globules of the ejected material. Arc confinement and controlled arc movement using magnetic fields have given rise to the "steered arc" source. The globules can be filtered from the arc using various means (for example, the "plasma duct") (Ref 73), all of which reduce the deposition rate. Carbon ions (500 eV) from a vacuum arc source have been used to deposit hydrogen-free, diamond-like carbon films (Ref 74).

If the anode is allowed to melt, material evaporates from the molten (consumable) anode surface. This vaporization technique is essentially the same as the vacuum-arc-remelting (VAR) process (Ref 75, 76). Some studies have been done using the vapor from the molten anode of a vacuum arc. This has the advantage that globules are formed to a lesser degree than in cathodic erosion (Ref 77, 78). A commercial source of metal ions from a vacuum arc is the metal vapor vacuum arc (MVVA) source (Ref 79).

Additional information is available in the article "Arc Deposition" in this Volume.

Globules. The number of globules produced from the cathode surface depends on the melting point of the cathode material and the arc movement. The distribution of globule emission is nonisotropic, with the maximum number being found at angles greater than 60° from the normal to the surface. The neutral atoms found in the arc vapor are thought to be produced by thermal evaporation from the ejected globules. This effect causes the composition of the deposited film to vary with thickness and position when an alloy material is deposited (Ref 80).

Laser Vaporization. Flash evaporation can also be done with pulsed laser heating of surfaces (Ref 81, 82). This technique is sometimes called laser ablation deposition (LAD) (Ref 83). Typically an excimer laser (yttrium-aluminum-garnet, or YAG, or argon-fluorine) is used to deposit energy in pulses. The YAG lasers typically deliver pulses (5 ns pulse length, 5 Hz frequency) with an energy of about 1 J/pulse (9×10^{-4} Btu/pulse), and the argon-fluorine lasers typically deliver pulses (20 ns, 50 Hz) with about 300 nJ/pulse (2.7×10^{-10} Btu/pulse). The vaporized material forms a plume above the surface, where some of the laser energy is adsorbed and ionization and excitation occur. In laser vaporization the ejected material is highly directed; this creates a problem with forming a uniform thickness over large areas. During vaporization molten globules are ejected, and these can be eliminated by using a velocity filter. Laser vaporization, combined with the passage of a high electrical current along the laser-ionization path to give heating and ionization, has been used to deposit hydrogen-free, diamond-like carbon films at an ablation energy density greater than 5×10^{14} W/m^2 (1.6×10^{14} Btu/ft^2 · h) (Ref 83). Laser vaporization with concurrent ion bombardment has been used to deposit a number of materials (Ref 84, 85), including high-quality, high-temperature superconductor oxide films (Ref 86), at low substrate temperatures. Laser vaporization can be used to vaporize material from a film on a transparent material onto a substrate facing the film, by shining the laser through the "backside" of the transparent material, vaporizing a controlled film area, and thus depositing a pattern directly onto the substrate (Ref 87).

Field Evaporation. Surface atoms of metals can be vaporized by a high electric field. This technique is known as field evaporation and can be directly observed in the field ion microscope (Ref 88). This vaporization technique is used to clean emitter tips in field ion microscopy and to form metal ions from liquid-metal-coated tips. Field evaporation has been used to directly deposit nanometer-size gold structures (Ref 89). The very sharp tips necessary to obtain the high field can be formed in a variety of ways (Ref 90).

Polymer Evaporation. Many monomers and polymers can be evaporated to produce thin organic films on a substrate surface. Some organics can be cross-linked in the vapor phase inside a heated furnace before condensing on the substrate surface (paralyene process) (Ref 91). Condensed polymers can be cross-linked on the surface by exposing them to an electron beam (Ref 92) or ultraviolet radiation (Ref 93).

Materials for Vaporization

Material placed in the vaporization source is called a *charge* and can be in the form of powder, chunks, wire, slugs, and so on. The desired purity of the source material depends on the application and the effect of purity on film properties and process reproducibility. It is possible to obtain some material with extremely high purity (>99.999%), although the cost increases rapidly with the purity level. Often impurities such as oxygen, nitrogen, carbon, and hydrogen are not specified by the supplier. They can be present in significant quantities as oxidized surfaces of reactive metals, hydrogen incorporated into electrorefined chromium, carbon monoxide in nickel purified by the carbonyl process, and helium in natural quartz. Generally, it is better to specify vacuum-melted materials from the supplier when possible. Very reactive

metals should be nitrogen-packed in glass ampules to prevent oxidation, and the ampules should be opened and handled in an inert gas dry box where the reactive gas content is kept low by the use of getter materials such as liquid NaK [K:Na (20-50%)].

Careful specification of purity, allowable impurities, fabrication method, postfabrication treatments, and packaging of the source materials purchased is important to obtaining a reproducible process. Using inexpensive material or material of unknown origin often creates problems. Source material should be carefully cleaned and handled, because on heating, the impurities and surface contaminants are the first materials to be vaporized. The source and source material can be outgassed and premelted prior to film deposition.

Materials Utilization. Often material utilization in an evaporation process is poor unless proper fixturing and tooling is used to intercept the maximum amount of the flux. This can be accomplished by having the substrates as close as possible to the vaporization source, though this can result in excessive heating of the substrate during deposition. Deposition on large numbers of parts or over large areas can be done using large chambers with many (or large) vaporization sources.

Excess deposited material builds up on walls and fixtures and can flake off, producing particulate contamination in the processing chamber. The deposit buildup on surfaces also generates high surface areas that can absorb contaminants and are slow to desorb the contaminants. This results in changes in the pumping characteristics of the deposition system with use. It is desirable to have an easy way to collect and remove the excess evaporated material, and it can also be important to collect the excess material for reclamation. Excess evaporant can be collected by surrounding the source with a removable collector that defines the flux of evaporant to the substrate and collects excess evaporant. The chamber can have a removable liner to collect excess material, and the fixtures can be surrounded with panels or foil that can be easily removed.

Reactive Evaporation

Films of compounds can be deposited by reactive deposition, in which the elemental constituents of the compound are vaporized and codeposited, or in which the deposited material reacts with a reactive gaseous ambient on the surface of the depositing film. Most reactive deposition involves a condensible species (that is, titanium, zirconium, or aluminum) and a gaseous species (O_2, N_2), although some compounds of two or more condensible species can be deposited (for example, titanium and carbon). When codepositing two reactive species, obtaining the correct composition is often difficult, because the relative fluxes must be carefully controlled and generally the substrate temperature must be high to ensure reaction (for example, TiC from titanium plus carbon).

In reactive evaporation the reactive gas is in its natural (that is, molecular) state (Ref 94, 95, 96). This technique generally requires that there be many more reactive gas molecules striking the depositing film than are needed for forming the compound, because the reaction coefficient is generally much less than one.

Activated Reactive Evaporation. If the reactive gas is "activated" by forming new molecular species (that is, ions, radicals, and excited species), the reactive deposition process is termed activated reactive evaporation (ARE) (Ref 97, 98, 99, 100). Because the reactive gas is activated, the gas density needed for reaction is less than that needed for reactive evaporation. The reactive gas can be activated by a plasma (Fig. 9), thermal decomposition, photoadsorption, or some other means. The use of atomic or radical beams of the reactive gas, directed toward the depositing material during deposition, allows reactive deposition to take place at a relatively low chamber pressure. An example of activated reactive evaporation that does not use a plasma is the deposition of a thin layer of titanium nitride to reduce secondary electron emission, by evaporating titanium in ammonia where the ammonia is decomposed by the hot evaporating filament to provide reactive nitrogen radicals (Ref 101).

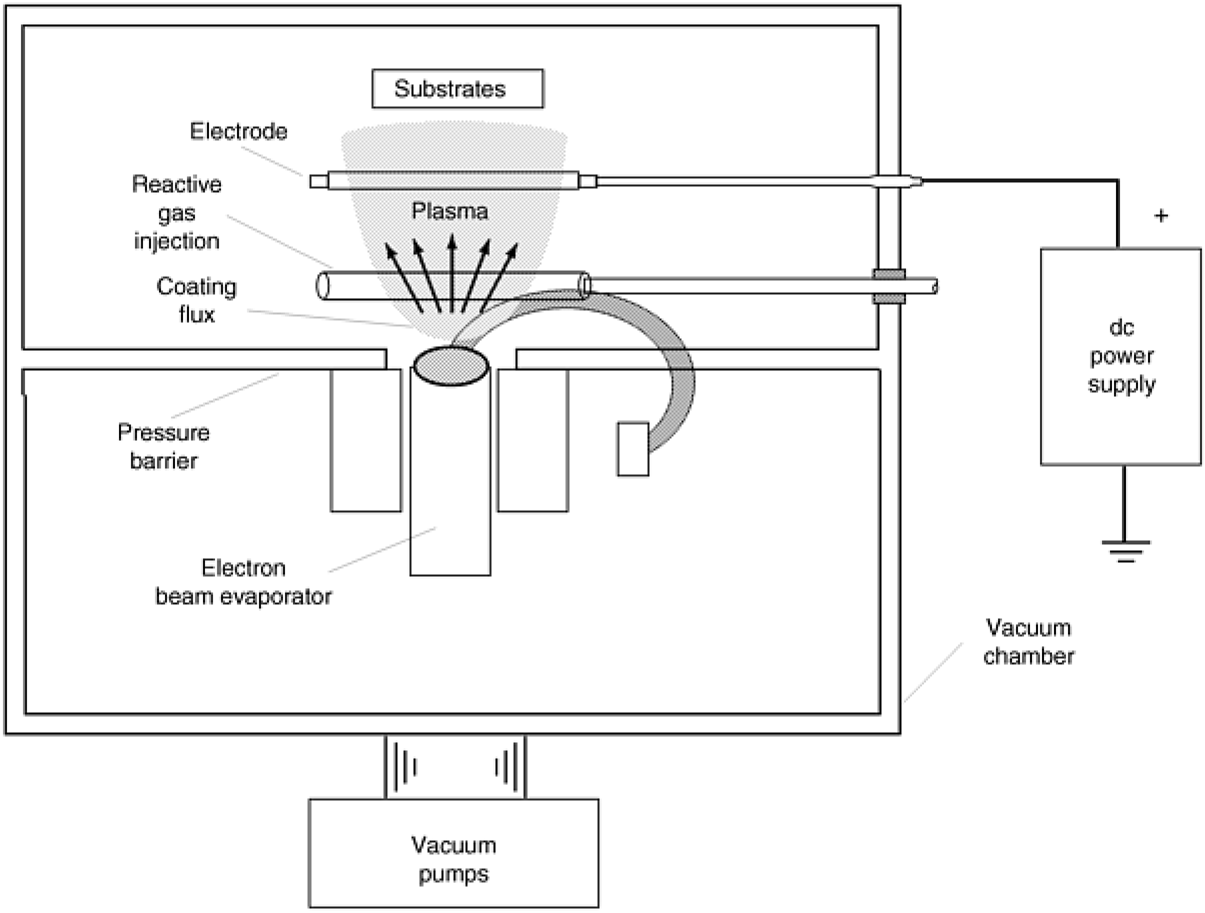

Fig. 9 Schematic of the activated reactive evaporation process using an electron-beam gun as an evaporation source. Source: Ref 99

In reactive evaporation, the interface can be graded by controlling the availability of the reactive gas. For example, in depositing titanium nitride the material can be graded from titanium to titanium nitride by controlling the availability of the nitrogen. Reactive evaporation can be used to form compounds when the evaporant is another compound. For example, cubic boron nitride (CBN) has been formed by the evaporation of H_3BO_3 in a plasma of NH_3 (Ref 102).

Additional Evaporative Vacuum Deposition Techniques

Other deposition processes that use the vacuum environment to control contamination and provide a long mean free path for vaporized material can be defined as *vacuum deposition* processes:

- Molecular beam epitaxy
- Ionized cluster beam deposition
- Ion beam sputter deposition
- Jet vapor deposition

Molecular Beam Epitaxy. Probably the most sophisticated vacuum deposition system/process is that used for molecular beam epitaxy (MBE), or vapor phase epitaxy (VPE) (Ref 103). Molecular beam epitaxy is used to form epitaxial films of semiconductor materials. A vacuum environment of better than 0.13 μPa (10^{-9} torr) is used to deposit atoms from carefully rate-controlled vapor sources (Knudsen-type sources) (Ref 9). The MBE deposition chamber can also contain a wide range of analytical instruments for in situ analysis of the growing film. These analytical techniques include methods for measuring crystal parameters, such as reflection high energy electron diffraction (RHEED) and low energy electron diffraction (LEED).

Gaseous or vaporized metal-organic compounds can also be used as the source of film material in MBE. The molecular species are decomposed on the hot substrate surface to provide the film material. The use of metal-organic precursor

chemicals is called metal-organic molecular beam epitaxy (MOMBE) (Ref 104). MOMBE is used in low-temperature formation of compound semiconductors with low defect concentrations.

Ionized Cluster Beam Deposition. Clusters of atoms (approximately 1000) can be charged and accelerated to such high velocities that the average kinetic energy of the depositing atom is greater than that associated with thermal vaporization. This is the basis of the ionized cluster beam (ICB) deposition process (Ref 105, 106). There is some controversy about how and if clusters are formed and what actually happens at the surface in this deposition process (Ref 107, 108, 109). There are numerous technical papers detailing the advantages of the ICB deposition process in forming epitaxial films at low temperatures that are defect free, have good adhesion, and have good surface coverage.

Ion-Beam Sputter Deposition. Ion guns can be used to sputter deposit films in a vacuum environment (Ref 110). This technique has limited applications because high-energy neutrals reflected from the sputtering target can bombard the growing film during deposition, giving rise to uncontrolled film property variations.

Jet Vapor Deposition. In the "jet vapor deposition" process, evaporated atoms/molecules are "seeded" in a supersonic jet flow of inert carrier gas into a rapidly pumped vacuum chamber (Ref 111, 112). The jet transports the atoms/molecules to the substrate surface, where they are deposited. The vapor source can be in the form of thermal evaporation or sputtering and is located in the jet nozzle. The deposition chamber pressure is about 130 Pa (1 torr) and is pumped using high-capacity mechanical pumps.

Advantages and Limitations of Vacuum Deposition Processes

Vacuum deposition has advantages and limitations relative to other physical vapor deposition (PVD) techniques.

Advantages of vacuum deposition include:

- Line-of-sight deposition allows the use of masks to define the area of deposition.
- Large-area sources can be used for some materials (for example, "hog trough" boat crucibles for aluminum and zinc).

- High deposition rates can be obtained.
- Deposition rate monitoring is relatively easy.
- Vaporization source material can be in many forms (for example, chunks, powder, wire, chips, and so on).
- Vaporization source material of high purity is relatively inexpensive.
- High-purity films are easily deposited from high-purity source material, because the deposition ambient can be made as noncontaminating as required.
- The technique is relatively inexpensive compared to other PVD techniques.

Limitations of vacuum deposition include:

- Line-of-sight deposition gives poor surface coverage, thus requiring elaborate tooling and fixturing.
- Line-of-sight deposition prevents uniform deposits over a large surface area unless complex fixturing and tooling are available.
- Deposition of many alloys and compounds is difficult.
- Capital equipment costs are high relative to those of other deposition techniques (for example, electroplating).
- High radiant heat loads are required during processing.
- Vaporized material is used inefficiently.
- Film properties are suboptimal (typical defects include pinholes, less than bulk density, columnar morphology, high residual film stress, and so on).
- Few processing parameters are available to control film properties.

Vacuum Deposition Applications

Applications of evaporation processes include:

- Electrically conductive coatings for ceramic metallization (for example, Ti-Au, Ti-Pd-Au, Al, Al-Cu-Si, Cr-Au, Ti-Ag), semiconductor metallization (for example, Al-2Cu on silicon), and metallization of capacitor foils (for example, zinc and aluminum)
- Optical coatings for reflective, antireflective, and abrasion-resistant topcoat (for example, SiO, MgF_2) applications
- Decorative coatings (for example, aluminum and gold)
- Moisture and oxygen permeation barriers for packaging materials (for example, aluminum and $SiO_{1.8}$ on polymer webs)
- Corrosion resistance (for example, aluminum on steel)
- Insulating layers for microelectronics (Ref 113)
- Coating of engine turbine blades (M-CrAl alloys) (Ref 19, 114, 115)
- Avoiding the pollution problems associated with electroplating (that is, "dry processing")
- Vacuum plating of high-strength steels to avoid the hydrogen embrittlement associated with electroplating (for example, cadmium on steel, or "vacuum cad plating")

Freestanding Structures. Evaporation processes can be used to form freestanding structures by depositing the film on an appropriately shaped mandrel. On the mandrel, either there is a "parting layer" (for example, evaporated NaCl) or the surfaces may be nonadhering (for example, copper on the oxide on stainless steel). In some cases, the mandrel must be dissolved to release the deposited form. This technique is used to fabricate thin-wall structures and windows (Ref 116).

Multilayer Structures. Many applications of evaporation processes require deposition of layered structures. These applications range from simple two- to three-layer metallization systems to x-ray diffraction gratings that consist of alternating low-mass material (carbon) and high-mass material (tungsten) and form a stack of thousands of layers with each layer only 3 to 4 nm (30 to 40 Å) thick.

Gas Evaporation and Ultrafine Particles

Vapor phase nucleation can occur in a dense vapor cloud by multibody collisions. The nucleation can be encouraged by passing the atoms to be nucleated through a gas to provide the necessary collisions and cooling for nucleation. These particles have a size range of 1 to 100 nm (10 to 1000 Å) and are called *ultrafine particles* or *ultrafine clusters*. The process of forming the particles is called *gas evaporation* (Ref 117, 118, 119). The size and size distribution of the particles depend on the gas density, the gas species, the evaporation rate, and the geometry of the system. When these particles deposit on a surface the resulting film is very porous and can be used as an optical radiation trap; for example, "black gold" infrared radiation bolometer films, germanium film solar absorber coatings (Ref 120) and low secondary electron emission surfaces (Ref 121). The particles themselves are used for various powder metallurgical processes, such as low-pressure, low-temperature sintering (Ref 122). Ultrafine particles of reactive materials are very pyrophoric because of their high surface area.

Evaporation into a plasma causes the ultrafine particles to have a negative charge and to be suspended in the plasma near walls where they can grow to appreciable size (Ref 123, 124, 125). Ultrafine particles of alloys can be formed by evaporation from a single source, or they can be evaporated from separate sources and nucleated in the gas. Ultrafine particles of compounds can be formed by having a reactive gas present during nucleation or by decomposing and reacting precursor gases in an arc or plasma.

Buckminster Fullerenes. Recent gas evaporation techniques have allowed the formation of the Buckminster fullerenes (C^{60} and C^{70} "Buckeyballs"), a newly discovered form of the carbon molecule that resembles the shape of a soccer ball (Ref 126, 127). The synthesis involves arcing two pure graphite electrodes in a partial vacuum containing helium. The carbon "soot" that forms contains from 3 to 40% fullerenes, depending on the experimental conditions. The fullerenes are extracted from the soot by dissolving them in boiling benzene or toluene, and then this extract is vacuum dried.

Evaporation Process Equipment

The primary function of the vacuum system associated with evaporation processing is to reduce contaminating residual gases and vapors to an acceptable level. Potential sources of the gases and vapors in the processing chamber and related systems include:

- Residual atmospheric gases and vapors
- Desorption from surfaces in the vacuum (for example, water vapor and oils)
- Outgassing from materials in the vacuum (for example, water vapor and oxygen)
- Vaporization of construction materials (especially at high temperatures)
- Leakage from real and virtual leaks
- Permeation through materials such as rubber O-rings
- Desorption, outgassing, and vaporization from fixtures, tooling, substrates, and deposition source materials introduced into the system

In all cases, specifications for system performance, deposition procedures, and vacuum conditions should be established when the system and procedures produce a reproducible workpiece with the desired properties. Figure 10 shows a vacuum deposition system that can use a plasma discharge for plasma cleaning or the ARE process. Usually there are tradeoffs between the optimum design for achieving a good vacuum and the practicality of design for processing. For example, processing may require a large access door so that fixturing and substrates can be assembled externally and installed in the chamber.

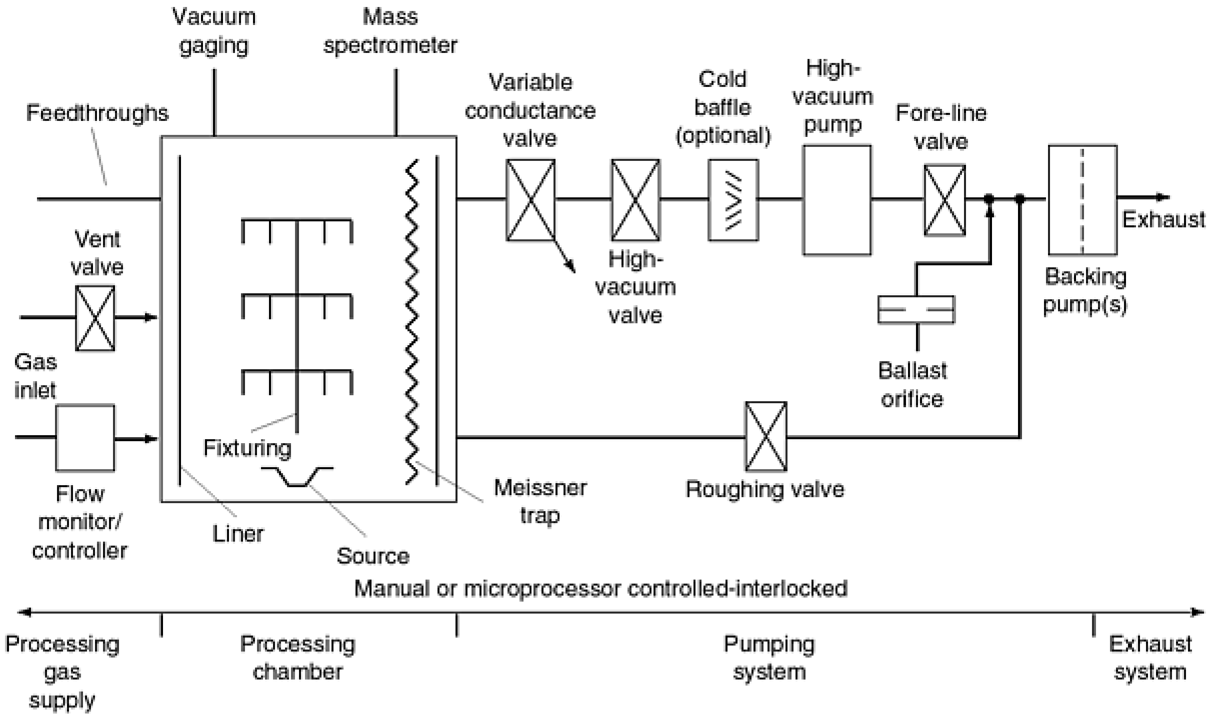

Fig. 10 Primary components of a batch-type vacuum deposition system that can be used for plasma processing

Processing Chamber. There are several chamber configurations for vacuum deposition systems (Fig. 11). The batch-type system is the most common but exposes the system to the ambient air with each deposition, which can introduce uncontrolled process variables. Load-lock systems allow the deposition chamber to be kept under a more controlled environment.

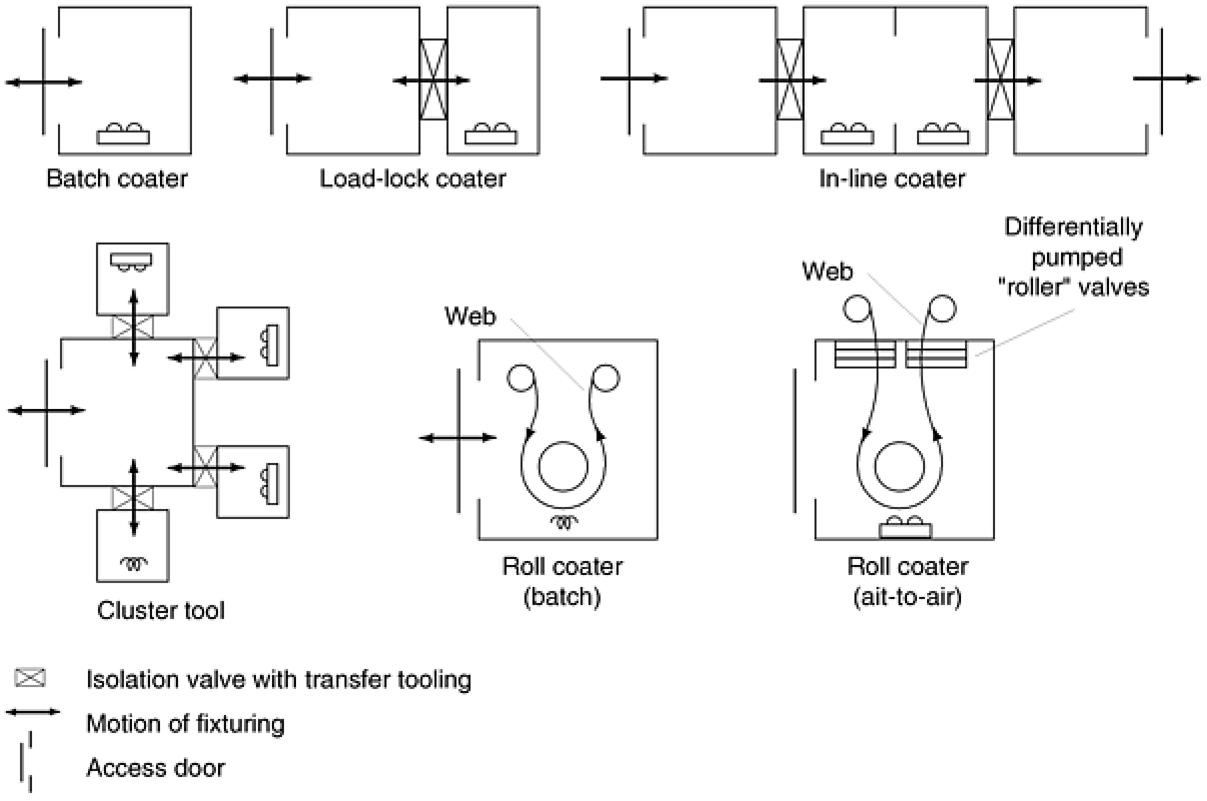

Fig. 11 Chamber configurations employed in vacuum deposition systems

Vacuum deposition systems need to be kept clean in order to operate efficiently. Deposit buildup results in increased pumpdown time because of slower desorption of adsorbed contaminants (for example, water). Deposit buildup also results in flaking from walls and fixtures, which can cause pinholes in coatings. Good vacuum practices should be used in all aspects of the use of deposition equipment. The design of the system should allow good access for cleaning and mounting of appropriate fixturing, sources, shutters, and so on.

Heating from the vaporization source can raise the system temperature to unacceptable levels, leading to desorption, outgassing, and the failure of organic seals. Heat is generally removed by water cooling the chamber walls or by using an internal heat sink, such as a water-cooled surface (Ref 128). The cooling channels in the chamber walls can be used to heat the surface using hot water when the system is opened to the ambient air. This heating minimizes water adsorption on the surface when the system is open to the ambient air.

Pumping System. Pumping in the vacuum deposition system is generally relatively simple because there are typically no high-gas loads. However, in some cases, the gas and vapor loads can be high from outgassing and desorption, and the system should be designed accordingly. An example is web (roll) coating, where trapped gases are released during unrolling of the plastic web in the deposition chamber. Where water vapor release is a problem, it is often desirable to have an in-chamber cryocondensation surface. These surfaces are cooled by refrigeration and "freeze out" the water vapor in the chamber at low temperatures (<-130 °C, or -202 °F).

In reactive deposition processes and gas evaporation, where the gas pressures are high, the vacuum pumping system can generate pressure differentials in the chamber. This can have a significant effect if the system has a great deal of fixturing in the processing volume. This problem has been noted at processing pressures as low as 0.13 Pa (10 mtorr).

Fixturing and Tooling. The definitions of *fixturing* and *tooling* are not universally accepted, but in general, *fixturing* is used to hold the substrates while *tooling* is used to move the fixtures. Fixturing and tooling should be constructed to minimize virtual leaks, particle generation by flaking, and shadowing effects on the deposition process. Fixtures and tooling should be easily removable for cleaning or rearrangement. Fixture surfaces often represent a major portion of the surface in the processing chamber and should be cleaned, handled, and stored with care.

Tooling is used to randomize the substrate position and angle with respect to the direction of the depositing flux. A common tooling in evaporation processing is a spherical dome-shaped (calotte) holder that maintains a constant line-of-sight distance between the source and substrates. Often this holder is rotated to randomize the position of the substrates. This results in improved surface coverage, a more uniform thickness distribution, and more consistent film properties (Ref 6, 129, 130). However, it should be realized that no amount of movement can completely overcome the angle-of-incidence and thickness variations on a complex surface. Angle-of-incidence differences can lead to significant film property variations.

Mounting of Substrates. Substrates should be mounted so that particles in the deposition ambient do not settle on the substrate surface. This requires mounting the substrates so that they face downward or to the side. Mechanical clamping is often used to secure the substrates, but this entails having a region that is uncoated. Mechanical clamping provides poor and variable thermal contact to the fixture surface and can result in variable substrate temperatures during the vaporization/deposition process.

Substrate Heating and Cooling. Substrates can be heated from a number of sources:

- Condensation of the depositing atoms
- Radiant heating from the vaporization source
- Separate radiant heaters (for example, quartz radiation lamps) in the system to heat the substrate directly
- Embedded heaters to heat the fixturing
- Accelerated electrons from a heated filament, used to heat conductive substrates or fixtures
- Laser radiation, used to provide local heating during the deposition process

Substrates can be cooled by being in contact with a cooled substrate fixture. Circulating chilled water or oil, a cooled water/ethylene glycol mixture (at -25 °C, or -13 °F), dry ice/acetone (at -78 °C, or -109 °F), or liquid nitrogen (at -196 °C, or -321 °F) can be used as coolants.

Masks. Because in vacuum deposition the vapor flux travels in a straight line to the substrate surface, physical masks can be used to intercept the flux to produce defined patterns of deposition on a surface. The effectiveness of masks depends on the mask-surface contact, mask thickness, edge effects, and mask alignment on the surface. Masks can be made by numerous methods (for example, etching or machining) (Ref 131) and can allow pattern resolutions as small as several microns. Masking allows the patterning of hard-to-etch materials and in situ patterning during deposition. Deposited masks are used in the lift-off patterning process (Ref 131). Programmed moving masks can also be used to control the film thickness distribution on a surface (Ref 14, 15, 132)

Shutters. The shutter is an important part of the vacuum deposition system. Shutters can be used to isolate the substrate from the source and to allow outgassing and wetting of the source without contaminating the substrate. Shutter design is limited only by the ingenuity of the designer. The shutter can be the moving part, or the substrate can be moved. Shutters can be in the form of fans, leaves, flaps, or sections of geometrical shapes (for example, cones, cylinders, and so on). In designing a shutter, care must be taken to keep the complexity to a minimum. Shutter design should provide for easy removal when cleaning is necessary. In some cases, it may be desirable to cool the shutter as an aid in pumping condensables.

Source fixturing involves making good electrical contact with the resistively heated vaporization source (for example, wire or sheet). Thermal expansion requires that the fixture be slightly flexible. If the fixture is too rigid, the vaporization source can be stressed and subsequently broken. If the source is flexible (for example, a wire or coil), the source can

distort and thus produce changes in the flux distribution pattern on heating and in actual use. In some cases, the source and its electrical connections are moved during deposition to increase coverage uniformity over a large stationary substrate.

High current connections to the source should be of a high-conductivity material such as copper. Physical contact to boats and crucibles can be improved by using spring contacts of a material such as tungsten, along with graphite paper shimming materials, such as that known by the tradename Grafoil. In some cases, cooled clamps can be used to hold the source. Multiple evaporation sources can be arranged to produce large-area or linear vaporization patterns.

In Situ Cleaning. Many vacuum deposition systems, particularly optical coating systems, are equipped with the capability to establish a plasma discharge for cleaning substrate surfaces prior to film deposition (Ref 1). Pure air is often used as the cleaning plasma for oxide surfaces. Often a plasma ring is used as the cathode in the processing chamber. The plasma ring should be shielded to prevent sputtered material deposits on the substrate. The cathode can be cooled if the power to the cathode is high.

The effectiveness of plasma cleaning depends on the packing of surfaces in the volume. If there is a large volume of fixturing and close spacing of surfaces in the chamber, the effectiveness of plasma cleaning will vary throughout the volume of the system.

Getter Pumping. When reactive materials are deposited, the fixturing and shields in the deposition system can be arranged to provide getter pumping by the excess deposited film material. This gettering lowers the contamination level in the system and at the substrate.

Process Monitoring and Control

To provide a reproducible vacuum deposition process, the principal deposition parameters that need to be monitored and controlled are:

- Residual gas pressure and composition prior to and during deposition
- Substrate temperature and temperature variations over the substrate surface
- Deposition rate
- Angle of incidence of depositing flux
- Purity of source material

- Preprocessing, such as surface preparation and substrate heating

In the case of reactive evaporation, the following parameters also need to be monitored and controlled:

- Availability of reactive gases over the substrate surfaces
- Activation of reactive gases
- Gas density distribution in the processing chamber

Substrate Temperature Monitoring. The substrate loses heat by conduction and radiation, thus often making it difficult to monitor substrate temperature. Thermocouples embedded in the substrate fixture often give a poor indication of the substrate temperature, because the substrate often has poor thermal contact with the fixture. In some cases, thermocouples can be embedded in or attached directly to the substrate material. Optical (infrared) pyrometers can be used to determine the temperature if the surface emissivity and adsorption in the optics are constant and known.

Passive temperature monitors can record the maximum temperature a substrate has approached during processing. Passive temperature monitors register color changes, phase changes (for example, melting of indium), or crystallization of amorphous materials (Ref 133).

Source Temperature Monitoring. Generally, source temperatures are very difficult to monitor or control with precision. In molecular beam epitaxy, the deposition rate is controlled by carefully controlling the temperature of a well-shielded Knudsen cell source using embedded thermocouples (Ref 7).

Deposition Rate and Deposited Mass Monitors. Quartz crystal monitors measure the frequency of the oscillations as a function of the mass added to the crystal face. By calibrating the frequency change with the mass deposited, the quartz crystal output can measure deposition rate and total mass deposited (Ref 134). Ionization rate monitors compare the ionization currents in a reference chamber and a chamber through which the evaporant flux is passing. By calibration, the differential in gage outputs can be used as a deposition rate monitor (Ref 135). A vacuum microbalance can be used to measure the deposition rate and the total amount of material deposited. In electron-beam evaporation, the ions that are formed above the molten pool can be used to monitor the vaporization rate and the mass deposited.

The total amount of deposited material is sometimes controlled by evaporating to completion a specific amount of source material. This avoids the need for a deposition controller and is used where many repetitious depositions are to be made.

Film Thickness Monitoring. There is no easy way to measure the geometrical thickness of a film during deposition because the thickness depends on the density for a given mass deposited. In general, thickness is determined from the mass deposited, assuming a density so that the mass monitor is calibrated to give thickness.

Optical Property Monitoring. In optical coating systems, in situ monitoring of the optical properties of the films is used to monitor film deposition and provide feedback that controls the evaporators (Ref 136, 137). Generally, the optical transmittance, interference (constructive and destructive), or reflectance at a specific wavelength is used to monitor the optical properties. Ellipsometric measurements can be used to monitor the growth of oxides on semiconductor materials.

Electrical Property Monitoring. An electrically conducting path between electrodes can be deposited using a mask, and the electrical resistivity of the path can be used as a deposition monitor (Ref 138).

Film Stress Monitoring. There are several techniques for measuring the film stress during the deposition process. These techniques typically measure the movement of surfaces, as monitored by changes in capacitance between two plates, or they measure the deflection of a beam by optical interferometry (Ref 139) or an optical lever arm. X-ray diffraction measurements of the lattice spacing can be used to measure film stress due to lattice deformation (Ref 140).

Sputter Deposition

S.L. Rohde, University of Nebraska-Lincoln

Introduction

SPUTTERING is a nonthermal vaporization process in which surface atoms are physically ejected from a surface by momentum transfer from an energetic bombarding species of atomic/molecular size. Typically, sputtering uses a glow discharge or an ion beam (Ref 1) to generate a flux of ions incident on the target surface. These ions cause atoms, and occasionally clusters of atoms, to be knocked free from the target surface by impact transfer, or sputtering. Sputtering is used in two principal applications: sputter etching, in which the primary objective is removal of material from the target surface (Ref 2); and sputter deposition, in which redeposition of these sputtered atoms onto another surface, or substrate, is the primary goal. The latter application is discussed in this article. The fundamentals of plasma formation and the interactions on the target surface are discussed first, followed by the differences between reactive and nonreactive sputtering, and several methods of process control. In the third section, the basic principles and relative advantages and disadvantages of the most common sputtering techniques are examined, specifically direct-current (dc) diode, radio-frequency (rf) diode, triode, magnetron sputtering, and a relatively new technique known as "unbalanced" magnetron sputtering.

Compared to other thin-film deposition methods, sputter deposition techniques have several distinct advantages:

- Use of an unlimited range of source and film materials (i.e., metals, semiconductors, insulators, alloys, and compounds)
- Small sputtering-yield variations from one material to another as compared to the relative variation in the evaporation rates at a given temperature
- Ease of low-temperature deposition of refractory materials
- Elimination of droplet emission from the source that can occur in thermal evaporation
- Absence of droplets, which are common in arc-deposited films
- Ease of forming multicomponent films
- Uniformity of film thickness over large areas
- High degree of film adhesion
- Environmentally friendly processing

Sputter deposition processes have several limitations as well:

- Target (source) materials must ordinarily be in sheet or tube form.
- Deposition rates are typically less than 300 nm/min (3000 Å/min).
- Setup costs are high because of the required vacuum environment.
- Line-of-sight process may not be suitable for three-dimensional components.
- Energy efficiency is low (70% or more of the input energy is expended in target heating).

Glow Discharge Sputtering

Glow Discharge Formation. The simplest case of a glow discharge, the dc diode discharge, is illustrated in Fig. 1. At the far left of Fig. 1(a) is the cathode and adjacent to it the cathode glow region, which is luminous because of positive and negative ion neutralization at the cathode surface. Next to the cathode glow region is the cathode dark space, or sheath, across which most of the voltage is dropped (Fig. 1b), providing the accelerating force driving the ions into the target. The net space charge (Fig. 1c) also changes dramatically across the cathode dark space. To the right of the cathode dark space are the negative glow, the Faraday dark space, the positive column, and the anode, as shown in Fig. 1(a).

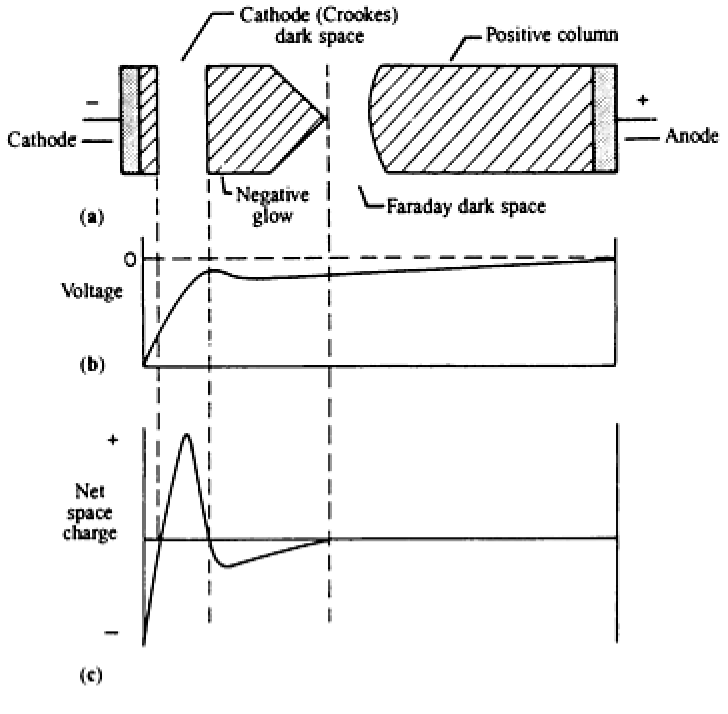

Fig. 1 Schematic illustration of the (a) primary regions, (b) voltage characteristics, and (c) net space charges for a dc glow discharge. Source: Ref 32

When an ion strikes the cathode, in addition to the generation of heat and the removal of neutral atoms and ions, there is about a 5 to 10% probability of secondary electron emission. These secondary electrons are then accelerated back across the dark space into the negative glow region where they expend most of their energy creating additional ions, approximately 10 to 20 ions/electron. It is these secondary electrons that are primarily responsible for sustaining the discharge, in this case, a cold cathode discharge. In the case of self-sustaining plasmas, the regions beyond the negative glow are less important, and in many cases the anode can be moved closer to the cathode, eliminating the positive column

and shrinking the size of the negative glow region, without greatly affecting the discharge characteristics. Thus in sputter deposition, the substrates are often immersed in the negative glow region. In this case, an additional dark space will form surrounding the substrates, and the thickness of this dark space, as well as the type and energy of the charged carriers reaching the substrate surface, will depend on whether the substrates are at the anode potential or are externally biased relative to the plasma.

Target Considerations. A great variety of interactions can occur on the target surface because of the impinging positive ions, as illustrated in Fig. 2. These interactions include liberation of neutral atoms, ionized atoms, backscattering, x-ray emission, photon generation, secondary electron emission, and desorption of gas atoms from the target surface. In the target itself, several other processes can occur, including the generation of collisional cascades, the creation of point defects, local heating, amorphization, implantation, and compound formation. Within the plasma, the secondary electrons cause additional ionization, supporting the discharge. The color of the optical emission of the plasma is characteristic of the target material, gas species, pressure, excitation, and so on. Thus, it is often possible to detect the presence of certain components in the discharge simply by monitoring the characteristic spectral wavelengths, and, hence, this feature of glow discharges is often used in process control.

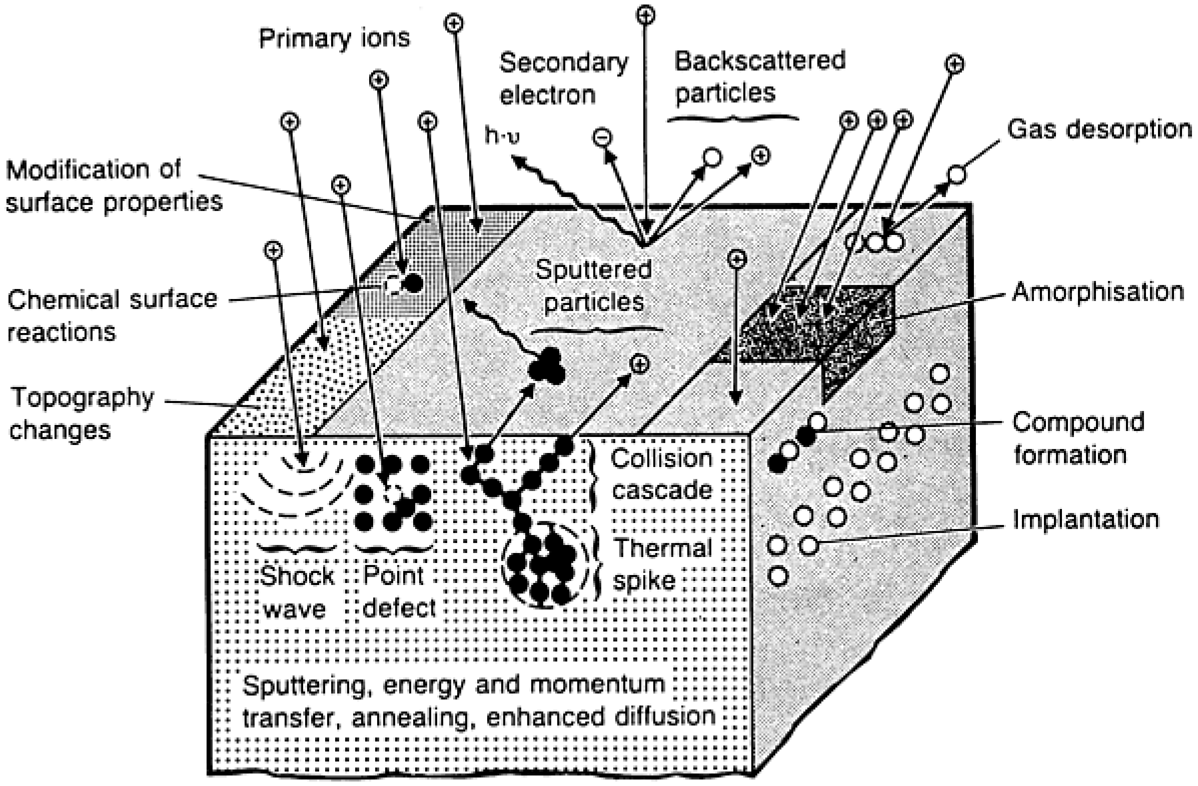

Fig. 2 Synopsis of the interaction events occurring at and near the target surface during the sputtering process. Source: Ref 5

One of the most important sputtering parameters is the sputtering yield, which is defined as the number of atoms ejected from the target surface per incident ion. The sputtering yield is dependent on the characteristics of the target material, incident ion energy, ion mass, and angle of incidence, as shown in Table 1. Detailed studies of sputtering yields for a large variety of materials can be found in the literature; see, for instance, Maissel (Ref 3) and Wehner (Ref 4). Although the variation in sputtering yields is as high as one order of magnitude, it is considerably lower than the rate variations that occur for evaporation from liquid sources at a specific temperature, which are often several orders of magnitude.

Sputtering processes are governed primarily by energy transfer, momentum transfer, annealing effects, and enhanced diffusion, which often limits the performance of targets and creates a need for process control (Ref 5). For example, adsorbed gases tend to desorb under the influence of ion bombardment and heating. This is an important consideration when using powder metallurgically prepared targets that can liberate water vapor and cause surface chemical reactions if not properly degassed. Additionally, chemical surface reactions occur in the presence of reactive or residual gases such as nitrogen, oxygen, or hydrocarbons and can cause compound formation on the target surface. These reactions usually result in decreased sputtering rates, and compound formation is further intensified by a low target heat conductivity and cooling rate.

Additionally, topographical changes in the target surface may occur over time, particularly in multiphase polycrystalline targets in which the crystallites have different sputtering yields, leading to cone formation and arcing on the target. It is essential to consider these interactions in the selection and operation of various targets. More detailed information on these aspects of sputter processes is provided in the general literature (Ref 6, 7, 8, 9, 10, 11).

Process Parameter Effects on Film Microstructure. Scattering within the discharge significantly affects the energy with which atoms impact the film surface and, hence, the microstructure and properties of the sputtered film. Ejected atom energies range from a few tenths of an electron volt up to nearly that of the ions impinging on the target, but because of intense scattering within the discharge, the atoms usually arrive at the substrate with energies of only a few electron volts. Scattering also causes the deposition rate to decrease as the target-to-substrate separation increases. Additionally, the incidence of scattering increases with increasing gas pressure, because the mean-free-path between collisions decreases as the pressure rises. Thermalization of these ejected atoms occurs after the ejected atoms suffer a sufficient number of energy-loss events that their energy is reduced to the thermal energy of the discharge. The distance required for thermalization depends on the pressure, initial atom energy, atomic mass, and several plasma characteristics and is typically a centimeter or less (Ref 12). In low-pressure, high-voltage discharges, the mean free path between collisions is long, and it is therefore possible for a statistically significant number of atoms to reach the substrate with energies in excess of the thermal energy; these atoms are termed *energetic neutrals*. Energetic neutrals can cause additional bombardment of the growing film; however, their energy is difficult to determine and their effect on film properties is not easily understood.

In addition to neutral atom bombardment, auxiliary substrate heating and negative substrate bias voltages are often employed during deposition, and these parameters also influence the microstructure of the growing film. Thornton (Ref 13) and others have examined the influences of substrate temperature and discharge pressure on film microstructure. It has been shown that, in general, increasing substrate temperatures can be associated with a transition from an open columnar arrangement (zone I), to a dense columnar formation (T-zone), to a second dense columnar microstructure (zone II), and, finally, to dense equiaxed grain structure (zone III), as shown in Fig. 3. Thus, increasing the growth temperature causes the density of the films to increase, whereas increasing the pressure produces the opposite effect (Ref 13). Of course, changes in microstructure with pressure are closely related to changes in the thermalization distance and hence the ion/atom energy. Some caution should be exercised in applying such models, because these early models were developed using only scanning electron microscope investigations, and more recent studies using transmission electron microscopy have shown these models to be overly simplistic.

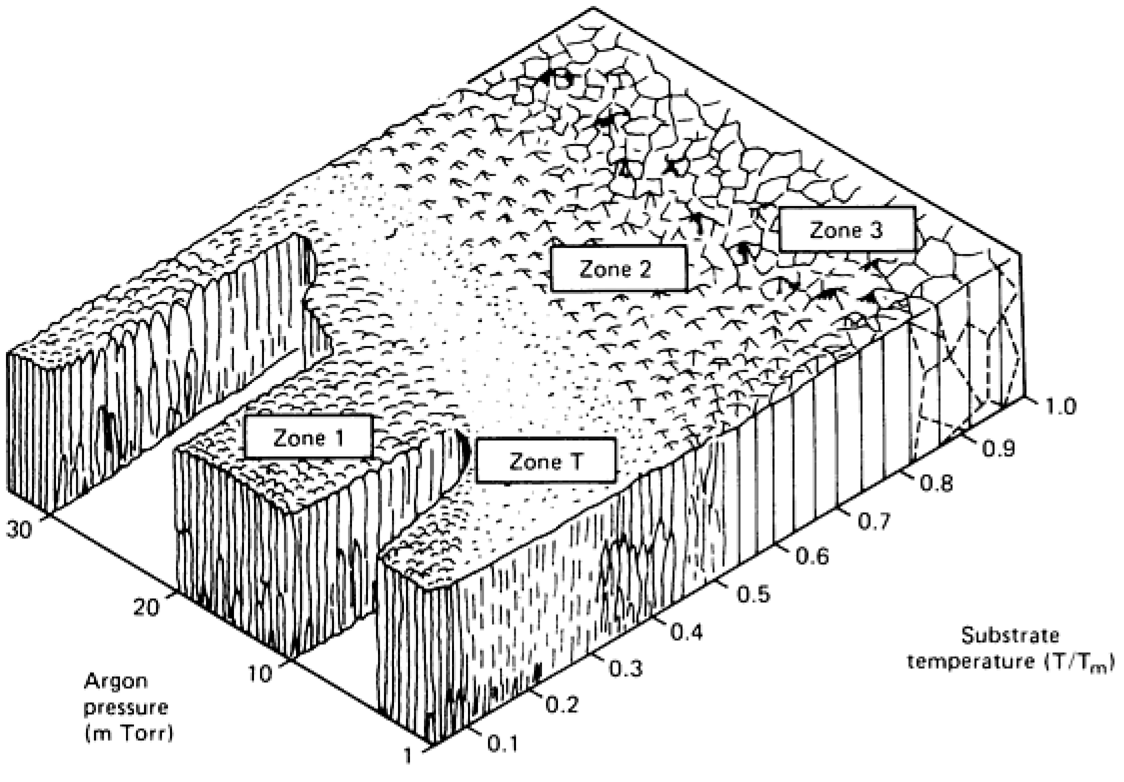

Fig. 3 Microstructural dependence of sputtered thin films on argon pressure and substrate temperature

Microstructural changes similar to those induced by temperature and pressure can be reproduced to some degree by applying a negative bias potential to the substrate during deposition. Under the influence of this negative potential, positively charged ions impact the substrate surface, resulting in increased adatom mobilities, substrate heating, point

defect generation, and so on. In this case, the dense T-zone moves toward lower temperatures with increasing negative bias (Ref 14). This effect has also been shown experimentally; for example, Mattox showed that ion bombardment during the condensation process resulted in increased film density of sputter-deposited refractory tantalum with increasing negative bias (Ref 15, 16). The evolution of film morphology is covered in detail in the article "Growth and Growth-Related Properties of Films Formed by Physical Vapor Deposition Processes" in this Volume.

Reactive Sputtering and Process Control

Reactive versus Nonreactive Processes. Both reactive and nonreactive processes may be used in the formation of sputter-deposited films. For nonreactive sputtering, an inert gas, which does not participate directly in the formation of compounds on either the target or the substrate, is used to generate a plasma and sputter material from the target. The inert gas is also sometimes termed the *working gas*. Argon is used in most cases because its mass is high enough to ensure adequate sputtering yields and it is less expensive than xenon or krypton. Although inert gas ions and atoms are not incorporated as primary constituents, incorporation even in very small concentrations can have deleterious effects on film properties. For example, argon incorporation can cause lattice expansions, increasing the internal stress of the films (Ref 17). Additionally, inert-gas ion bombardment of the substrate/film couple using an applied negative-substrate bias can increase inert gas incorporation as well as alter the growth mode, stoichiometry, and properties of deposited films. Nonreactive sputtering processes are common in the deposition of thin metallic overlayers for electron microscopy, industrial-scale deposition of metals and metallic alloys, industrial-scale deposition of some insulators, and research-scale deposition of insulators and compounds. The primary advantage of this type of thin-film deposition is its simplicity.

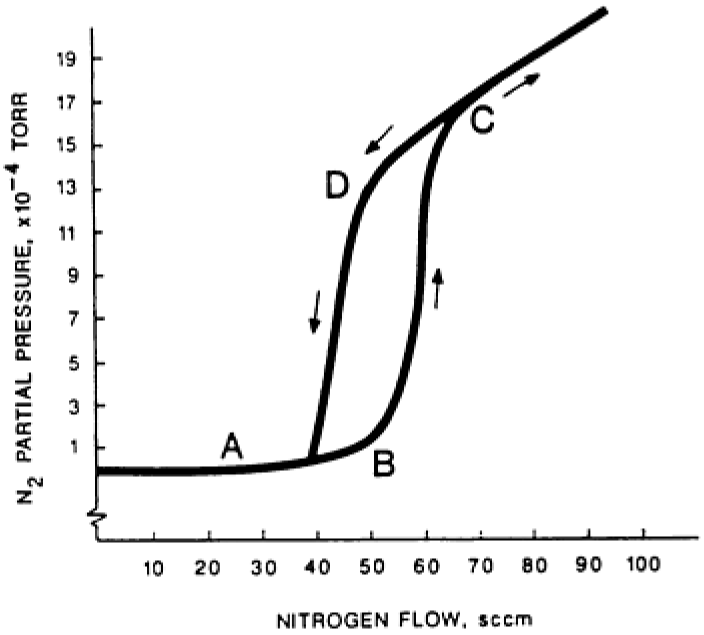
Nonreactive processes can be used to directly sputter compound targets such as TiN, which is used in many decorative and wear-resistant applications. However, this use presents several difficulties: (a) the rate at which The pure metal (titanium) can be sputtered is about an order of magnitude lower than the rate at which pure titanium can be sputtered; (b) off-stoichiometry of the films can occur during deposition; and (c) the thermal conductivity of the compound is often much lower than that of the pure metallic species, and thus the target power must be reduced accordingly due to the heating and fracture of the target. These difficulties often preclude the cost-effective use of nonreactive processes in many applications. In these cases, use of reactive sputtering becomes a necessity.

Reactively sputtered films can be deposited using a variety of methods including dc diode, rf diode, triode, magnetron, and modified rf magnetron sputtering. In any case, there are only two basic reactive sputtering modes: compound-coated cathode and metallic cathode. Sputtering in the compound-coated cathode mode is straightforward: sufficient reactive gas is bled into the chamber during sputtering to form the desired compound on the target surface; this compound is then sputtered off and redeposited on the substrate. In many ways, there is little difference between reactive sputtering in the compound-coated cathode mode and nonreactive sputtering from a compound target. The sputtering rates are usually much lower for compounds because of a reduction in the sputtering yield and an increase in the secondary electron emission that is observed with most compound targets. Additionally, depending on the sputtering technique, materials, and deposition conditions, the film may not possess the same chemical composition as the target material. For these reasons, sputtering in the metallic cathode mode is often preferable.

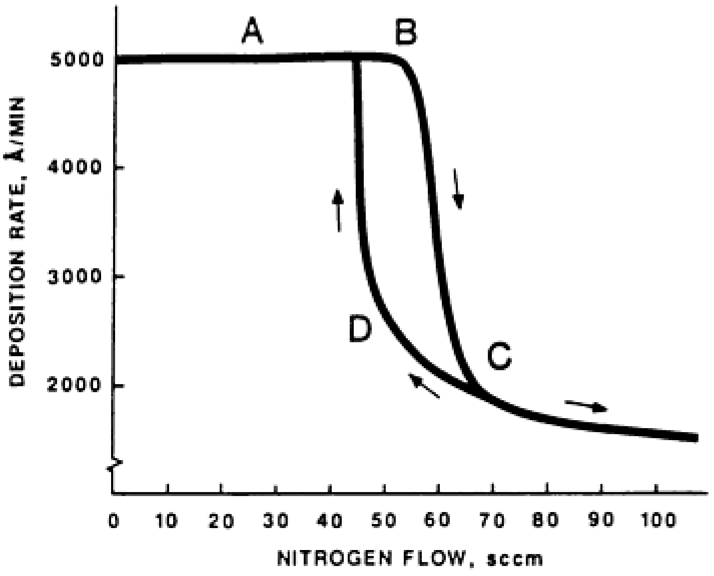
In the metallic cathode mode, the target is maintained as a clean metallic surface and compound formation is limited to the deposited material. Although simple in concept, careful process control is necessary to avoid contamination of the target or deposition of substoichiometric films. Control of the reactive gas species is often costly, requiring at a minimum an automated feedback control and a sensor system to measure partial pressure of the reactive species. However, this is often the only cost-effective means of depositing compound thin-film materials on an industrial scale.

Process Control. The process control necessary for successful reactive sputtering in the metallic cathode mode is often quite difficult to achieve. When flow control is used, the reactive gas is bled into the chamber until there is sufficient gas to form the desired compound at the substrate. However, in most cases this also means that there is sufficient reactive gas present to form the compound on the target surface as well. This phenomenon is known as *poisoning of the target* and generally results in a several-fold decrease in the sputtering rate and, hence, the deposition rate.

During the early 1980s a number of gas-control methods were proposed based on timed or pulsed gas flows. Although they provided significant improvements in the film deposition rates, truly homogenous films are unlikely to result from this type of pulsing technique (Ref 18). The problem is that simple gas flow control does not permit direct control of the partial pressure of the reactive gas species in the chamber. This is illustrated in the hysteresis behavior observed in measuring the reactive gas partial pressure as a function of gas flow, shown for the case of TiN deposition in Fig. 4(a). In this case, stoichiometric TiN is formed under the partial-pressure conditions of point "B." Clearly this exact condition is difficult to maintain by manually pulsing the gas flow, and in the case of slow pulsing, it is likely that the full hysteresis is traveled with each pulse, creating nonstoichiometric layered films.



(a)



(b)

Fig. 4 (a) Nitrogen partial pressure vs. reactive gas flow in a mixed Ar-N_2 discharge under mass flow control, at a target power of 10 kW. (b) Deposition rate vs. flow hysteresis behavior for TiN_x deposition, at a target power of 10 kW, in a mixed Ar-N_2 discharge. Source: Ref 18

As discussed, as the target surface becomes compound coated the deposition rate drops precipitously. This effect can be illustrated by plotting the deposition rate as a function of the reactive gas flow, as shown in Fig. 4(b); again the desired operating conditions are given by point "B." However, the problem of achieving stable operation at point "B," in both Fig. 4(a) and 4(b), is nontrivial because a relatively small increase in flow results in a large decrease in the deposition rate, which is then accompanied by a rapid increase in the partial pressure of the reactive species in front of the target.

This instability is influenced by several other factors. During film deposition at the optimum flow rate, the target can very quickly become completely poisoned if the partial pressure or flow increases slightly, as commonly occurs during slight arcing at the target surface. The consequent decrease in the sputtering rate in turn results in an excess partial pressure of

the reactive gas species in front of the target, creating a circular chain of events that amplifies the initial instability. Another factor fueling this instability is the target power, because the current-voltage requirements of the target change as the target becomes poisoned. In order to avoid driving the process up or down the hysteresis curve, the input current and/or voltage must be adjusted to maintain a constant target power constant.

Associated with this hysteresis effect is the problem of maintaining film stoichiometry. It has been shown that for Ti_xN_{1-x} film microhardness increases monotonically with increasing nitrogen flow rate until stoichiometric TiN is formed (i.e., point "B" in Fig. 4 a and b). Once this optimal nitrogen flow rate is exceeded, the microhardness drops precipitously and the target becomes poisoned (Ref 19). Before film growth can be resumed, intensive "presputtering" is required to return the target surface to a purely metallic state.

A significant advance in process control was the development of automated flow-control systems using a feedback control loop. Sproul and Tomashek introduced the first closed-loop feedback control system in 1984, which monitored the nitrogen peak height obtained from mass spectrometer analysis and generated a feedback signal for a gas flow controller (Ref 20). Because the peak height obtained from the mass spectrometer can be correlated to a certain gas partial pressure within the chamber, this type of automated flow control is, in effect, a partial pressure control system. Similarly, Affinito and Parsons developed a microprocessor-based system to monitor a number of discharge parameters and provide feedback control of the reactive gas. In this case, control of the reactive gas was possible for nitrogen, but not for oxygen (Ref 21). Both of these control systems work well, but in most cases it is necessary to differentially pump the mass spectrometer head, which adds to the cost and complexity of these systems and can also generate undesirable delays in the control process and signal distortions.

Schiller et al. developed a somewhat different control system, the plasma emission monitor (PEM), that uses the optical emission spectra from the target material to produce a feedback signal to control the reactive gas flow and more directly monitor the conditions at the target surface (Ref 22). The optical emission spectra from the plasma near the target is collected using a collimator connected to a quartz fiber. This signal is fed into a monochromator that is linked to a photomultiplier. The photomultiplier outputs an amplified electrical signal to a control unit where the incoming signal level is compared to a preset "optimum" signal level. A control signal is then sent from the control unit to a piezoelectric gas-control valve that is opened or closed in response to a change in the spectral signal. Typically, the optimum reactive gas level is set as some fraction of the spectral peak height of the metallic species. The spectral peak height of pure metal must be measured for each run just prior to the introduction of the reactive gas, and a thin metallic layer may be deposited before the reactive process attains stoichiometry. In some applications this thin metallic underlayer can create a problem; however, this difficulty can be overcome. The primary advantage of the PEM technique is that neither a mass spectrometer nor differential pumping of the sensor is required, so it is less expensive. This and several similar systems are now commercially available.

Another commercially available device for partial-pressure control is the optical gas controller (OGC), which uses the optical emission generated within the sensor from a gas sample drawn directly from the chamber to determine the partial pressure and drive the closed-loop control system at sputtering pressures (Ref 23, 24). Like the PEM system, no mass spectrometer or differential pumping is required. However, unlike the PEM system, the OGC is based on electron-impact ionization spectroscopy. This permits the process gases to be ionized under reproducible conditions within the sensor head, but it also adds the limitation that the sensor must be located very close to the target to provide accurate control (Ref 24, 25, 26, 27).

Alternatively, research by Penfold (Ref 28), Kadlec et al. (Ref 29), and others has shown that the hysteresis effect can be eliminated entirely by increasing the pumping speed of the system beyond a critical level. While successful, this technique is rather expensive in practice, resulting in reduced deposition rates, inefficient gas use, and very high pumping throughput requirements. Whatever the method, effective process control of sputtering is critical in the production of reproducible high-quality thin films at rates that allow them to be commercially competitive with other thin-film processes.

Sputtering Techniques

Since the discovery of sputtering by W.R. Grove in the mid-1800s, a number of sputter deposition techniques have been developed to deposit thin films of various materials, and much has been written about these techniques (Ref 6, 7, 8, 9, 10, 11, 30, 31). The following section provides a brief overview of several common techniques, including dc diode, rf diode, triode, magnetron, and unbalanced magnetron sputtering.

Diode sputtering is the oldest sputtering technique. A dc diode plasma may be formed by applying a relatively large potential (approximately 300 to 5000 V) between the cathode and anode electrodes in the presence of a sufficient gas density (approximately 10 to 500 μbar). Under a sufficiently large electric potential, the gas atoms between the electrodes become ionized and diffuse through the plasma. However, only the ions in the near-cathode region will "feel" the effect of the potential drop and thus be accelerated across the cathode dark space, impacting the target or cathode surface (see Fig. 1). It is these ions that are responsible for the sputtering.

A common application of dc diode sputtering is the deposition of thin conductive films on samples for electron microscopy. This has two notable advantages:

- A large variety of single- and multi-component target materials can be used.
- It is a simple process, perhaps its greatest advantage.

However, dc diode sputtering also has definite limitations:

- The target must be electrically conductive.
- Deposition rates are generally low.
- Electron bombardment heating of the substrate may be significant because the discharge is not confined.
- Energy efficiency is low because since 75 to 95% of the power supplied to the targets is dissipated through target heating (Ref 32, 33, 34).

Radio-Frequency Sputtering. The use of an oscillating power source to generate a sputtering plasma offers several advantages over dc methods. Principally, when the frequency of oscillation is greater than about 50 kHz, it is no longer necessary for both electrodes to be conductive because the electrode can be coupled though an impedance (Ref 35). The coupled electrode must be much smaller than the direct electrode in order to effectively sputter only the insulating or coupled electrode; this is usually accomplished by connecting the rf generator directly to the grounded chamber walls or substrate fixtures. An impedance matching network is integrated into the circuit between the rf generator and the load to introduce the inductance necessary to form a resonant circuit. It is important in rf systems to provide adequate grounding, minimize the lead lengths, and eliminate any unneeded flange projections to reduce excessive inductive and capacitive losses.

An additional benefit of using rf frequencies above 50 kHz is that the electrons in the negative glow region have sufficient energy to directly ionize the gas atoms; hence, the number of electrons required to sustain the discharge is substantially reduced (Ref 32). This, in turn, means that lower sputtering pressures can be used, reducing the potential for film contamination.

At frequencies above the low megahertz range, the ions, because of their relatively large mass, are no longer able to follow the oscillations of the potential, and, hence, there is little ion accumulation at the cathode (Ref 30). Thus, any frequency above about 5 MHz can be efficiently used for sputtering; however, the most commonly used frequencies are 13.56 and 27 MHz, because these are the FCC-specified frequencies for medical and industrial use (Ref 35). The applications of rf sputtering are quite varied and include deposition of metals, metallic alloys, oxides, nitrides, and carbides (Ref 36, 37, 38).

A number of comprehensive reviews and discussions of rf discharges are available in the literature (Ref 34, 35, 39, 40, 41). In general, the primary advantages of rf sputtering are:

- Ability to sputter insulators as well as almost any other material
- Accessibility of lower operating pressures

Unfortunately, the deposition rates in rf sputtering are often limited by the low thermal conductivity of the insulating target materials. This low thermal conductivity of the materials, leads to the formation of "hot spots" on the target; the hot spots generate stresses that cause fracture of the brittle target materials. For this reason, it may be preferable to deposit insulating films reactively from a metal source. Although compound materials can be readily sputtered in an rf discharge, the resulting films may not be representative of the initial target composition.

Triode sputtering uses a cathode separate from the sputtering target to sustain the plasma. The target electrode then extracts ions from the plasma. This additional electron source, typically either a simple biased conductor or a thermionic electron emitter, provides a means of sustaining the discharge that is independent of the secondary electron generation at the cathode. Thus, the discharge may be maintained at pressures as low as 0.001 Pa (10^{-5} torr) or at discharge voltages as low as 40 V (Ref 42). By varying the emission of the electron source, the discharge current can be varied independently of the sputtering voltage, allowing high ion densities at the target and substrate while maintaining a low discharge potential.

Triode discharges, both dc and rf, have been used successfully to deposit films of a great variety of materials for semiconductor, wear-resistant, optical, and other coating applications (Ref 42, 43, 44, 45, 46, 47, 48, 49). The primary advantages of triode sputtering are:

- Lower discharge pressures
- Lower discharge voltages
- Higher deposition rates
- Independent control of the plasma density and the bombardment conditions of the sputtering target

The major weaknesses of triodes are that they:

- Are often more complicated to use

- Can increase film contamination from the electron source
- Are difficult to scale up for industrial processing
- May not be suitable in temperature-sensitive and reactive processes because of the electron source

Magnetron sputtering differs from other techniques in that most of the plasma is confined to the near-target region. This plasma confinement is achieved by establishing strong magnetic fields above the target surface that reshape the trajectories of the secondary electrons ejected from the target surface into convoluted spiral-like patterns skipping across the surface of the cathode (Fig. 4). In such a magnetic arrangement, the secondary electrons are trapped and most of their energy is expended in the near-target region, increasing ionization and, hence, greatly improving the sputtering and deposition rates. This method is quite successful in producing high-quality, low-impurity films at reasonable deposition rates, and it has seen widespread commercial use since its development in the mid-1970s.

In magnetron sputtering, as for all sputtering techniques, planar target geometries are the most commonly used sources, as illustrated in Fig. 5. Both circular and rectangular planar magnetrons are commercially available in sizes ranging from a 2.5 cm diameter magnetron gun configuration to rectangular cathodes as large as 2 m in length. However, all planar magnetrons tend to erode preferentially in the areas where the magnetic field is parallel to the target surface. This creates a racetrack-like erosion pattern that often leads to an annular distribution of sputtered atoms.

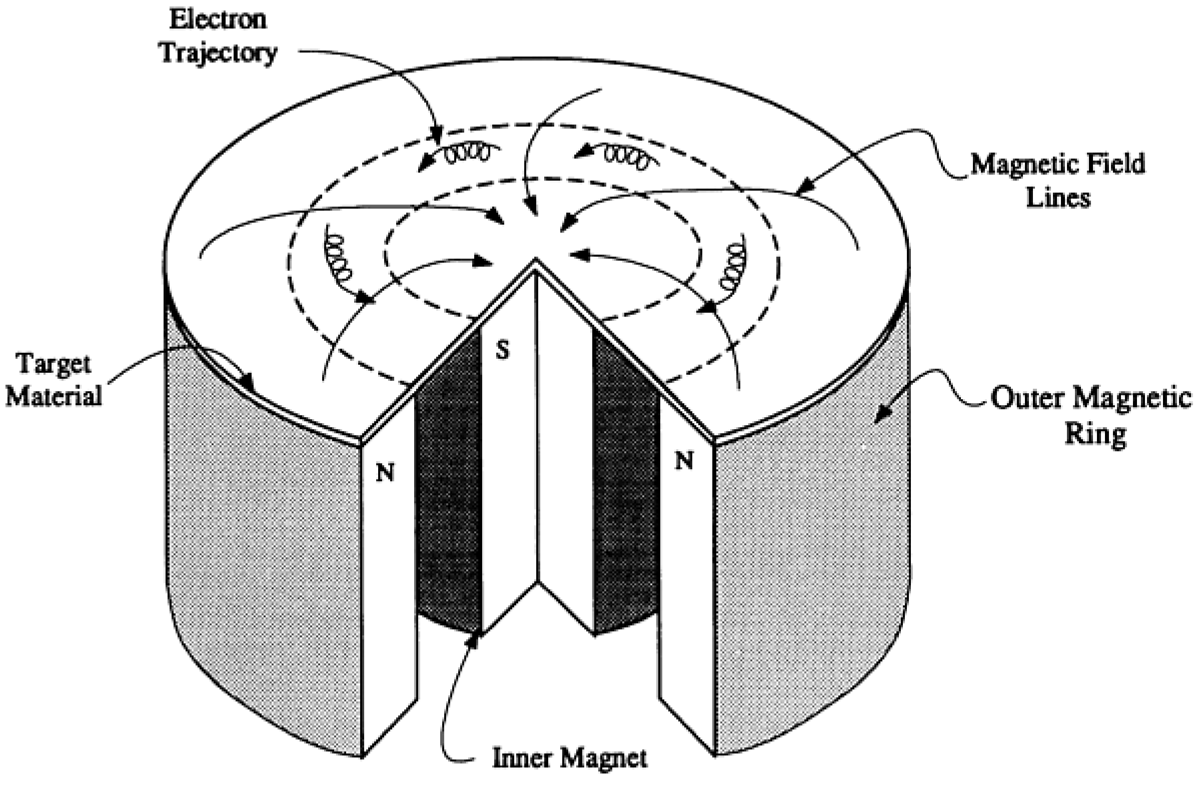

Fig. 5 Circular, planar magnetron cathode schematic, illustrating the magnetic confinement and the resulting electron trajectories

The issue of uneven target erosion has been studied in detail and a number of geometries have been developed to improve target use (Ref 50, 51, 52). For example, cylindrical magnetron geometries (Fig. 6) provide improved target use and typically yield higher sputtering rates, as do most other nonplanar geometries (Ref 53). However, the commercial applications of these magnetron systems has been hampered by the difficulties of producing nonplanar targets and the expense of creating large arrays of shaped magnets. Some of the most successful commercial nonplanar geometries are variations of the rotatable cylindrical cathode (Fig. 6 c, d).

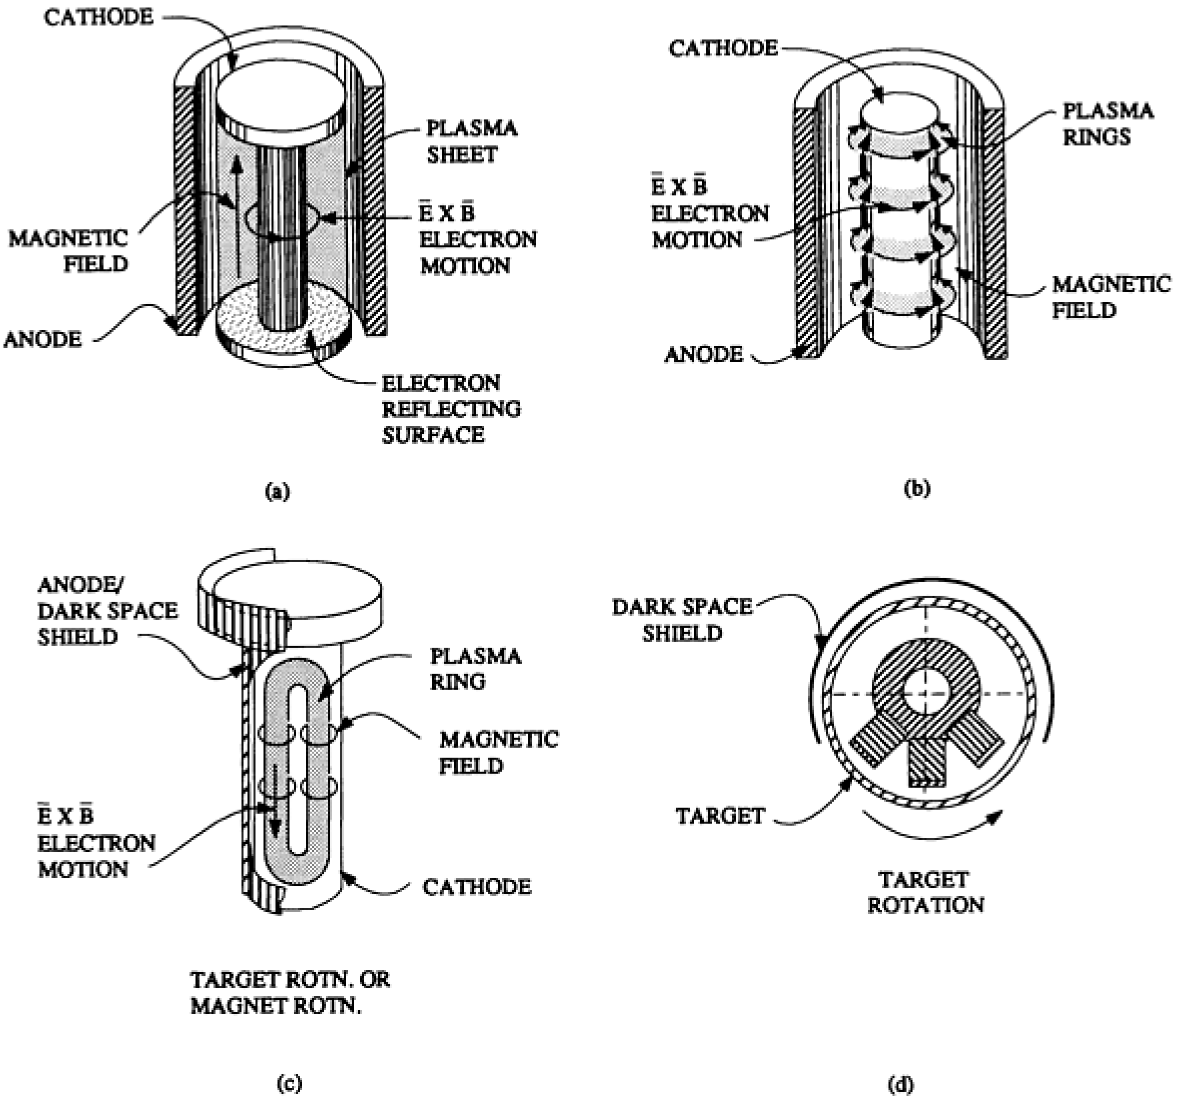

Fig. 6 Schematic illustration of several cylindrical magnetron sources. (a) A cylindrical post magnetron with a longitudinal magnetic field. (b) A cylindrical magnetron with a radial magnetic field. Source: Ref 53. (c) A rotating cylindrical magnetron and (d) its cross section. Source: Ref 54

Additionally, magnetron sources can be operated in triode mode or using an rf power source. For example, a hollow cathode discharge directly in front of the magnetron source can be used as the third electrode of a triode to increase ionization and enhance magnetron performance. However, this type of system suffers from many of the same scale-up difficulties as other triode systems (Ref 55). Additionally, when using an rf discharge voltage, it is important to realize that the magnetron source functions as a "true" magnetron only during a portion of the voltage oscillation. Because the electric field vector varies in amplitude and direction, the forces acting on the electrons in the plasma vary during the cycle, and thus the plasma is no longer confined to the vicinity of the target (Ref 56, 57, 58).

There are several advantages to magnetron sputtering:

- Increased deposition rates (i.e., higher sputtering rates)
- Reduced sputtering from the substrate and chamber walls
- Reduced substrate heating from electron bombardment during deposition
- Reduced "working" gas pressure requirements
- Ease of conversion to industrial-scale processing

Of course, there are also a number of limitations:

- Target use of planar geometries is usually less than 40%
- There may be annular distribution of sputtered atoms, particularly from planar magnetrons
- Porous films may result from large target-to-substrate separations because of reduced electron and ion bombardment at the substrate
- There is inherent nonuniformity in the plasma because of the magnetic fields of the cathode

To overcome some of the line-of-sight limitations that are typical of most sputter processes, a number of magnetron systems have been developed to coat three-dimensional components by sandwiching the components between a face-to-face pair of magnetrons. This technique is very successful as long as the target-to-substrate separation (d_{t-s}) is small; hence the components must also be fairly small. At large d_{t-s} separations, the ion bombardment of the films is frequently insufficient to produce dense film microstructures, and matte, void-containing coatings result.

In general, ion bombardment during deposition can be used to alter favorably the nucleation behavior, growth kinetics, morphology, composition, and mechanical properties of thin films. These effects can be observed as changes in the residual stress, lattice parameter, resistivity, stoichiometry, orientation, film density, and apparent hardness of the resulting films (Ref 59). The extent to which a deposited film is affected by the ion bombardment is dependent on both the kinetic energy and the flux density of the impinging ions, or more correctly the ion-to-deposited-atom ratio and the mass ratio of the ions relative to the surface atoms.

Typically in magnetron sputtering, ions are extracted from the discharge surrounding the substrate by applying a negative potential of 50 to 500 V to the substrate. However, the current density incident on the film-substrate surface is generally quite low, 0.05 to 0.10 ions per deposited atom in conventional dc magnetrons (Ref 60). If this ratio can be increased without increasing the energy of the bombarding ions, denser film microstructures can be produced, while inducing minimal damage within the crystalline lattice. This is desirable because increasing the bias voltage typically results in the generation of defects within the grains and increased film stresses, resulting in poor adhesion and inferior film quality. To circumvent these limitations it would be preferable to increase the ion current density (i.e., the ion-to-deposited-atom ratio) while maintaining a reduced bias voltage, thus keeping the energy of the impinging ions low (Ref 92). In an effort to increase low-energy ion bombardment during film growth a new class of magnetron sources, known as *unbalanced magnetrons*, has been developed.

Unbalanced Magnetron Sputtering. Window and Savvides (Ref 60) introduced the unbalanced magnetron in 1986 in an article that described seven different magnetic configurations and grouped them in three basic types (Fig. 7). The type I magnetron is characterized by a strong inner pole and weak outer pole, and the type II is the converse. The intermediate type is nearly balanced and is typical of most conventional magnetrons. With type I geometry, ion bombardment at the substrate is very limited, resulting in ion-to-deposited-atom ratios as low as 0.25:1. In comparison, the type II geometry gives strongly enhanced ion bombardment, resulting in ion-to-deposited-atom ratios of the order of 2:1 at low substrate bias potentials. Thus, in most applications, only type II unbalanced magnetrons are of commercial interest.

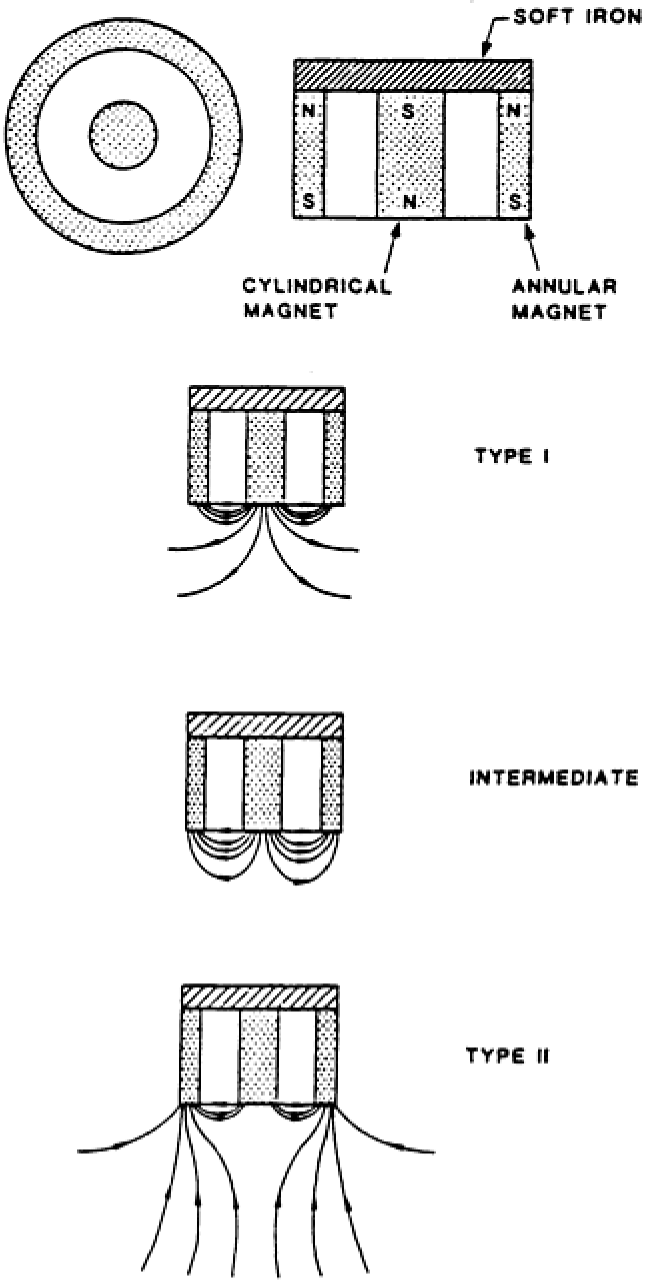

Fig. 7 Three types of magnetron configurations: type I, intermediate, and type II. Source: Ref 60

For unbalanced magnetrons, the ion current density has been shown to increase almost linearly with the discharge current and to be only weakly dependent on the gas pressure (Ref 61). In addition, the degree of "unbalance" and, hence, the ion current density, can be controlled independently of the discharge current by changing the magnetic field configuration (Ref 62, 93).

Several research groups have applied the unbalanced magnetron concept in a variety of sputtering applications, using both permanent magnets and electromagnets (Ref 33, 60, 61, 62, 63, 64, 65, 66, 67, 68, 69, 70). In contrast to the ion-to-deposited-atom ratios for conventional magnetrons, ratios as high as 10:1 have been reported for unbalanced magnetrons, a figure more akin to ion plating processes (Ref 63).

Using a single unbalanced planer magnetron with a pair of electromagnetic coils, Musil and Kadlec (Ref 69) were able to deposit TiN films with ion current densities as high as 6 mA/cm^2 and low substrate bias voltages ranging from -5 to -100 V at target-to-substrate distances of up to 200 mm. This work directly addressed the problem of decreasing substrate ion current density with increasing target-to-substrate distances. In many commercial applications, where it is more cost-

effective to coat large batches of components, the increased ion current density at the substrate provides unbalanced magnetrons with a distinct advantage over conventional magnetrons.

By allowing greater d_{t-s} separations, large multicathode unbalanced systems can be used to coat either large components or numerous smaller parts in a single run. Commercial multicathode systems as large as 1 m in diameter are currently available (Ref 71, 72). The primary restriction on these systems is that there must be an even number of cathodes so that the fields of each unbalanced magnetron cathode can be linked north pole to south pole with the adjacent cathodes. The interrelationship between cathodes is fairly complex because of the magnetic interactions and will differ according to the angle between cathodes (Ref 62). Hence, finite element modeling may be useful in modeling the magnetic interactions before building such systems.

Applications of Sputtered Films

In the fields of microelectronics and optoelectronics, sputtered thin films have been used extensively for:

- Metallization and diffusion barriers in microelectronic circuits (Ref 73, 74, 75)
- Insulating layers in microelectronic circuits
- Thin-film layers in compact disks
- Transparent conducting electrodes
- Thin-film resistors and capacitors
- Piezoelectric transducers
- Amorphous optical films in integrated circuits
- Thin-film lasers
- Memory devices
- High-temperature superconductors

A variety of sputtering techniques can be used in most applications, but rf and magnetron sputtering seem to be most prevalent. Magnetrons are fairly common because they allow very low substrate temperatures. Because most of the above applications are planar in nature, sufficient ion bombardment at the substrate is not an issue. Sputtered thin films are also used extensively in wear-resistant applications such as:

- Decorative coatings on eyeglass frames, watch cases, and other consumer goods (Ref 19, 76)
- Protective coatings on high-speed cutting tools (Ref 77, 78, 79)
- Tribological coatings on bearing surfaces (Ref 80, 81, 82)
- Heat-reflecting optical coatings on architectural glass panels (Ref 83)
- Multilayer dielectric coatings of laser mirrors and filters
- Chromium-base replacements for electrodeposited hard chrome (Ref 84, 85)

Transition metal nitrides, carbides, and oxides such as TiN, TiAlN, CrN, Ta_2O_3, and Al_2O_3 are frequently used in these applications because of their extreme hardness, corrosion resistance, attractive colors, and high spectral reflectance. In decorative applications, for instance, TiN-based films can be tailored to produce the color and brightness of gold but with superior scratch resistance at a reduced cost. With the previously described process control methods, various color values can be preselected and reproduced. In magnetron sputtering, substrate temperatures as low as 150 to 220 °C can be maintained throughout the deposition process, and, thus, temperature-sensitive materials such as electroplated brass, die-

cast zinc, and bronze can be used as substrate materials for decorative coatings. Sputtered decorative coatings are usually deposited in thicknesses ranging from 0.2 to 2 μm.

Although electronic and wear-resistant coatings are the two broadest categories of commercially produced sputtered thin films, there are many other applications. For example, sputter-deposited metallic thin films are widely used as moisture and gas-diffusion barrier coatings on polymer films in the packaging industry. The applications for sputter-deposited thin films continue to broaden in scope each year.

Future Trends

In the future, there are certain to be new applications for sputtering technology and new thin-film coatings tailored to special needs. Recently there has been a move away from simple binary alloy coatings into multicomponent coatings to provide increased film "tailorability." This trend can be observed both in microelectronics, with investigations into ternary and quaternary II-V and II-VI systems, and in the area of hard, wear-resistant coatings of TiAlN, TiZrN, and TiVN (Ref 86). For example, for enhanced corrosion resistance for turbine blades, (Ti,Al)N alloys appear very promising as a replacement for the current TiN coatings (Ref 85), especially because the high-temperature oxidation resistance of (Ti,Al)N coatings is also superior.

Multilayer coatings are another area in which there is likely to be continued development in the next decade. These materials are already beginning to see commercial use in optical and wear-resistant applications. Very recently, work

involving polycrystalline metal-nitride superlattice materials has produced films with hardness values in excess of 5000 HV.

It is foreseeable that sputtered chromium nitride coatings will also see increased use, because CrN has mechanical properties and color much like those of traditional electrodeposited hard chrome coatings and, in many applications, provides superior performance. In the past its cost has been prohibitively high, but with growing concern over process safety and environmentally hazardous wastes, sputter deposition processes are becoming increasingly attractive. Hence, the CrN sputter deposition process is an excellent candidate to replace traditional electroplating or chemical vapor deposition processes, at least in high-performance applications of hard chrome.

Improvements in the thermal stability of hard coatings for temperatures up to 800 °C and beyond seem possible in the near future. Development of more stable high-temperature coatings would open up a whole range of new applications.

In the area of decorative coating, there is a demand for distinctive new colors to supplement the well-known golden and black color tones that are currently available.

Although sputtered thin-film materials will continue to be developed, there will be some notable changes in the techniques used to deposit these films. One approach currently under investigation is to combine specific positive aspects from various deposition techniques. For instance, it has been shown that during the etching phase of the arc deposition process, titanium ions penetrate into regions below the substrate surface, forming intermetallic-like compounds and developing a gradually decreasing titanium atom density with depth into the steel substrate (Ref 87). This effect is thought to strengthen the adhesion performance of arc ion-plated coatings. On the other hand, unbalanced magnetron sputtering offers the possibility of depositing dense but rather low-stress coatings (Ref 88). A combination of arc etching and unbalanced magnetron sputter deposition may open new avenues (Ref 89, 90).

Another combined process, sputtering and plasma nitriding, can be used to increase the life of sputter-coated tools. $Ti_{0.5}Al_{0.5}N$ sputter coating of hobs has been shown to produce a sixfold improvement in tool life (Ref 91). After resharpening, however, the improvement decreased to a twofold increase in tool life when compared to the uncoated hobs. Instead of recoating the hobs by sputter deposition after each resharpening step, a simple plasma nitriding treatment was successful in restoring a fourfold increase in tool life. The $Ti_{0.5}Al_{0.5}N$ sputter-deposited coatings did not deteriorate appreciably under repeated plasma nitriding.

Examination of these trends suggests that sputtering processes should continue to hold a strong position among the competing deposition techniques. The environmentally friendly nature of sputtering processes should also make them increasingly attractive in the future.

Ion Plating

Donald M. Mattox, IP Industries

Introduction

ION PLATING is a generic term applied to film deposition processes in which the substrate surface and the growing film are subjected to a continuous or periodic flux of energetic massive bombarding particles (ions, radicals, atoms, or molecules--reactive or inert) sufficient to cause changes in the film formation process and the properties of the deposited film (Ref 1, 2, 3, 4). The bombarding species and the depositing species can be from a number of sources. Bombardment can take place in a plasma or vacuum environment. When a beam of energetic particles is used in vacuum, the process is often called ion-beam-assisted deposition (IBAD).

A vacuum can be defined as an environment where the gas density is low and the mean free path for collision is very long. In vacuum-barrel deposition processing, this means that the pressure is lower than about 1.3 mPa (1×10^{-5} torr). A plasma is a low-pressure gas that contains enough ions and electrons to have an appreciable electrical conductivity. This requires a gas pressure of greater than 13 mPa (1×10^{-4} torr). Plasmas can be low-pressure (less than about 0.4 Pa, or 3 mtorr) or higher-pressure (greater than about 0.4 Pa, or 3 mtorr), depending on whether or not collisions in the gas phase are sufficient to "thermalize" high-energy particles leaving a source (Ref 5, 6). This differentiation is important when using sputtering as a source for deposition because reflected high-energy neutrals from the target can have an important effect on the growing film. Figure 1 shows the distance traveled by particles of differing masses (12 and 400 atomic mass unit, or amu) and energies (5 eV, or 0.8 aJ, and 1 keV, or 160 aJ) in argon before becoming thermalized. It should be noted that the gas density in a plasma system can vary with position due to preferential gas motion and particle temperature distribution (Ref 7, 8, 9).

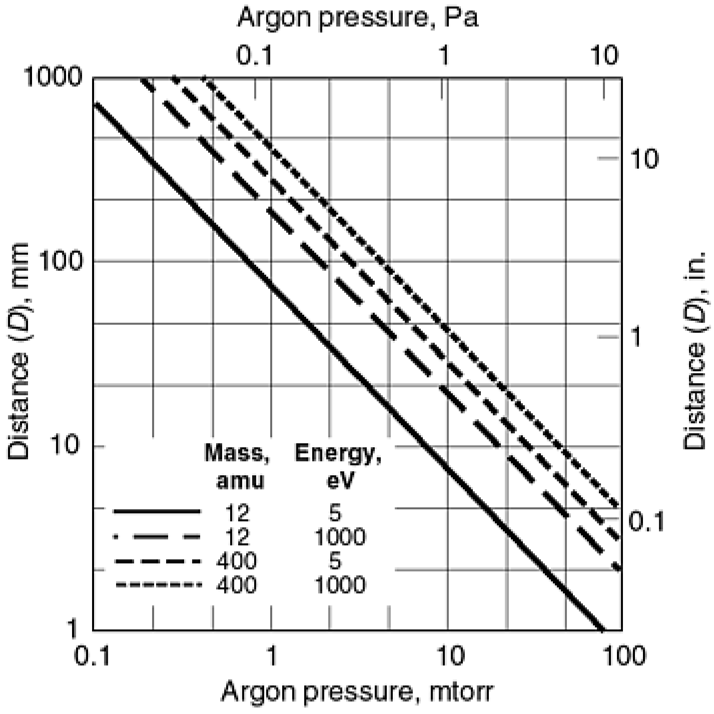

Fig. 1 Plot of distance traveled vs. argon gas pressure to show effect of variations in mass and energy of particles before thermalization. Results calculated from test data obtained at room temperature. Source: Ref 5

There are two basic versions of the ion plating process. In *plasma-based ion plating* the substrate is in contact with a plasma, and the ions are accelerated from the plasma and arrive at the surface with a spectrum of energies. In *vacuum-based ion plating* the film material is deposited in a vacuum and the bombardment is from an ion or plasma "gun." The plasma-based ion plating process was first described in the technical literature in 1963 (Ref 10, 11, 12), and the first reference to vacuum-based ion plating was in 1973 (Ref 13). In *reactive ion plating*, the plasma or ion/plasma gun can

form ions of a reactive species to both bombard and react with the depositing material to form a compound film material. In some cases, such as when using low-voltage, high-current electron-beam evaporation or arc vaporization, an appreciable portion of the vaporized source material can be ionized to allow bombardment by "film ions." Often the term *ion plating* is accompanied by modifying terms such as *sputter ion plating*, *reactive ion plating*, *chemical ion plating*, *alternating ion plating*, *arc ion plating*, and so on, which indicate the source of depositing material, the method used to bombard the film, or other particular conditions of the deposition.

Figure 2(a) shows a simple plasma-based ion plating configuration using a resistively heated vaporization source, and Figure 2(b) shows a simple vacuum-based system using an electron-beam evaporation source. In plasma-based ion plating, the substrate can be positioned in the plasma generation region or in a remote or downstream location outside the active plasma generation region.

Effects of Bombardment on Film Formation

Film Properties. The properties of a film of a material formed by any physical vapor deposition (PVD) process depend on four factors, namely:

- Substrate surface condition: morphology (roughness, inclusions, particulate contamination), surface chemistry (surface composition, contaminants), surface flaws, outgassing, and so on
- Details of the deposition process and system geometry: angle-of-incidence distribution of the depositing adatom flux, substrate temperature, deposition rate, gaseous contamination, and so on
- Details of film growth on the substrate surface: nucleation, interface formation, interfacial flaw generation, energy input to the growing film, surface mobility of the depositing adatoms, growth morphology of the film (i.e., roughness), gas entrapment, reaction with deposition ambient (including reactive deposition processes), lattice defects produced, grain size and orientation, recoil implantation (atomic peening), and so on
- Postdeposition processing and reactions: reaction of film surface with the ambient, thermal, or mechanical cycling; corrosion; interfacial degradation; burnishing of soft surfaces; shot peening; encapsulation ("topcoat"); and so on

In order to have reproducible film properties, each of these factors must be controlled. Figure 3 depicts the effect of energetic particle bombardment on surfaces and the near-surface region (Ref 14). The near-surface region is defined as the region of physical penetration by the bombarding species and is about 1 nm/keV (10 Å/keV). These effects include:

- Reflection of some of the impinging high-energy particles as high-energy neutrals
- Generation of collision cascades in the near-surface region
- Physical sputtering
- Generation of lattice defects
- Trapping of the bombarding species
- Stuffing of atoms into the lattice by recoil processes
- Recoil implantation of surface species
- Enhanced chemical reactivity (bombardment-enhanced chemical reactivity)
- Enhanced diffusion in the surface region
- Heating of the near-surface region

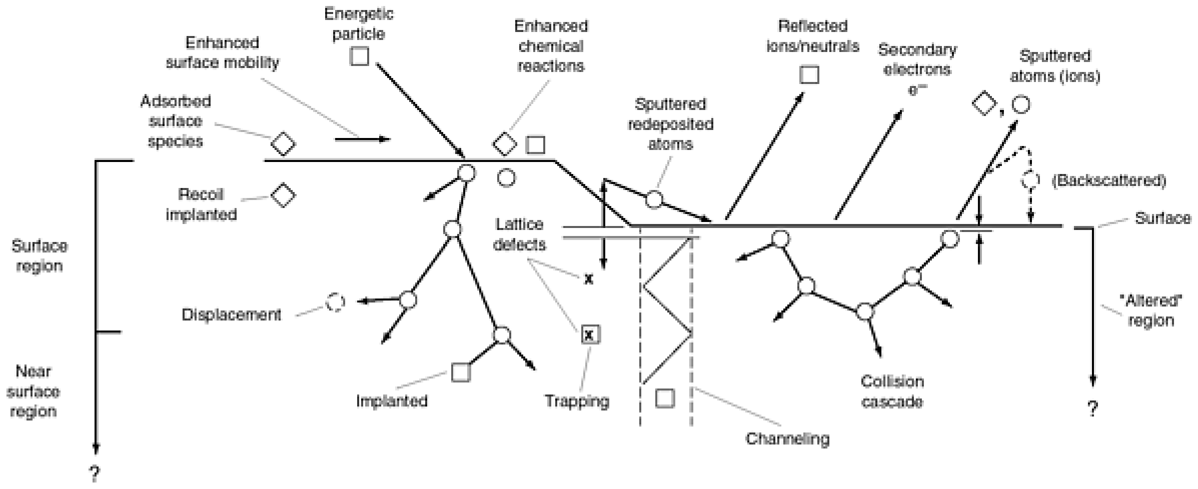

Fig. 3 Schematic showing interactions in the near-surface region and on a surface during massive energetic

particle bombardment. Source: Ref 14

Most of the bombarding energy is given up in the near-surface region in the form of heat. In a growing film that is being concurrently bombarded by energetic particles, the surface and near-surface region is continually being buried and bombardment effects are trapped in the growing film (Ref 14, 15).

Surface Preparation. Bombardment of the substrate surface by energetic particles prior to the deposition of the film material allows in situ cleaning of the surface (Ref 16). Any surface placed in contact with a plasma will assume a negative potential with respect to the plasma (self-bias), due to the more rapid loss of electrons to the surface compared to the loss of ions to the surface. This sheath potential will accelerate ions across the sheath to bombard the surface. The sheath potential that is developed depends on the flux and energy of the electrons striking the surface. For a weakly ionized direct current (dc) plasma, the sheath potential will be several volts. For a system where electrons are accelerated to the surface, the self-bias can be many tens of electron volts. When the surface is conductive, a dc potential can be applied directly to the surface (applied bias). If the surface is nonconductive, a radio frequency (rf) potential can be applied to the surface to give a periodic high negative potential (applied bias) to the surface.

For inert gas ions with less than about 25 eV (4 aJ) energy, cleaning by bombardment is in the form of desorption of volatile materials ("ion scrubbing"). For reactive gases such as hydrogen or oxygen, the cleaning is in the form of reaction with contaminants such as hydrocarbons and desorption of volatile reaction products such as CO or CH_3. Energetic reactive ions produce etching of the surface by reacting with the substrate surface material and producing a volatile compound ("plasma etching") (for example, $SiCl_4$ from bombardment of silicon with an energetic Cl-containing ion from a vapor such as CCl_4) (Ref 17, 18). More energetic inert particles produce physical sputtering ("sputter cleaning").

This in situ cleaning or surface preparation allows good interfacial contact for adhesion (Ref 19) and the generation of ohmic contacts to semiconductor materials. If done at low bombarding energies, the cleaning of semiconductor materials can be done without introducing surface defects that affect the electronic properties of the surface/interface (Ref 20). Bombardment can also make the surface more "active" by the generation of reactive sites and defects. For example, unbombarded silicon surfaces metallized with aluminum show no interdiffusion, but the bombarded surface gives rapid diffusion (Ref 21).

Bombardment can also be used to change the surface properties such as morphology (roughening) or chemical composition. For example, bombardment of a carbide surface by hydrogen ions results in the decarburization of a thin surface layer to produce a metallic surface on the carbide (Ref 22), and bombardment from a nitrogen plasma can be used to plasma nitride a steel surface prior to the deposition of a titanium nitride film (Ref 23, 24).

Nucleation. In ion plating, it is important that bombardment of the substrate surface during the surface preparation stage be continued into the deposition stage, where adatoms (atoms adsorbed on a surface so they will migrate over the surface) are continually being added to the surface. This prevents the surface from being recontaminated. Nucleation of adatoms on the surface is modified by concurrent energetic particle bombardment. This modification can be due to a number of factors, including cleaning of the surface, the formation of defects and reactive sites on the surface, recoil implantation of surface species, and the introduction of heat into the near-surface region (Ref 14, 25). Generally, this modification of nucleation increases the nucleation density. In addition, where there is high energy bombardment, sputtering and redeposition allow nucleation and film formation in areas that would not otherwise be reached by the depositing adatoms.

Interface Formation. Bombardment enhances the formation of a diffusion- or compound-type interface on the "clean" surface if the materials are mutually soluble, or it enhances the formation of a pseudodiffusion-type of interface, due to the energetic particle bombardment, if the materials are insoluble (Ref 14). Interface formation is aided by defect formation and the deposition of energy (heat) directly into the surface without the necessity for bulk heating (Ref 26, 27). In some cases, the temperature of the bulk of the material can be kept very low while the surface region is heated by the bombardment. This allows the development of a very high temperature gradient in the surface region, which limits diffusion into the surface (Ref 28). Ion bombardment along with a high surface temperature can cause all of the depositing material to be diffused into the surface, producing an alloy or compound coating.

Film Growth. Energetic particle bombardment during the growth of the film can modify a number of film properties, including (Ref 14):

- Density

- Bulk morphology
- Surface morphology
- Grain size
- Crystallographic orientation
- Electrical resistivity
- Porosity

The changes in film properties are due to a number of factors, including

- Input of energy into the surface region during deposition
- Forward sputtering and redeposition of deposited atoms that densify the film
- Bombardment-enhanced chemical reaction
- Sputtering of loosely bonded contaminants and unreacted reactive species

Surface Coverage. The macroscopic and microscopic surface coverage of a deposited film on a substrate surface can be improved by the use of concurrent bombardment during film deposition. The macroscopic ability to cover complex geometries depends mostly on scattering of the depositing material in the gas phase (Ref 29, 30). On a more microscopic scale, sputtering and redeposition of the depositing film material will lead to better coverage on micron-sized and submicron-sized features (Ref 31, 32, 33, 34, 35, 36) and to reduced pinhole formation. On the atomic scale, the increased surface mobility, increased nucleation density, and erosion/redeposition of the depositing adatoms will disrupt the columnar microstructure and eliminate the porosity along the columns. As a result, the use of gas scattering, along with concurrent bombardment, increases the surface-covering ability and decreases the microscopic porosity of the deposited film material as long as gas incorporation does not generate voids.

Reactive Deposition. In reactive ion plating, codepositing species, or depositing species and gaseous species, react to form a nonvolatile compound film material (Ref 37). For example, depositing titanium atoms can react with "activated" gaseous nitrogen to form TiN, with codeposited carbon (Ref 38, 39) to form TiC, or with a combination to form TiC_xN_y. In plasma-based ion plating, the plasma activates reactive species and creates new species in the gas phase. The concurrent bombardment of the surface enhances chemical reaction (bombardment-enhanced chemical reactions) (Ref 40, 41, 42, 43), desorbs unreacted adsorbed species (Ref 44), and densifies the film (Ref 45). In general, it has been found necessary to have concurrent bombardment in order to deposit hard and dense coatings of materials. Figure 4 shows the relative effects of heating and concurrent bombardment on the resistivity of ion plated and non-ion plated TiN films (Ref 46, 47).

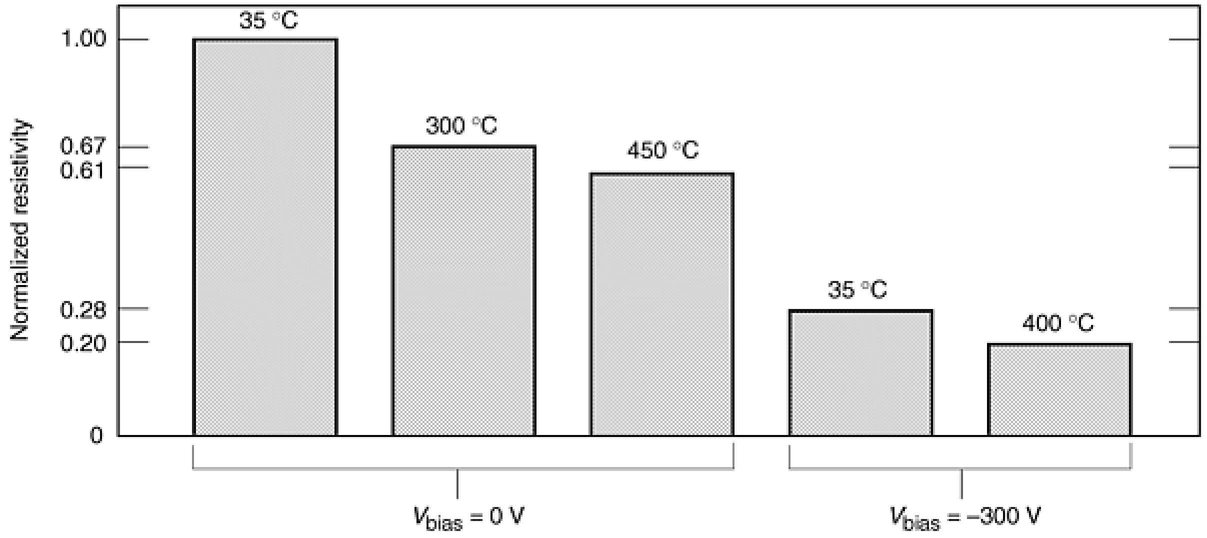

Fig. 4 Relative effect of deposition temperature and bias on reactively sputter-deposited titanium nitride. A lower resistivity rating indicates that the titanium film is more dense (that is, hard) and stoichiometric. Source:

Ref 46

In vacuum-based ion plating, the bombardment of the depositing film by energetic reactive gas ions enhances the chemical reaction (Ref 48, 49). In reactive deposition, the extent of the reaction depends on the plasma conditions, bombardment conditions, and the availability of the reactive species. By limiting the availability, the composition of a deposit can be varied. For example, in the reactive ion plating of TiN, by reducing the availability of the nitrogen in the plasma at the beginning of the deposition, an initial layer of titanium is deposited. The composition can then be graded to TiN by increasing the availability of nitrogen in the plasma, thus forming a "graded" interface.

Properties of Films Deposited by Ion Plating. The properties of films formed by processes depend on a number of factors. Because the ion plating process has more deposition parameter variables than other PVD processes, the film properties can be varied over a wide range, depending on the process parameters.

Film Adhesion. The adhesion of a deposited film to a surface depends on the deformation and fracture modes associated with the failure (Ref 19). Energetic particle bombardment prior to and during the initial stages of film formation can enhance adhesion by:

- Removing contaminant layers
- Changing the surface chemistry
- Generating a microscopically rough surface
- Increasing the nucleation density by forming nucleation sites (defects, implanted species, and recoil-implanted species)
- Increasing the surface mobility of adatoms
- Decreasing the formation of interfacial voids
- Introducing thermal energy and defects directly into the near-surface region, thereby promoting reaction and diffusion

Film adhesion can be degraded by the diffusion and precipitation of gaseous species to the interface. The adhesion can also be degraded by differences in the coefficient of thermal expansion of the film and substrate material in high-temperature processing, or the residual film growth stresses developed in low-temperature processing.

Residual Film Stress. Invariably, atomistically deposited films have a residual stress that may be tensile or compressive in nature and may approach the yield or fracture strength of the materials involved. Generally, vacuum-deposited films and sputter-deposited films prepared at high pressures (>0.7 Pa, or 5 mtorr) have tensile stresses that can be anisotropic, with off-normal angle of incidence depositions. In low-pressure sputter deposition and ion plating, energetic particle bombardment can give rise to high compressive film stresses due to the recoil implantation of surface atoms (Ref 50, 51, 52, 53, 54). This effect is sometimes called *atomic peening* and generally requires 20 to 30 eV (3 to 5 aJ) per deposited atom of additional energy from bombardment. Studies of vacuum-evaporated films with concurrent bombardment have shown that the conversion of tensile stress to compressive stress is very dependent on the ratio of bombarding species to depositing species. The residual film stress anisotropy can be very sensitive to geometry and gas pressure (Ref 55, 56) during sputter deposition, due to bombardment of high-energy reflected neutrals and the effect of gas-phase and surface collisions at higher pressures. Figure 5 shows the effect of gas pressure on residual film stress in postcathode magnetron sputter deposition of molybdenum.

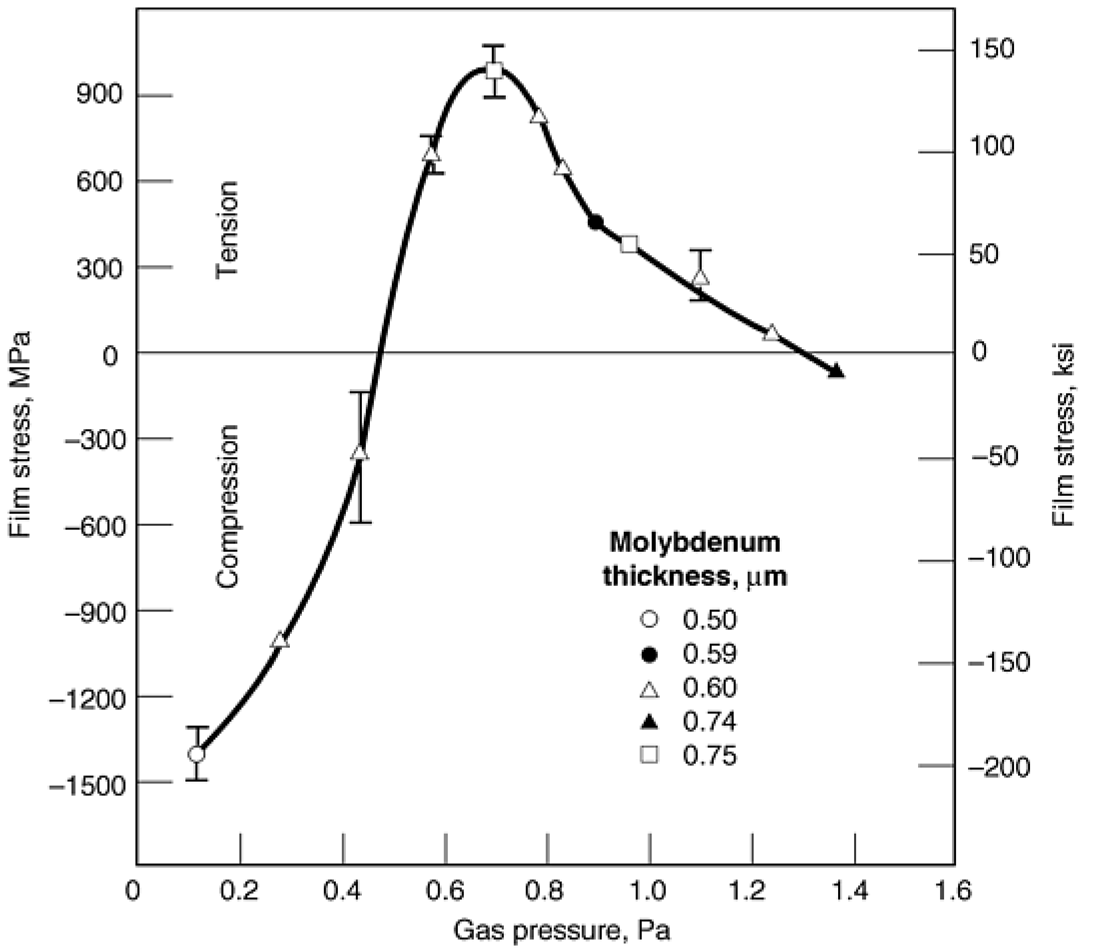

Fig. 5 Effect of gas pressure on residual stress in molybdenum films formed by postcathode magnetron sputter deposition. High compressive stress at low pressures is a result of reflected high-energy neutral bombardment. The low stress at high pressures is a result of columnar growth in a low-density film. Bars on points indicate range of values. Source: Ref 56

The lattice strain associated with the residual film stress represents stored energy, and this energy, together with a high concentration of lattice defects, can lead to:

- Lowering of the recrystallization temperature in crystalline materials
- A lowered strain point in glassy materials
- A high chemical etch rate
- Electromigration enhancement
- Room-temperature void growth in films
- Other such mass transport effects

Film Density. Under nonbombardment conditions at low temperature, the morphology of the deposited material is determined by geometrical effects with the film density being a function of the angle of incidence of the depositing particles. Under ion plating conditions, forward sputtering, sputtering and redeposition, increased nucleation density, and increased surface mobilities of adatoms on the surface under bombardment conditions can be important in disrupting the columnar microstructure and thereby increasing the film density and modifying film properties (Ref 57, 58). The bombardment also improves the surface coverage and decreases the pinhole porosity in a deposited film. This increased density and better surface coverage is reflected in film properties such as (Ref 59, 60, 61):

- Better corrosion resistance

- Lower chemical etch rate
- Higher hardness
- Lowered electrical resistivity of metal films
- Lowered gaseous and water vapor permeation through the film
- Increased index of refraction of dielectric coatings

However, it has been found that if the bombarding species is too energetic and the substrate temperature is low, high gas incorporation, defect concentration, residual stress, and the formation of voids can lead to poor-quality films.

Film Porosity. The porosity in atomistically deposited films results from:

- Incomplete surface coverage
- Deposition on particulate contamination that is subsequently dislodged
- Formation of a columnar film morphology
- Precipitation of voids at grain boundaries
- Precipitation of incorporated gases in the film

The increased surface-covering ability, densification of the film material, and disruption of the columnar morphology in ion plating decrease the film porosity unless bombardment gases are incorporated in the depositing film.

For more information about bombardment effects on film formation, see the article "Growth and Growth-Related Properties of Films Formed by Physical Vapor Deposition Processes" in this Volume.

Sources of Substrate Potential

The most common versions of ion plating use a potential on the substrate surface to accelerate ions to the surface. The potential on the surface can be applied by several methods.

Applied Bias (dc). A dc potential can be applied directly to an electrically conducting surface. Bombardment will be relatively uniform over flat surfaces where the equipotential field lines are conformal to the surface, but it will vary greatly if the field lines are curved, because ions are accelerated normal to the field lines. The dc discharge that is generated will fill the chamber volume if the pressure is sufficiently high. For pressures too low to establish a dc discharge, a magnetron configuration can be used to enhance the plasma over the surface of a web strip passing over the magnetron surface.

In the application of a dc potential, often the applied voltage and measured current (power expressed in watts/cm^2) to the surface is used as a process parameter and control variable. However, it must be realized that the bombarding ions generally have not been accelerated to the full applied potential due to the position of their formation, charge exchange collisions, and the physical collisions in the gas. The measured current consists of the incident ion flux (the ions may be multiply charged) and the loss of secondary electrons from the surface. The cathode power is a useful process parameter to maintain reproducibility only if parameters such as gas composition, gas pressure, system geometry, and so on are kept constant.

Applied Bias (rf). An rf potential (e.g., 13.56 MHz) must be applied to a surface if the surface is an insulator. Otherwise, charge buildup on the surface will result in arcing over the surface or through the insulating layer if it is thin (Ref 62). When applying an rf potential, the potential of the surface in contact with the plasma will vary continuously, although it will always be negative with respect to the plasma. The dc component of the bias will depend on the presence of blocking capacitance in the circuit and whether a dc bias supply is present. The energy of the ions that bombard the

surface will depend on the frequency of the rf source and the gas pressure. Maximum bombardment energy will be attained at low frequencies and low gas pressures. When using rf sputtering as a vapor source, a different rf frequency and power may be used on the substrate (Ref 63).

The rf bias has the advantage that it can establish a discharge in the space between the electrodes at a pressure lower than that required in a dc bias. It has the limitation that the rf electrode is like a radio antenna, and the plasma density formed over the surface depends on the shape of the substrate/fixture system. In some cases, the substrate/fixture should be surrounded by a "cage" to smooth out the electric field and give a more uniform plasma density. In all cases, ground shields should be kept well away from the rf electrode, and in the case of an insulator, the insulator should completely cover the rf electrode.

Applied Bias--dc plus rf. A dc potential and an rf potential can be applied at the same time if an rf choke is used in the dc circuit to prevent the rf from entering the dc power supply. By applying a dc bias, the insulating surface is exposed to bombardment for a longer period of time during the rf cycle.

Self-Bias. A negative self-bias is induced on an insulating or floating surface due to the higher mobility of the electrons compared to that of the ions. The higher the electron energy, the higher the negative self-bias generated. Figure 6 shows a technique for inducing a high self-bias by accelerating electrons away from a source and magnetically confining them so that they must bombard a substrate surface. It is possible to generate a positive self-bias if the electrons are prevented from bombarding the surface by using a magnetic field, because ions can reach the surface by scattering and diffusion. For example, substrates in a postcathode magnetron sputtering system can have a positive self-bias.

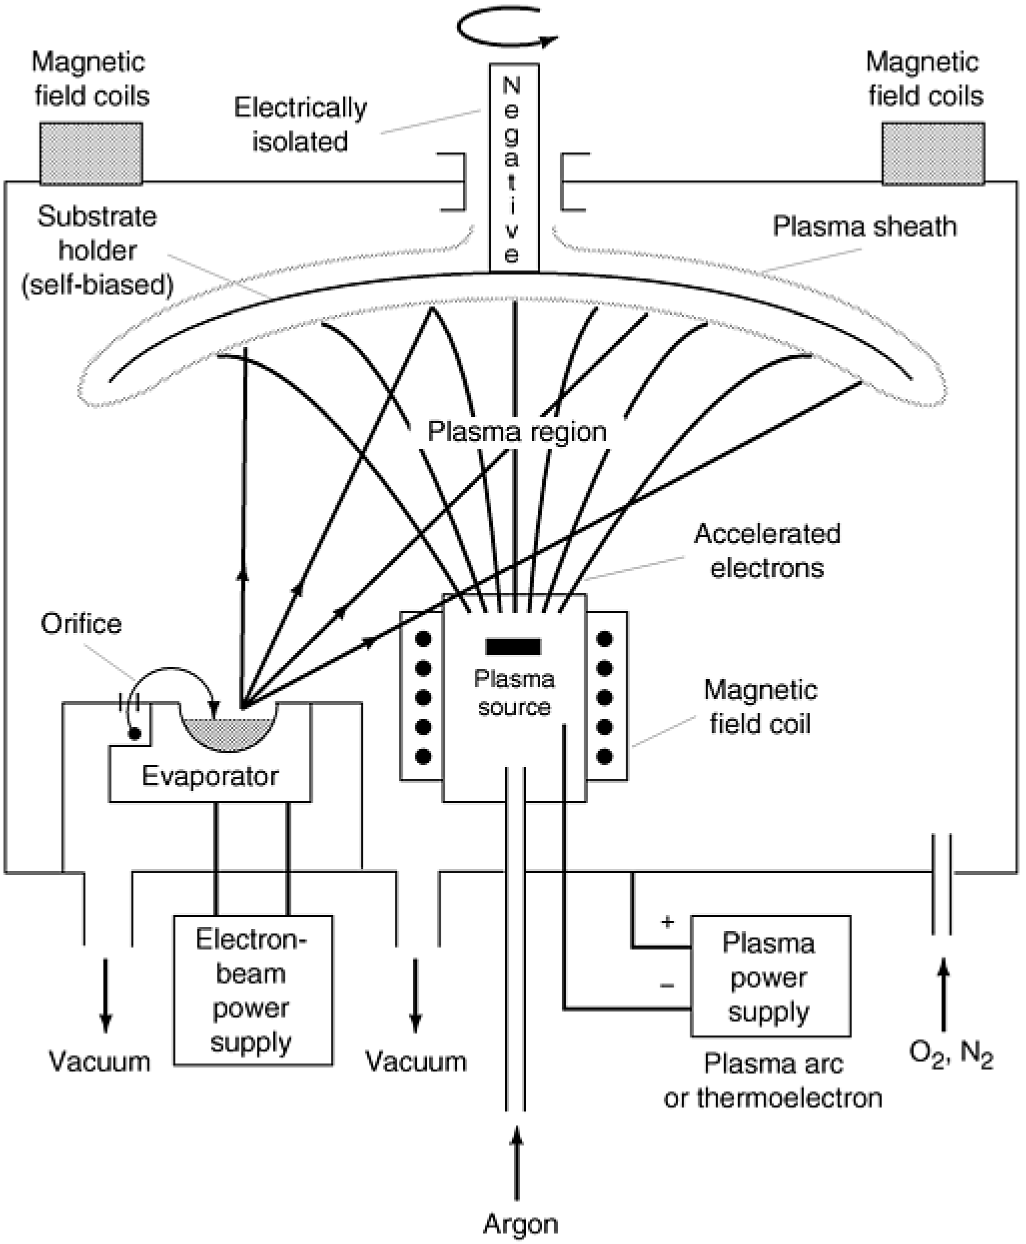

Fig. 6 Generation of a high self-bias and a plasma using accelerated electrons, an electrically isolated substrate holder, and a confining magnetic field. The vaporization source is a differentially pumped e-beam evaporator.

Sources of Bombarding Species

The energetic species used to bombard the growing film can be either ions or neutrals, although acceleration of charged ions is the most common way to obtain a controlled bombardment.

Plasmas. A common source of energetic bombarding species is ions accelerated from an inert or reactive gas plasma. The plasma can be formed using a number of configurations. The most common configuration is the dc diode with an

electrically conductive substrate serving as the cathode. When the substrate or depositing film is an electrical insulator, the plasma can be formed by making the substrate an rf electrode in an rf plasma system.

Bombardment can be enhanced by having a superimposed rf and dc potential on the substrate. In some cases, the plasma can be formed by the electrons used to vaporize the source material (Ref 64, 65, 66, 67, 68).

In some cases, auxiliary plasmas are used to provide the ions. Often these auxiliary plasmas are formed using a hot electron-emitting filament (Ref 69), a hollow cathode (Ref 70, 71), or a plasma arc source. The electrons can be confined with a magnetic field, as shown in Fig. 7.

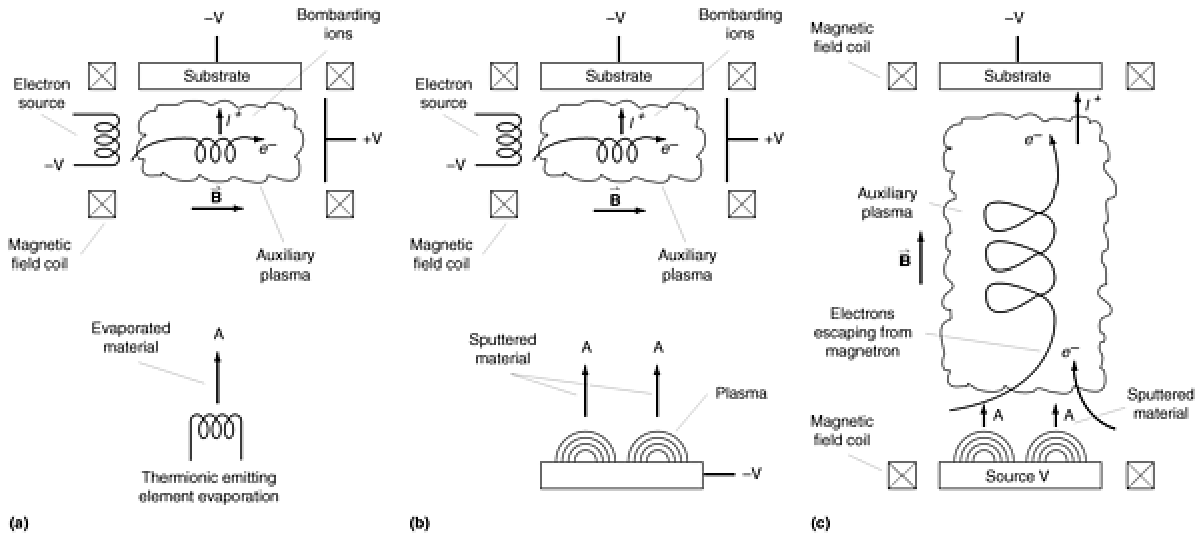

Fig. 7 Schematic showing selected methods used to provide a plasma near the substrate. (a) Hot cathode configuration. (b) Magnetically confined plasma configuration. (c) Unbalanced magnetron configuration

Gas Ions and Film Ions Generated by Arc Sources. Low-voltage, high-current arcs are a source of ions. If the arc is in a vacuum, then the vaporized electrode material is highly ionized and is often multiply charged (Ref 72, 73). In a vacuum, a positive space charge in the plasma between the electrodes accelerates the ions away from the electrodes. If the gas pressure is low, the ion can bombard a surface with appreciable energy. An arc can also be established with a gas present to generate a *plasma arc*. In a plasma arc, both the vaporized material (film ions) and gaseous species are ionized and can be accelerated to bombard the growing film. The ions from the arc can be used to sputter clean the surface at a high particle energy. If the accelerating voltage is high enough, the ion bombardment can prevent any net deposition on the substrate (Ref 65, 74).

High Energy Neutrals. In sputter deposition, ions bombarding a sputtering cathode can be neutralized and be reflected with an appreciable portion of their incident energy. If the gas pressure is low (~< 0.4 Pa, or 3 mtorr, as shown in Fig. 1), the high-energy reflected neutrals can bombard the growing film and affect the film properties (Ref 75, 76).

High-energy neutrals are also formed by charge exchange processes in the higher-pressure dc diode plasma configurations where the substrate is the cathode (Ref 77, 78, 79, 80).

Sources of Depositing Species

Thermal Vaporization. The various thermal vaporization sources can be used in ion plating. For plasma-based ion plating, the resistively heated sources are most often used. Low-energy electron-beam heating from hollow cathode sources and thermionic sources can be used, often with a magnetic confining field. This allows the electrons to heat the material to be vaporized and also to create the plasma. High-energy electron-beam heating can be used, but this requires isolating the electron-emitting filament from the plasma by the use of a conductance baffle with a hole to allow the electron beam to enter the plasma/crucible region (differentially pumped e-beam) (Ref 1, 81).

At high vaporization rates, gas phase nucleation generates ultrafine particles in the plasma (Ref 1). These particles become negatively charged, are suspended in the plasma, and do not deposit on the substrate. However, when the plasma is extinguished, the ultrafine particles will deposit on surfaces in the system.

Physical sputtering is often used as a source of depositing material. However, when using dc magnetron sputtering configurations, the plasma is confined in a region near the target and is not available as a supply of ions for substrate bombardment. In this case, the plasma used to supply these ions can be from an unbalanced magnetron configuration, the use of rf in conjunction with the dc magnetron, or the use of an auxiliary plasma source. A hot filament auxiliary plasma source and an unbalanced magnetron plasma source configurations are shown in Fig. 7(a) and 7(c), respectively.

Arc Vaporization. An arc can also be established with a gas present, giving a plasma arc. In a plasma arc, both the vaporized material and gaseous species are ionized (Ref 82, 83, 84). Either a solid cathodic arc surface or a molten anodic arc surface (Ref 85, 86) can be used. Ion species are then accelerated to the substrate under an applied bias. A problem with the cathodic arc vaporization source is that the arc causes the emission of molten globules (that is, macroparticles or macros) that deposit on the film surface. Various techniques are used to eliminate the globules from the plasma. Arc

vaporization sources are widely used in tool coating, even though they present a source of globules. The arc source and a sputtering source can be combined into one design (Ref 87). It has been found that by using the arc discharge for sputter cleaning, the cleaning and heating can be performed much faster than by using a dc diode discharge, due to the high ionization and the multiply charged heavy metal ions in the arc discharge (Ref 88). In addition, the surface smoothness is increased during arc-sputter cleaning (Ref 74). Figure 8 shows some arc-source ion plating configurations.

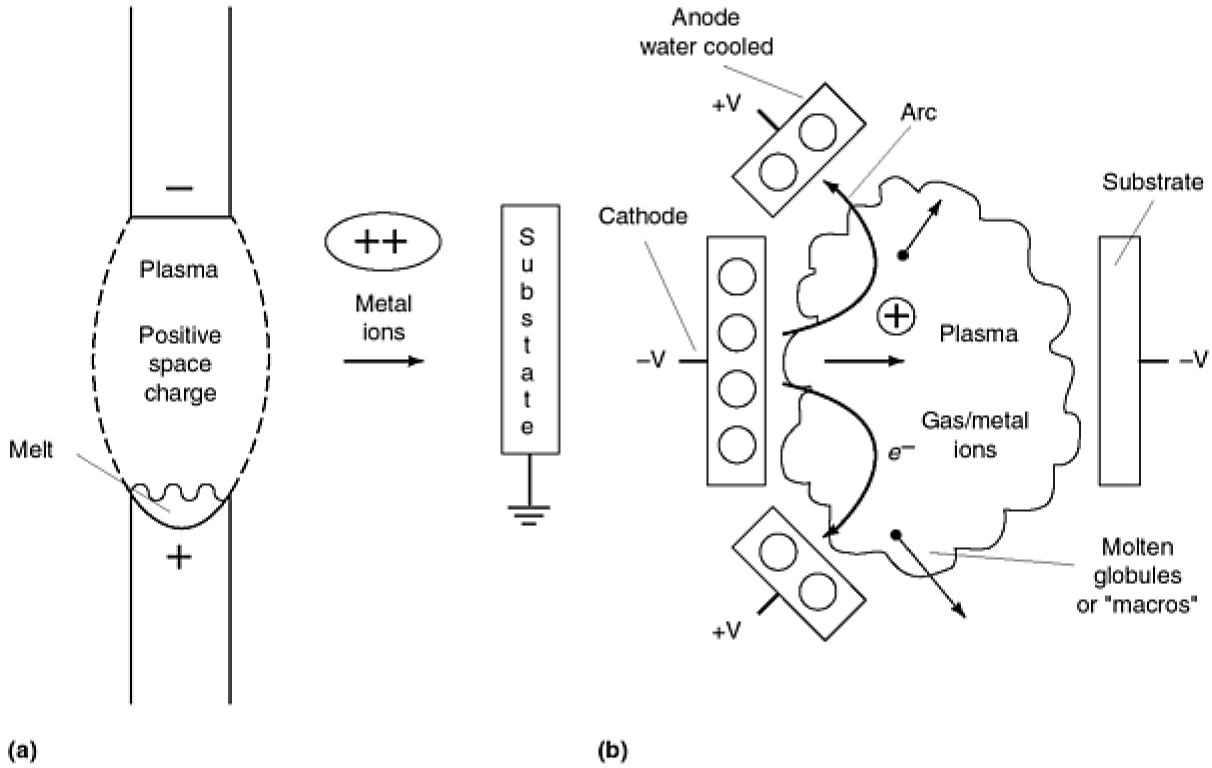

Fig. 8 Typical arc sources used in ion plating. (a) Vacuum arc/molten anode source. In the vacuum, the ions are accelerated away from the positive space charge in the plasma. (b) Cathodic arc vaporization source. In the plasma, the film ions are thermalized in the plasma, but both the film ions and the gas ions are accelerated to the substrate under an applied bias.

Chemical Vapor Precursor Gas. Gaseous chemical vapor precursor species containing the material to be deposited can be used as a deposition source. Using a chemical vapor precursor species in a plasma is very similar to plasma enhanced chemical vapor deposition (PECVD), in which the plasma is used to decompose the chemical species and to bias PECVD where ions from the plasma are accelerated to the substrate surface (Ref 43). Typical chemical vapor precursor gases are $TiCl_4$ for titanium, SiH_4 for silicon, and C_2H_4 for carbon, diamond-like carbon (DLC), and diamond.

The chemical vapor precursor may not be completely dissociated, so that it will deposit a compound material or material that has some of the original compound-forming material in it. For example, SiH_4 can be used to deposit amorphous silicon containing hydrogen. The chemical vapor precursor can be injected into the plasma (Ref 1, 89) in plasma-based ion plating or into a confined plasma ion source in vacuum-based ion plating (Ref 90, 91, 92).

Laser vaporization with concurrent ion bombardment has been used to deposit high-quality high-temperature superconductor films at relatively low substrate temperatures (Ref 93). Laser vaporization creates a large number of ions in the vapor "plume," and these can be accelerated to the substrate surface. This technique has been used to deposit hydrogen-free DLC films (Ref 94).

For more information about sources of depositing species, see the other articles in this Section.

Ion Plating Bombardment Parameters

A variety of ion plating configurations can be used (Fig. 9). Each configuration will have somewhat different parameters that need to be controlled. Ideally, the ion plating parameters that should be controlled are:

- Ion species and ionization state
- Particle energy
- Flux ratio
- Gas composition and mass flow
- Bombardment uniformity
- Substrate temperature
- Gas incorporation
- Fixturing

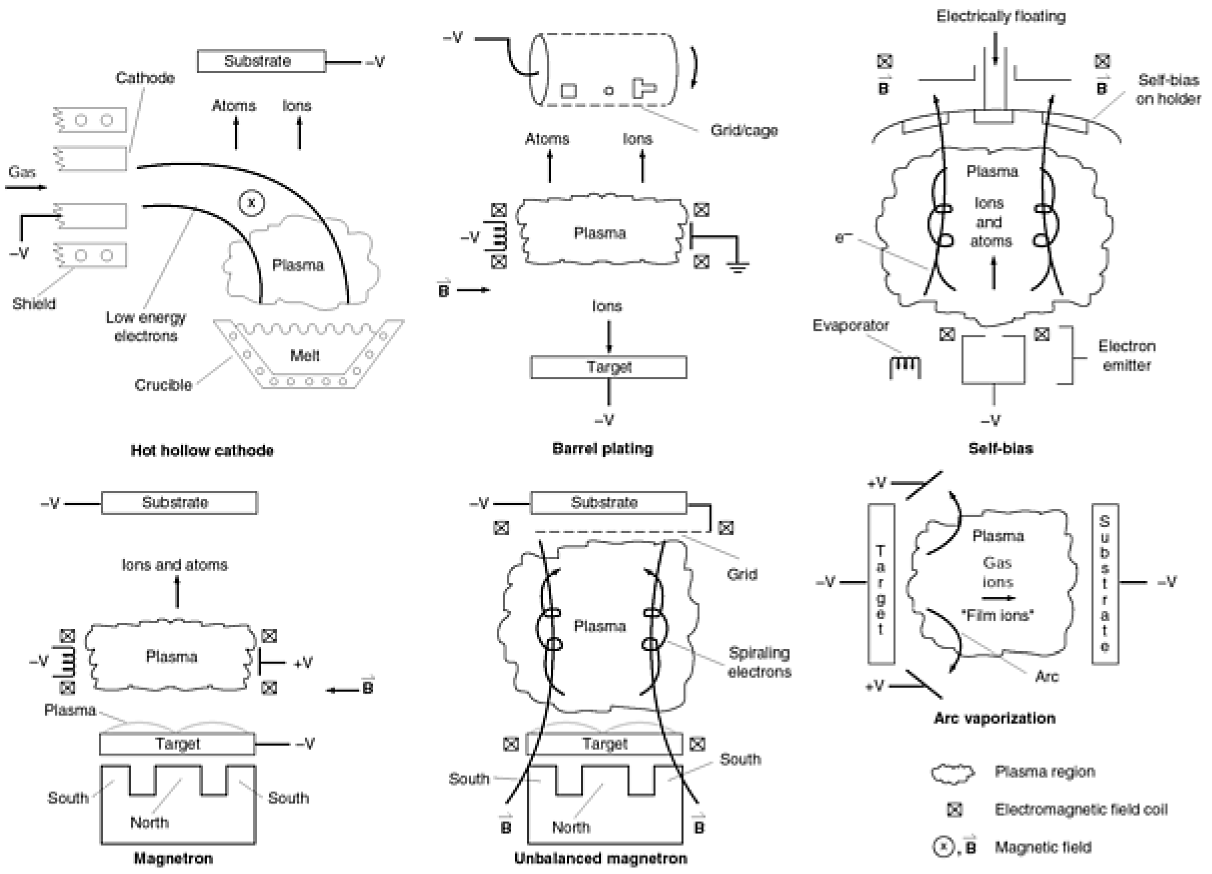

Fig. 9 Typical configurations used in ion plating

Ion Species. The mass of the bombarding species is important to the energy and momentum transferred during the collision. From the laws of conservation of energy and the conservation of momentum, the energy, *E*, transferred by the physical collision between hard spheres is given by:

$$E_t/E_i = 4M_tM_i \cos^2 j \,/(M_i + M_t)^2 \qquad \textbf{(Eq 1)}$$

where *E* = energy, *M* = mass, i = incident particle, t = target particle, and *j* = the angle of incidence as measured from a line joining their centers of masses. The maximum energy transfer occurs when $M_i = M_t$ and the motion is along a path joining the centers ($j = 0°$). In some cases, bombardment by self-ions (that is, ions of the target material) can result in self-sputtering. This occurs when atoms of the sputtered material become ionized and bombard the target.

The most common inert gas species used for plasma formation and ion bombardment is argon, because it is the least expensive of the inert gases. Krypton is sometimes used, and historically mercury was used. Common reactive gases used in plasmas are nitrogen and oxygen. A mixture of inert gas and reactive gas is often used to increase the momentum transfer efficiency in reactive deposition. Helium is sometimes mixed with other gases to increase the thermal conductivity of the gas mixture to aid in substrate cooling.

Particle Energy. The energetic particle energy and energy distribution are important parameters. The energy should be high enough to give appreciable energy transfer on collision, but it should not be high enough to be physically implanted and trapped in the depositing film where it can precipitate and form voids. Neither should it be high enough to cause excessive sputtering. For low-temperature deposition, the ion energy should not exceed about 300 eV (48 aJ). If the substrate is heated to 400 °C (750 °F) or greater, the energy can be increased, because the implanted ions are continually being rapidly desorbed. For low-pressure sputter deposition, the presence of high-energy reflected neutrals from the sputtering target can be an important parameter.

Flux Ratio. The ratio of depositing atoms to bombarding species is important to the film properties. Typically, to complete the disruption of the columnar morphology of the growing film and to obtain the maximum density and least microporosity, the energy deposited by the bombarding species should be about 20 eV (3 aJ) per depositing atom or about 20 to 40% resputtering (Ref 95, 96, 97).

Gas Composition and Mass Flow. Gas composition is an important processing variable in ion plating. In reactive deposition, the gas mass flow can be an important variable that is sensitive to the fixture/system geometry. The gas used for an inert plasma should be free of contaminants (for example, water vapor and oxygen) that will become activated in the plasma. Inert gases can be purified using heated reactive surfaces (for example, titanium or uranium chip beds). Reactive plasmas should be free of contaminants. For example, in reactive gases or gas mixtures, water vapor can be removed by cold traps using zeolite adsorbers.

Mixtures of gases can be used to deposit films having differing compositions and properties such as color. For example, titanium deposited in a nitrogen plasma to form titanium nitride is a gold color, but with a mixture of nitrogen and methane the color can be made bronze, rose, violet, or black as the TiC_xN_y varies in composition.

The gas distribution into the deposition system is an important factor in obtaining uniform bombardments over a surface and uniform activation of a reactive gas.

Bombardment Reproducibility. In vacuum-based ion plating, the ion and atom fluxes can be measured directly by using a Faraday cup ion collector and a mass deposition meter (for example, a quartz crystal deposition monitor). The presence of high-energy reflected neutrals from the sputtering target in the vacuum environment is difficult to measure and can be an unknown processing parameter when a sputtering source is used. In plasma-based ion plating, the ion flux and flux energy distribution are difficult to measure directly. In both vacuum-based and plasma-based ion plating bombardment and deposition, consistency, uniformity, and reproducibility are controlled by having a consistent vaporization source, system geometry, fixture motion, gas composition, gas flow, and substrate power (that is, voltage and current).

Fixturing is often the key to bombardment and deposition uniformity. Fixtures can be in the form of holders that move the substrates or move the deposition sources (Ref 98). Often a three-dimensional object is rotated in front of the deposition source to randomize the deposition angle of incidence, increase uniformity of bombardment, and give a more uniform morphology to the deposit (see the article "Growth and Growth-Related Properties of Films Formed by Physical Vapor Deposition" in this Volume). In some cases, especially when using an rf bias, irregularly shaped objects are surrounded by a grid that is electrically tied to the object, thus giving a smooth equipotential surface around the object. Figure 10 shows the use of a rotating "cage" to hold loose parts to be coated (Ref 99).

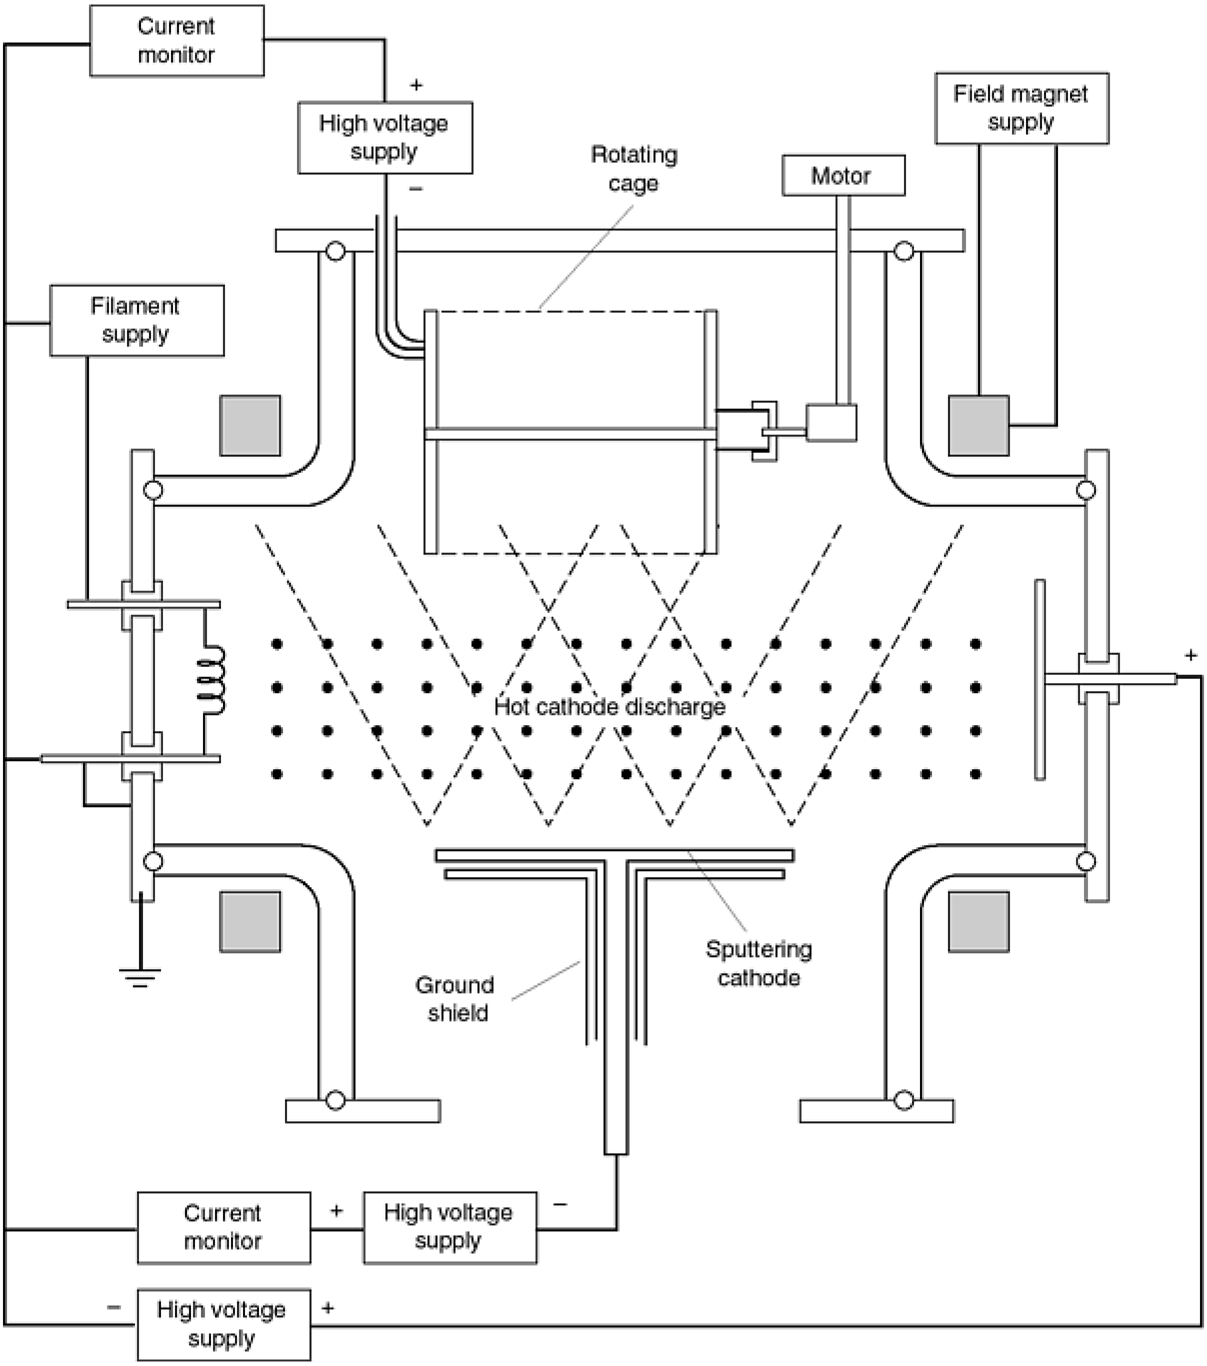

Fig. 10 Schematic showing key components of a barrel-plating configuration used in ion plating. The grid allows the acceleration of ions through the grid-holes to bombard the small parts enclosed within the rotating barrel (cage). Source: Ref 99

Substrate Temperature. In some cases, ion plated films are deposited without deliberate heating of the substrate. This is particularly advantageous when the substrate is thermally sensitive (for example, a plastic). In the extreme, the deposition can be periodic to allow cooling of the substrate between depositions. For example, the substrates can be mounted on a drum and alternately rotated in front of a deposition source and allowed to cool between depositions (Ref 100, 101, 102).

For the highest-density deposit and the most complete reaction, an elevated temperature is generally desirable (Ref 103). Substrate heating can be done by ion bombardment prior to and during deposition (Ref 74), but often a more controllable technique is to have an auxiliary heating source, such as a radiant heater or electron-bombardment heating. In tool coating, for example, the tool is often heated to just below the tempering temperature.

Gas Incorporation. At low substrate temperatures, bombarding gas can be incorporated into the growing film, particularly if the bombarding energy is high. To minimize gas incorporation, the bombarding energy should be kept low (that is, less than 300 eV, or 50 aJ), or a heavy bombarding particle (for example, krypton or mercury) can be used, or the substrate temperature can be kept high (that is, greater than 300 °C, or 570 °F). Low-temperature bombardment can be used to deliberately incorporate gas into the surface of a depositing film. In sputter-ion vacuum pumps, for example, trapping is used to pump inert gases and to incorporate insoluble light and heavy gases in depositing films (Ref 104, 105).

Process Monitoring and Control

The equipment used for ion plating is very similar to that used in sputter deposition (see the article "Sputter Deposition" in this Volume). The exception is that in ion plating, the substrate is a sputtering target and often has a complex configuration that requires fixturing in order to obtain uniformity of bombardment, reactive gas availability, and film deposition. The plasma-based ion plating process is generally made reproducible by duplicating the geometry and process parameters used. The effects of the bombardment are generally determined by the property changes measured after deposition.

The amount of bombardment is often quoted as the amount of resputtering or the amount of energy per deposited atom that is added by the bombardment. Typically, for the maximum densification about 20 eV (3 aJ) per deposited atom must be added by bombardment. To avoid gas incorporation at low substrate temperatures, the bombardment energy should be less than 300 eV (50 aJ), which means that there must be about one high-energy particle to ten depositing atoms. Another measure of the bombardment is the resputtering rate of the film. Typically a resputtering rate of 20 to 30% is needed for full densification (Ref 96).

When using the IBAD configuration, the ion plating variables can often be measured directly. For example, in a grid-extraction ion gun, the ion energy is determined by the extraction grid voltages and the ion flux can be measured using a

Faraday cup. In the vacuum environment, the deposition rate can be easily monitored using a quartz crystal deposition monitor.

Advantages and Limitations of Plasma-Based Ion Plating

Plasma-based ion plating is the most commonly used ion plating configuration.

Advantages of plasma-based ion plating (Ref 1, 2, 106) include:

- Excellent surface-covering ability ("throwing power") under the proper conditions
- Ability to have in situ cleaning of the substrate surface
- Ability to introduce heat and defects into the first few monolayers of the surface to enhance nucleation, reaction, and diffusion
- Ability to obtain good adhesion in many otherwise difficult-to-deposit systems
- Enhancement of reactive deposition process (activation of reactive gases, bombardment-enhanced chemical reaction, and adsorption of reactive species)
- Flexibility in tailoring film properties by controlling bombardment conditions (for example, morphology, density, and residual stress)
- Equipment requirements are equivalent to those of sputter deposition
- Source of depositing material can be from thermal vaporization, sputtering, or chemical vapor precursor gases

Limitations of plasma-based ion plating include:

- Many processing parameters must be controlled
- Contamination can be released from surfaces and "activated" in the plasma to become an important process variable
- To bombard growing films of electrically insulating materials, the surfaces must either attain a self-bias or must be biased with an rf potential
- Processing and "position equivalency" can be very dependent on substrate geometry and fixturing (that is, obtaining uniform bombardment and reactive species availability over a complex surface may be difficult)
- Bombarding gas species can be incorporated in the substrate surface and deposited film if too high a bombarding energy is used
- Substrate heating can be excessive
- High residual compressive growth stresses can be introduced into the film layer

Applications of Ion Plating

Typical applications of the ion plating process include:

- Good adhesion between a film and substrate (for example, silver on steel for mirrors, silver on beryllium for diffusion bonding) (Ref 65)
- Electrical conductive layers (aluminum, silver, and gold) on plastics and semiconductors
- Low-shear solid film lubricants (for example, silver and gold) (Ref 107)
- Wear and abrasion-resistant coatings [for example, TiN, TiC_xN_y, $(Ti\text{-}Al)C_xN_y$, $Ti_{0.5}Al_{0.5}N$] on cutting tools (Ref 74), dies, molds, and jewelry
- Decorative coatings (TiN yields gold-colored deposit, TiC_xN_y yields rose-colored deposit, TiC yields black deposit, ZrN yields brass-colored deposit) applied to hardware, jewelry, guns (Ref 108), and cutlery
- Corrosion protection [aluminum on uranium (Ref 109); mild steel (Ref 110, 111) and titanium; carbon and tantalum on biological implants]
- Deposition of electrically conductive diffusion barriers (for example, HfN and TiN on semiconductor devices)
- Deposition of insulating films (for example, SiO_2 and ZrO_2)
- Deposition of optically clear, electrically conducting layers (indium-tin-oxide) (Ref 112)
- Deposition of permeation barriers on webs (Ref 113, 114, 115)

Ion plating has also been used to coat very large structural parts with aluminum for corrosion protection (replacing cadmium) (Ref 104).

Ion plating provides a means of modifying film properties that does not exist in other PVD techniques. This gives it a place in the range of PVD deposition techniques available for "surface engineering." Often the applications of ion plating are very substrate-specific, so that fixturing is a very important consideration in coating uniformity, unit cost, and cost-of-ownership for a specific application. The ability to devise an optimal fixture design is often the key to a successful process.

Ion-Beam-Assisted Deposition

Graham K. Hubler, Naval Research Laboratory; James K. Hirvonen, U.S. Army Research Laboratory

---

Introduction

ION-BEAM-ASSISTED DEPOSITION (IBAD) refers to the process wherein evaporated atoms produced by physical vapor deposition (PVD) are simultaneously struck by an independently generated flux of ions. The extra energy imparted to the deposited atoms causes atomic displacements at the surface and in the bulk, as well as enhanced migration of atoms along the surface. These resulting atomic motions are responsible for improved film properties, including better adhesion and cohesion of the film, modified residual stress, and higher density, when compared with similar films prepared by PVD without ion bombardment. When the ion beam or the evaporant is a reactive species, compounds such as refractory silicon nitride ($Si_3 N_4$) can be synthesized at very low temperatures. Furthermore, adjustment of the ratio of reactive ions to atoms arriving at the substrate surface allows adjustment of the stoichiometry of solid solutions. Detailed reviews of the IBAD process can be found in Ref 1, 2, and 3.

Process Utilization. The feature that distinguishes IBAD from the other PVD processes discussed in this Section of the Volume is that the source of vapor and the source of energetic ions are separated into two distinct hardware items, as opposed to plasma-based techniques, such as direct current (DC), radio frequency (RF), and magnetron sputtering; plasma-enhanced chemical vapor deposition; and certain forms of ion plating in which both the evaporant flux and ion flux are derived by extraction from a plasma. Therefore, there is more control over the deposition parameters in the IBAD process, because the ion flux and the evaporant flux can be varied independently. The other major difference between the plasma techniques and IBAD is the higher pressure (0.13 to 13 Pa, or 10^{-3} to 10^{-1} torr) required by the operation of the plasma-based methods in order to sustain a plasma. Because IBAD techniques typically operate in the collision-free pressure regime, the evaporant and beam atoms follow straight-line paths to the substrate. This also limits IBAD to line-of-sight applications.

The two most common geometries used in IBAD processing are shown in Fig. 1. Details of the methods are described elsewhere (Ref 4, 5, 6). Normally, a broad beam from an ion source, such as a Kaufman-type ion gun, impinges on a substrate simultaneously with the deposited atoms. The PVD source is usually an electron-beam source, but it could also be a thermal source or a sputter target, in the case of dual-ion-beam sputtering. The simplest geometry for the generation of uniform films and the treatment of complex geometries is a small angle (<30°) between the vapor and ion sources.

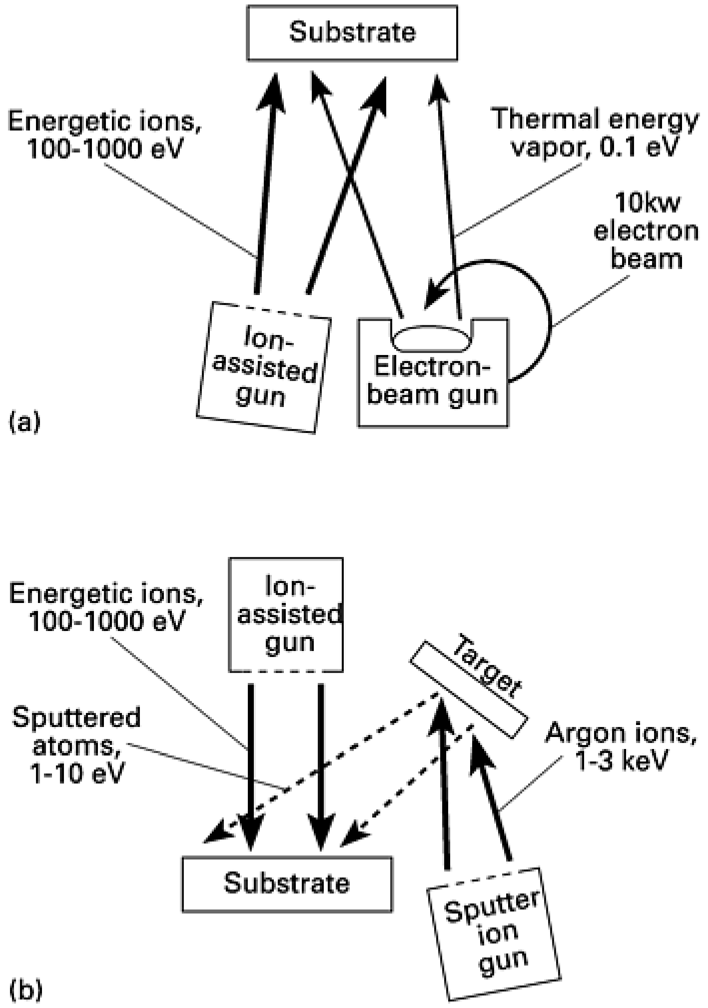

Fig. 1 Two common processing techniques. (a) Ion-beam-assisted deposition (IBAD). (b) Dual-ion-beam sputtering (DIBS)

Typical levels of ion-beam energy are between approximately 50 and 1000 eV for Kaufman-type ion guns. The ion beam has a uniform flux over a large area, depending on the diameter of the ion extraction apertures (typically, 30 to 80 mm, or 1.2 to 3.1 in.). The energy levels for beams from an ion implanter are 20 to 100 keV. Large areas are obtained by rastering the beam over the exposed surfaces. Research indicates that while the adhesion of IBAD films at low energies (500 eV to 3 keV) is excellent (Ref 7, 8, 9), an additional improvement in adhesion can sometimes be gained at higher energies (20 to 40 keV) if the film and substrate are not normally miscible. On the other hand, other properties, such as the absorption in optical films, increase as the energy increases because of greater displacement damage (Ref 10, 11, 12). Minimal absorption is obtained at energies below 500 eV. Therefore, for films intended for environmental protection, wear resistance, decorative coatings, and similar applications, a slight advantage might be derived from utilizing higher beam energies, although it would not normally be enough to warrant the greater expense of high-energy ion sources and beam-handling optics. However, for films intended for optical and microelectronics applications, lower energies are preferred in order to minimize beam damage resulting in optical absorption and the formation of electrically active defects.

For the low-energy range (50 to 1000 eV), inelastic collisions of the incident ions with the surface atoms deposit the energy into the surface according to the expression:

$$E \text{ (per film atom)} = R(E_b)$$

where R is the ratio of beam atoms to evaporant atoms arriving at the surface and E_b is the energy per atom in the ion beam. For the arrival of four beam atoms for every ten evaporant atoms (R = 0.4) and a beam energy of 200 eV, the average energy deposited in the surface for every film atom is 80 eV. This should be contrasted to the thermal energy of

evaporated film atoms without ion bombardment, which is E = 0.15 eV/atom. This parameter can be tightly controlled and independently varied over a wide range by changing the beam output of the ion source and the energy of the ion beam. In plasma-based techniques, there is a larger spread of energies of the energetic flux components, with unknown ratios of the ion to thermal atom flux. The independent control of these parameters is more limited.

Physical and Chemical Aspects. The physical processes that occur at the surface during the film formation of IBAD are shown in Fig. 2. The lower right portion of Fig. 2 shows a very dilute neutral plasma consisting of background gas ("g") at a thermal energy of 0.03 eV, which is present throughout the chamber, as well as vapor atoms ("v") with an energy of either 0.15 eV (produced by the electron-beam evaporator shown in Fig. 1a) or 1 to 10 eV (produced by the sputter source shown in Fig. 1b). The vapor atoms have a velocity vector directed toward the substrate and are confined to the region between the vapor source and the substrate. The gas and the vapor impinge on the film surface at individual rates that are determined by the chamber pressure and the evaporation rate, respectively. The lower left portion of Fig. 2 shows a 200 eV N^+ beam directed toward the substrate. Some of this charged plasma is charge-exchange neutralized in near collisions with the ambient gas atoms, resulting in an energetic 200 eV neutral N^0, which continues in the direction of the substrate, and a 0.03 eV N^+ charged atom that gets expelled from the positive column of charge represented by the ion beam. As a result of charge exchange, the neutralized (high-velocity) atoms will not be counted by the charge-collection system.

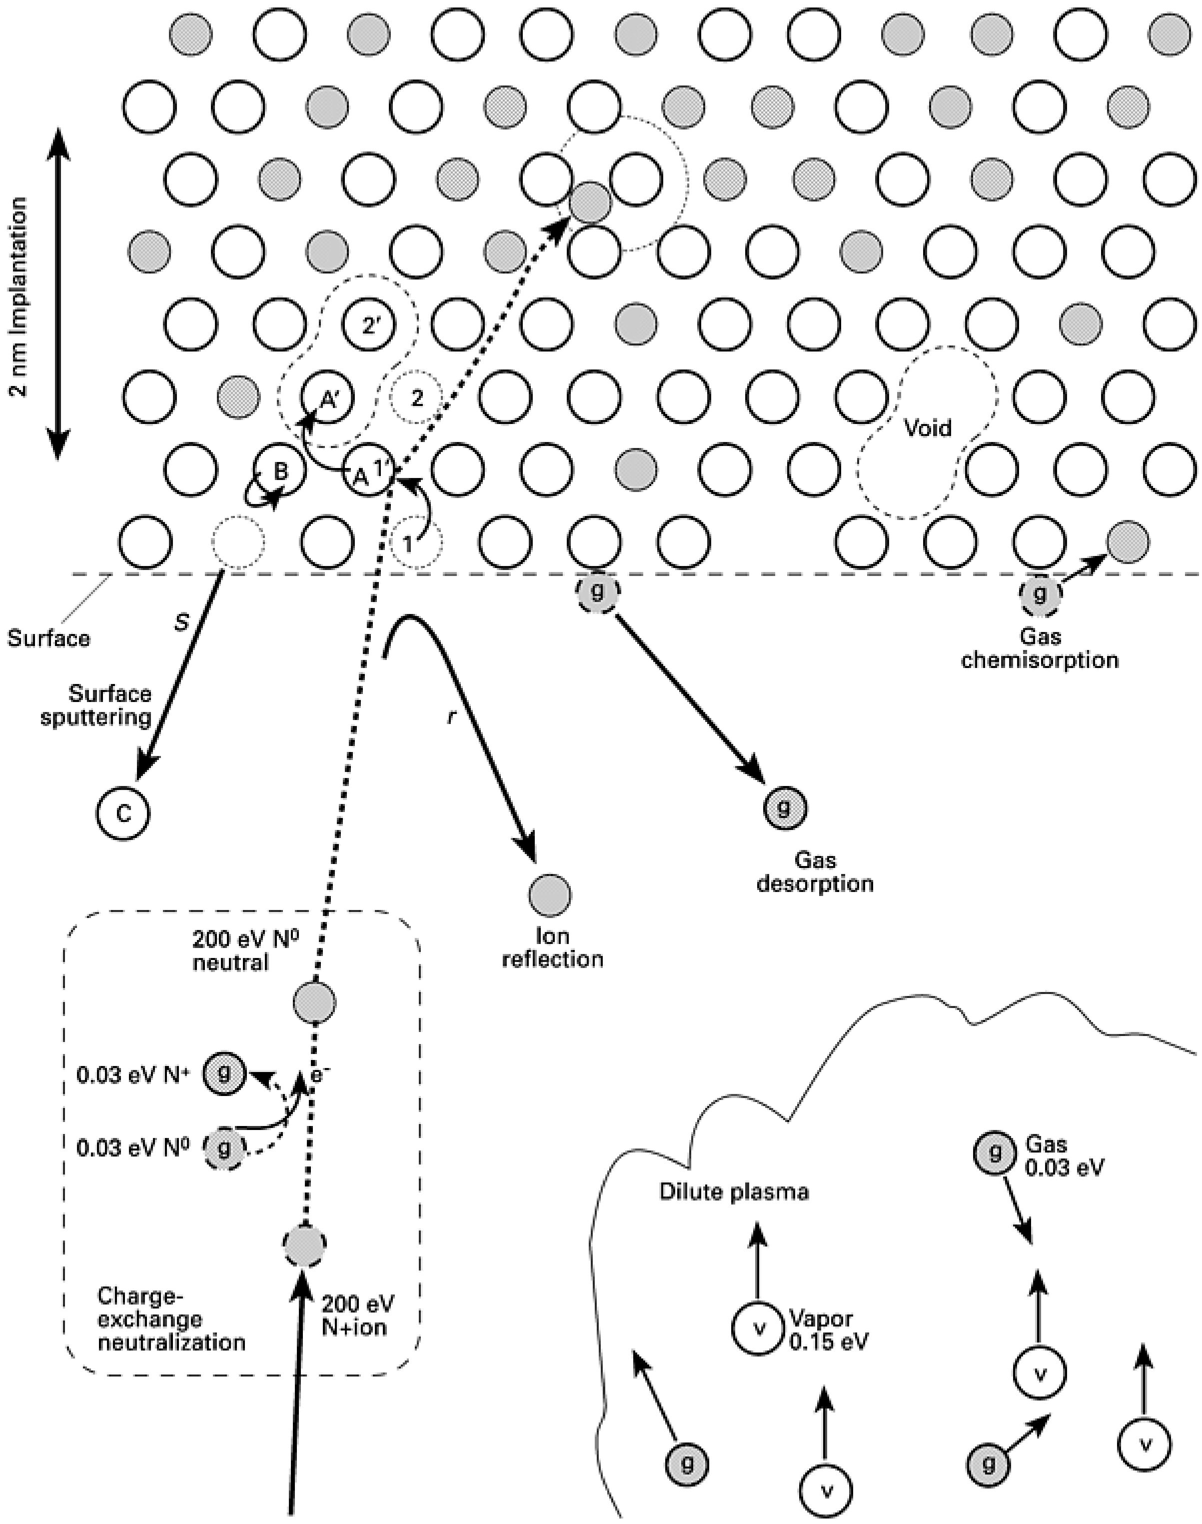

Fig. 2 Physical and chemical processes at the film-vacuum interface during ion-beam-assisted deposition and dual-ion-beam sputtering

In the central portion of Fig. 2, the ions, which consist of N^+ in this example, are either implanted into the first few atomic layers or reflected from the surface with a reflection coefficient, *r*. As a result of ion bombardment, some of the deposited and/or implanted atoms are sputtered from the surface with a sputtering coefficient, *S*. The sputtering process is shown as resulting from a three-step process, in which energy is transferred in a collision sequence, or cascade, from the ion to atom A, and then to atom B, which causes atom C to be sputtered. Additional surface processes shown are:

- The ion-stimulated thermal desorption of a physisorbed gas atom (binding energy ~0.05 eV) caused by a

thermal spike event in the vicinity of the ion impact

- The ion-stimulated chemisorption of the gas impurity to form chemical bonds with the deposited atoms (binding energy ~2 eV per bond)

The upper portion of Fig. 2 shows the processes that occur within the film. For this example, imagine that the vapor atoms are titanium and the ions are nitrogen. The large, open circles are titanium atoms condensed out of the vapor phase that form the film. They are more numerous near the surface because the nitrogen ions represented by the small, shaded circles have a finite range in the lattice of five atomic layers. In the deepest three layers shown, there are equal numbers of titanium and nitrogen atoms, giving stoichiometric titanium nitride. This also means that the rate of arrival of titanium atoms has been adjusted to be nearly equal to the rate of arrival of the nitrogen ions. Also shown in the near-surface region is a void that is formed in most metallic depositions at thermal energies. The random nature of the positions along the surface, where the vapor atoms land, coupled with the low mobility of the atoms after impact, leads to void formation.

The upper left portion of Fig. 2 represents the process of film densification. As the ion enters the lattice, it slows down upon inelastic collisions with other atoms in the lattice. The dashed line enclosing atoms A' and 2' indicates a void, identical to the one shown on the right, which was present prior to the arrival of the ion. In this schematic, the unprimed symbols are the atom positions before the ion collision, the primed symbols are their positions after the ion collision, and the faint dashed circles represent missing atoms after the collision is over. Upon entering the lattice, the ion strikes atom A, knocking it into one of the void positions (A'), but on the way, atom A also strikes atom B, whereupon its motion causes atom C to be sputtered, as already noted. Next, the ion knocks atom 2 into void position 2', leaving position 2 empty, and the thermal excitation of the ion impact causes atom 1 to jump into position 1', the position formerly held by atom A. Thus, before the collision, there were two atoms missing in the bulk, whereas after the collision, only one atom is missing, and the film has a net increase in density. Finally, the N ion comes to rest in an interstitial position, which represents a defect in the crystalline structure. This defect can be eliminated by a subsequent collision or it can remain in the film.

The atomic displacement mechanisms in the bulk of the film depicted in Fig. 2 are generic to any energetic deposition process. The plasma and surface processes depicted in that figure are conceptually simple, compared with the physical description of processes that occur in plasma-based deposition systems. For that reason, the production of reproducible films and graded composition films by IBAD is straightforward.

Processing Equipment

Laboratory. Most of the IBAD systems that exist in government, industry, and university laboratories are designed for sample sizes with diameters less than 30 mm (1.2 in.). These facilities are able to perform depositions on a small scale for limited batch sizes.

One common means of fabricating an IBAD system is to utilize commercially available electron-beam-source "box coaters" that are capable of large-area, high-volume coating applications and then modify them to accept commercially available low-energy, high-current ion guns of various designs. Deposition rates are determined by the electron-beam-source evaporation rate and the required arrival ratio of ions to atoms for a particular coating. When the required arrival ratios are between 0.1 and 1.0, the maximum current of a Kaufman-type ion gun (~1 mA/cm^2) translates into deposition rates of about 40 to 4 μm/h (100 Å/s to 10 Å/s), respectively, for a system based on an electron beam source.

Production. Many applications require large areas to be coated. Linear ion guns are made with lengths up to 1000 mm (40 in.) and widths of 20 mm (0.8 in.), whereas circular-aperture ion guns have diameters ranging from 10 to 380 mm (0.4 to 15 in.). Systems that can handle workpieces with a 1 m (40 in.) diameter have been built. In nonoptical applications, where film uniformity is not as strict a requirement, very large areas could be coated using existing equipment by the routine manipulation of the workpieces.

Even larger surface areas can be handled by using continuous coating schemes. The primary obstacle to scale-up is the requirement of line-of-sight processing, especially for odd-shape parts. Cylinders can easily be coated, but it is not yet clear whether complex shapes, like gear teeth, can be uniformly and reliably coated. Figure 3(a) shows a scheme developed for the large-area, high-volume deposition of optical films, which could be adapted easily for sheet-metal applications (Ref 13). Figure 3(b) depicts a prototype large-area, high-volume system used for sheet steel (Ref 14), which will be discussed later.

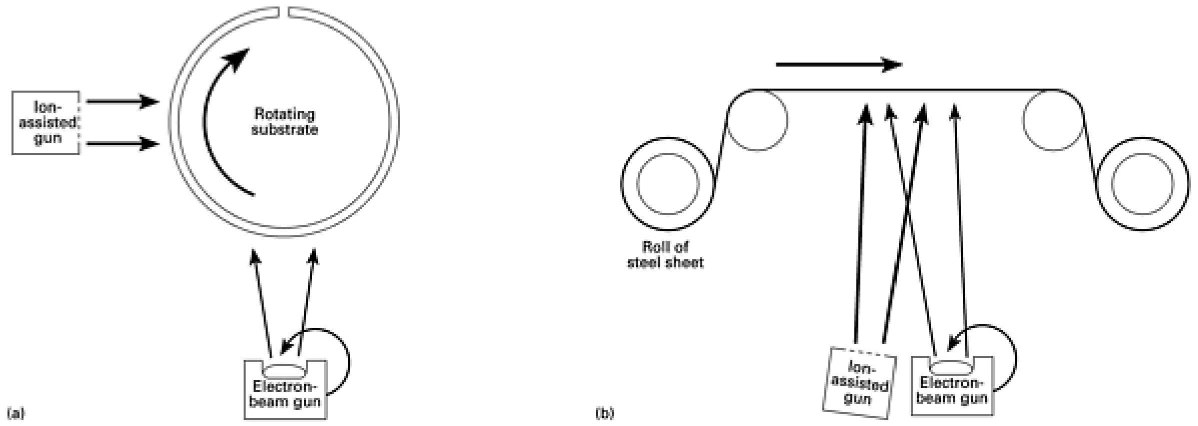

Fig. 3 Two methods used for large-area, high-volume implementation of ion-beam-assisted-deposition. (a) For optical films. (b) For steel sheet

Dual-ion-beam-assisted deposition (DIBS) systems, which utilize ion-beam sputter deposition, are also commercially available for use on substrates that are up to 120 mm (4.7 in.) in diameter. Some of these units are used for semiconductor applications, as well as for nonelectronic applications, such as the deposition of molybdenum disulfide films for friction reduction. In the case of sputter deposition, maximum deposition rates depend on the material to be deposited and are considerably less than for systems based on an electron beam. Ion-beam-sputtering systems are particularly suited to highly controlled, thin-film, multilayer coating applications, where up to six different sputtering targets can be sequentially moved into the sputter target position. High-quality, multilayer x-ray mirrors; laser mirrors; metallic multilayers; and other products have been manufactured using this method.

Processing Variables and Parameters

In general, there are three modes of IBAD. Several examples of the material systems that are deposited using each of the modes are given in Table 1. Mode 1 of this table identifies a simple type of ion assist, in which inert heavy ions, such as argon, are used to improve the properties of an elemental film or a compound film that undergoes congruent evaporation. In this case, it is important to minimize the amount of argon incorporated into the film, which increases with the arrival ratio, *R*, and the beam energy. Therefore, the lowest *R* value possible, consistent with obtaining the desired film properties, should be used. This mode also includes materials such as cerium oxide, which is typically slightly substoichiometric when simply deposited by evaporation. An ion assist with argon ions can be used for densification only, or oxygen ions can be used for densification and to restore stoichiometry.

Table 1 Three modes of film formation for ion-beam-assisted deposition (IBAD)

Vapor	Ion or ion/gas	Film
Mode 1: IBAD		
Ge	Ar	Ge
Ag	Ar	Ag
CeO_2	O	CeO_2
Ta_2O_3	O	Ta_2O_5
Mode 2: IBAD (Compound synthesis)		
Si	N	Si_3N_4
B	N	BN
Si	CH_4	SiC
Cu	O	Cu_2O
Mode 3: Reactive IBAD		
Ti	N/N	TiN
Ti	Ar/N	TiN
Nb	N/N	NbN
Al	O/O	Al_2O_3

Ge, germanium; Ar, argon; Si, silicon; N, nitrogen; Si_3N_4, silicon nitride; TiN, titanium nitride; Ag, silver; B, boron; CeO_2, cerium oxide; O, oxygen; CH_4, methane; SiC, silicon carbide; Nb, niobium; Ta_2O_3, tantalum oxide; Ta_2O_5, tantalum pentoxide; Cu, copper; Cu_2O, copper oxide; Al, aluminum; Al_2O_3, aluminum oxide

Mode 2 in Table 1 identifies an ion assist and compound synthesis group, in which there is little reaction probability of the ambient gas with the evaporant. All of the material that forms the compound in this deposition mode comes from the evaporation source, as well as directly from the ion beam.

Mode 3 in Table 1 covers compound synthesis that is possible only for very reactive materials. It can occur either with the gas associated with the ion beam (e.g., N_2 for titanium nitride) or when inert ions such as argon are used in conjunction with a secondary (background) gas supply of N_2. In the latter case, the purpose of the ions is to activate and control surface chemical reactions.

Table 2 is a selected compilation of materials that have been grown using IBAD processes. For application to metals, the oxides and pure metals are often used as corrosion-resistant coatings, whereas nitrides and some oxides are used as wear-resistant and corrosion-resistant coatings. The widespread application of these coatings for nonelectronic purposes is still new, but there is some evidence that the appropriate thickness for hard coatings for sliding wear resistance is 0.2 to 2 μm (8 to 80 μin.), and that for pin-hole-free corrosion-resistant coatings, a minimum thickness of 2 μm (80 μin.) is required. For abrasion-resistant coatings, very thick and hard coats can be deposited, although this has not been emphasized in the initial development of the technique. Optical coatings up to 15 μm (215 μin.) thick also have been deposited. Typical process parameters are shown in Table 3.

Table 3 Typical values of ion-beam-assisted deposition process variables

Variable	Value
Vapor deposition rate, μm/h (μin./h)	1-40 (40-1600)
Chamber base pressure, Pa (torr)	226×10^{-7} (2×10^{-7})
Operating pressure, Pa (torr) (with backfill gas), Pa (torr)	0.003 to 0.03 (2×10^{-5} to 2×10^{-4}) 0.007 to 0.03 (5×10^{-5} to 2×10^{-4})
Ion current, mA/cm^2 (mA/in.^{2}) Fraction-exchange neutralized	0.1-2 (0.6-13) 0.05-0.40
Arrival ratio	0.1-1.5
Substrate temperature, °C (°F)	<100 (<210)

Coating Properties

Adhesion. Because an ion gun is available in an IBAD system, substrates are normally sputter cleaned prior to deposition. This promotes improved bond formation between the substrate and the film. However, there are additional benefits from bombardment during deposition. One is that the surface is sputter cleaned of contaminants at the same time the substrate is exposed to the fluxes and is continuously cleaned during deposition. Another benefit is that there is atom movement across the interface caused by ballistic collisions such that film atoms are driven a few atomic layers into the substrate and substrate atoms are mixed into the film. This promotes the completion of interfacial bonding and also produces a robust, nonabrupt interface several atomic layers thick. The adhesive strength of these IBAD interfaces is typically 10 to 100 times higher than for the same films deposited at thermal energies with an electron beam or other PVD source without ion assistance. This bonding is enhanced for coating/substrate systems exhibiting high atomic miscibility.

Some of the systems that show adhesion improvement when deposited by IBAD are gold on copper (Ref 107), gold and silicon on glass (Ref 94), aluminum on iron (Ref 8), titanium nitride on steel (Ref 52), and copper, silver, and gold on polytetrafluoroethylene (Ref 104). Many more combinations have yet to be investigated. An excellent review (Ref 109) of the adhesion improvement of films by post-deposition bombardment gives further insight into the mechanisms of adhesion enhancement.

Stress. Most deposited thin films retain a residual compressive or tensile stress that limits the thickness that can be deposited. The accumulated stress either ruptures the interface bonds, causing delamination, or exceeds the cohesive forces of the material, causing film disintegration. Studies have shown that in most cases, a judicious combination of ion-bombardment parameters and substrate temperature can be chosen that will produce very small residual stresses in the coating. Therefore, conditions can normally be found where there are no thickness limitations to applications of IBAD coatings. This is a very important property for industrial applications.

Examples of low-stress films deposited by IBAD include chromium on glass by 11.5 keV argon bombardment (Ref 8), tungsten on silicon by 400 eV argon bombardment (Ref 101), boron and chromium on iron by 6 keV argon bombardment (Ref 94), and permalloy (iron-nickel) films on polypyromelitimide using 300 eV argon bombardment (Ref 103).

Density. An extremely important practical attribute of IBAD is the increase in film density, when compared with PVD films deposited without the aid of energetic ions. Such PVD films typically contain voids or columnar structures that produce a 10 to 20% density deficit relative to the bulk material. This is especially true for covalently bonded semiconductors and refractory metals. It is well established that the energetic ion beam applied to the film in the IBAD process can eliminate the voids and produce essentially bulk-density films. The mechanism for this densification is related to atomic displacements in the collision cascades, enhanced surface and bulk diffusion, recoil implantation, and ion mixing mechanisms (Ref 1, 2, 3).

Information on the densification of metal films is sparse and gives a mixed picture of whether or not IBAD causes densification. Gold films were found to be more dense (Ref 107), as were carbon films (Ref 97), but copper (Ref 105) and silver (Ref 106) films were found to be less dense. There is ample evidence for densification with semiconductors and oxides. The energy dependence for densification was studied for argon ions from 65 eV to 3 keV, and it was found that an arrival ratio of 0.1 at the low-energy level or 0.0003 at the high-energy level produced bulk-density germanium films (Ref 3, 110). For zirconium oxide films, IBAD using oxygen or argon ions produced nearly bulk-density films, when compared with evaporated films (Ref 16). In general, densification is found to occur in films deposited with an ion assist.

Microstructure. The effects of ion beams on the microstructure of films are numerous and complicated. For this reason, only some general observations are noted here. Most covalently bonded materials, such as semiconductors and silicon nitride or silicon carbide ceramics, are amorphous when deposited at room temperature. Silicon and germanium will be crystalline above the temperature of approximately 0.4 T_m, which is the melting temperature in degrees kelvin. Using IBAD, this characteristic temperature for achieving crystallinity can be lowered by approximately 200 K, because the atomic motion induced by the energetic atoms serves the same purpose as high substrate temperature (Ref 111).

Metals and ionic materials tend to be polycrystalline. In general, the ion beam decreases the grain size at low temperatures, but can increase it at higher temperatures, where annealing effects overcome the damage caused by the ion beam (Ref 102). The general observation that IBAD films are more ductile than bulk materials that usually contain larger grains has been attributed to this smaller grain size.

The orientation of films can be altered such that textured films are commonplace. The degree of texturing depends on beam angle, beam energy, beam flux, and substrate temperature (Ref 49). At high ion/atom ratios, the texture is such that the most loosely packed planes, which are favorable for ion channeling, are parallel to the ion-beam direction. At low ion/atom ratios, forward scattering of film atoms causes a close-packed fiber texture in the film plane for near-normal ion incidence (Ref 112). In some cases, epitaxial films can be induced to grow with an ion assist where they would not in the absence of ions. Examples include copper and aluminum on silicon (Ref 113, 114).

Morphology. In general, IBAD films are very smooth. If the substrate is initially atomically smooth, then processing conditions can be found for most coating materials that produce a remarkably small deterioration in smoothness. For very rough surfaces, the line-of-sight coverage means that there may be shadowing effects where part of the surface is not covered. This would render an anticorrosion coating useless, but it is not necessarily detrimental to antiwear coatings. For substrates of intermediate roughness, IBAD coatings tend to produce a smoother surface. In some rare cases and with specific processing parameters, the surface is roughened by an IBAD film, usually for low-melting-point metal films.

Advantages and Limitations

The IBAD process is a hybrid of PVD and ion implantation. It combines the advantages of both techniques, while eliminating most of the disadvantages of each. Table 4 lists the advantages and limitations of IBAD.

Table 4 Advantages and limitations of ion-beam-assisted deposition

Advantages, achievable benefits
Low deposition temperature
High adhesion

Control of stress level
Bulk density achievable
Control of microstructure (nanocrystalline; metastable crystalline or amorphous; textured; and epitaxial, for some materials)
Reproducible
Precise modulation of composition with depth
Highly versatile for metals, ceramics, semiconductors, dielectrics
Limitations
Moderately higher cost than physical vapor deposition
Line-of-sight processing
Technology in commercial infancy (limited vendors)

Even polymers with low melting points can be coated, because the deposition temperature can be maintained between room temperature and nearly 100 °C (210 °F). The properties of adhesion, stress, and density are superior to those of PVD films, and there is a high degree of control over the microstructure. Depending on the deposition parameters, films can be deposited as:

- Nanocrystalline
- Amorphous
- Textured crystalline or epitaxial (for some materials)
- Metastable crystalline

Finally, the composition, or crystalline phases, can be precisely modulated as a function of thickness to produce functionally gradient materials with properties such as graded hardness, coefficient of thermal expansion, refractive index, density, tensile strength, and stress.

Applications

In order to place IBAD processing in the proper context with respect to potential applications, examples of current and projected IBAD uses are described below. Applications are discussed in the areas of optical films, oxidation- and corrosion-protection coatings, and tribological coatings. Applications are quite extensive in the optical thin-film industry, where the primary advantage offered by IBAD is film densification. Refractive index stability and freedom from environmental degradation are thus direct benefits of using the IBAD process in these applications. Research in the area of wear- and corrosion-resistant coatings for metals and ceramics is in an early development stage.

Films deposited using dry, benign, energetic deposition techniques are also attractive for replacing wet electrochemical processes, such as chromium and cadmium plating, that can pollute the environment. As a result of research already conducted, corrosion and wear problems involving planar and cylindrical geometries of parts less than 1 m (40 in.) in size can already be addressed technically using these energetic-deposition techniques. The issue that needs further attention,

then, is how each technique and the economics thereof relates to the scale-up of specific applications and associated geometries.

Optical Films. As already stated, the IBAD process was promoted earliest by those workers interested in optical thin films. This involved, in turn, two kinds of applications: those in which densification is the primary concern and those in which graded refractive index profiles are required.

For applications involving densification, low-energy argon or oxygen ions are typically used to bombard the optical thin films during deposition (Ref 16). As a result, the density is increased, sometimes up to that of the bulk material. The primary attraction is not necessarily that the refractive index is increased to near-bulk values, but that the index value is stable under humidity and temperature variations, because there are no voids or pores in the film that adsorb water vapor. This simplifies optical-coating design and promotes better control and reproducibility in the fabrication process. Another benefit of using low-energy ions is that adhesion to the substrate is improved, which also helps to increase production yields.

The IBAD process is just starting to be used to fabricate graded index coatings for antireflection coatings, reflection filters, and mirrors (Ref 115). Some of these devices can be tens of microns thick, which means that stress control becomes very important. In general, low energies are desired for the deposition of optical films to reduce absorption caused by radiation damage.

Ion-Beam Deposition. Several groups are depositing diamond-like carbon (DLC) by either direct ion-beam deposition or sputter deposition of carbon in the presence of ion bombardment (Ref 90). Using a Kaufman-type ion source, methane is introduced into the plasma and, at energies between 100 and 1000 eV, DLC is deposited at rates between 0.1 and 1 nm/s (1 and 10 Å/s). Applications include hard, protective coatings for optics and windscreens on vehicles. Although DLC absorbs strongly in the visible range, coatings that are between 20 and 200 nm (200 and 2000 Å) in thickness remain transparent enough to be used as protective transmission coatings. As of 1994, commercial sources are available to produce these coatings over reasonably large areas (200 mm, or 8 in., in diameter). The advantages of these coatings include low porosity, high scratch hardness, and high adhesion to most substrates.

Aqueous Corrosion. The first industrial application of IBAD for purposes of wear or corrosion resistance appears to be the coating of electric razor screens with titanium nitride (Ref 7). In this case, the choice of IBAD processing was dictated by both the superior adhesion of the films and a decreased number of pin holes, combined with low-temperature deposition on 316 stainless steel substrates. Because IBAD films are dense and have few pin holes, they are attractive for corrosion-protection applications.

Only a limited number of studies on the corrosion behavior of IBAD coatings have been made, but the early results look promising. Platinum, titanium carbide, titanium nitride, boron, diamond-like carbon, chromium nitride, boron nitride, chromium oxide, silicon nitride, and silicon coated on metals using the IBAD process provide excellent corrosion resistance (Ref 7, 8, 9, 43, 45, 116).

One company (Ref 13) has set up a processing line that coats steel sheet continuously with aluminum, titanium nitride, or aluminum oxide for decorative panel applications. Figure 3(b) depicts the apparatus. Part of the cost of the process is recovered by the use of inexpensive steel substrate and coating materials. The resulting films are adherent and more ductile than bulk materials, because of the microcrystalline or amorphous structures. Therefore, they can yield with the metal sheet so that some working of the metal should be possible after the coating is applied.

High-Temperature Oxidation. Work on achieving oxidation protection with IBAD coatings is also very new. Only a few results are in the literature describing the use of chromium nitride (Ref 100), titanium nitride (Ref 100), and silicon nitride (Ref 76) to protect titanium alloys. This seems to be a promising area for further research.

Ion-Induced Chemical Vapor Deposition (CVD). Several researchers have used reactive IBAD (mode 3 of Table 1) to produce unique hydrocarbon or ceramic films (Ref 117). In this process, a gas is introduced into the chamber, the substrate is cooled to induce condensation of the gas, and an ion beam strikes the surface. During the process, hydrocarbon bonds are broken, volatile species are released, and a coating is produced. For silicone oil vapor, the films can range from very low friction solid lubricants to very hard, corrosion-resistant silicon oxycarbide (SiO_xC_y) coatings, depending on the arrival ratio of ions to vapor-condensed atoms. This process is similar to CVD, in which the high temperature of the substrate provides the energy to initiate chemical reactions that are responsible for film formation. In

the ion-beam case, the same or similar reactions can be beam-induced at room temperature, opening the possibility of depositing CVD-like films on polymers and other temperature-sensitive substrates.

Friction and Wear. The IBAD process is being used to deposit solid-lubricant coatings, such as molybdenum disulfide. Advantages are that the coatings adhere to the substrate and have a longer lifetime as a result of densification (better coherence) (Ref 87, 118).

Hard coatings, such as titanium nitride, are by far the most extensively studied (Ref 1). The hardness of these coatings can be varied over a large range by microstructure control (Ref 55). The ductility of these films, even for the highest hardness, is much larger than that for bulk material or CVD titanium nitride films. Boron nitride is also a coating that is readily deposited by IBAD and has good wear characteristics (Ref 119). The IBAD technique is the only one, as of 1994, that is capable of depositing cubic boron nitride that is theoretically as hard as diamond (Ref 72). Currently, molybdenum disulfide, titanium nitride, and ion-stimulated CVD of silicone are the most developed materials for tribological applications.

Future Trends

As a surface modification technique, IBAD is attractive because it retains the best features of PVD and ion implantation and eliminates the worst features. The application of IBAD films as wear- and corrosion-resistant coatings for metals and ceramics is just beginning. Because relatively thick coatings (i.e., many microns) of controlled composition and stress are achievable, it is expected that IBAD processing will be accepted into those application areas that currently use conventional PVD techniques without ion assistance.

Health and Safety

There are no special health concerns associated with these techniques. The considerations are identical to those for conventional electron-beam evaporation sources and sputtering targets. The techniques involve very little solid waste of benign elemental materials.

Arc Deposition

David M. Sanders, Joseph W. Glaser, and Steven Falabella, Lawrence Livermore National Laboratory

---

Introduction

THE VACUUM ARC is a form of electrical discharge that is sustained primarily on the electrons and ions that originate from the electrodes used to produce the arc. The value of using vacuum arc deposition to produce coatings stems from the copious quantity of ions of electrode material composition that are generated during the discharge. Because the output of the vacuum arc is highly ionized, it is possible to control both the trajectory of the coating material during its transit from source to part and the energy with which ions impinge on that part. This level of control can be contrasted to competing vacuum coating technologies, such as electron-beam evaporation and magnetron sputtering, where the atoms of coating material travel from the source to the part to be coated in an electrically neutral state.

Adjusting the deposition energy can produce coatings that have greater density, purity, and adhesion. Under favorable circumstances, the quenching of ions can produce coatings with structures that have unusual properties, such as the extremely hard and smooth amorphous diamond coatings that will be described in this article. Although the use of ion trajectory control to improve coating properties has not been extensively explored, it has been used to overcome the major drawback of the cold cathodic arc process: the production of micron-scale particles of electrode material, or macroparticles. Macroparticle formation and the approaches used for removal are described in Ref 1, 2, and 3.

Due to the ion charge state, vapor produced by vacuum arc techniques is typically more reactive than that produced using evaporative or sputter techniques. This increased reactivity can lead to compound coatings in which better stoichiometry is produced when deposition occurs in the presence of a reactive gas. For instance, when compared with electron-beam evaporation and magnetron sputtering, the cathodic arc can produce stoichiometric titanium nitride over a much wider range of nitrogen partial pressures (Ref 4). This can be particularly important when depositing compound coatings on complex shapes.

The most widely used type of vacuum arc is a cathodic arc with a cooled cathode. Because the source material remains solid, it can operate in any orientation. This avoids the difficulties associated with the reactivity of liquid metals. Once the arc is initiated, it self-focuses into a small spot at which the heat and the electron flux are sufficient to vaporize and ionize the cathode material and liberate enough electrons to sustain the discharge. The arc currents are typically 100 A, whereas the ion currents fraction is approximately 10% of that.

Process Utilization

Arc sources can be classified according to the duration of operation, the type of electrode that provides the metal vapor, and whether the arc comprises discrete spots or is distributed over a larger area of the electrode. There are pros and cons associated with using each type of arc. For example, in a pulsed cathodic arc source, the arc duration is typically short enough that direct cathode cooling is not needed, which simplifies the design and makes it easier to change target materials. In addition, the confinement of the arc spot to the cathode surface is not problematic, because the short arc duration typically means that there is not enough time for the arc spot to leave the cathode surface. Short arc durations also permit deposition of materials, such as silicon, that are vulnerable to cracking because of relatively poor thermal conductivity, coupled with a negative resistivity coefficient with respect to temperature, which slows arc spot motion. However, pulsed sources that have low duty cycles also have correspondingly low integrated coating rates.

Continuous cathodic arc sources are typically sustained by a low-voltage, high-current power supply, such as an arc welding supply. In this arc mode, the arc spots that appear to move rapidly on the negative electrode are actually separate arcing events that occur in rapid succession. The rate of apparent motion of the arc spot(s) is a strong function of:

- Cathode composition
- The presence and composition of any working gases
- The component of any magnetic fields parallel to the cathode surface

Continuous cathodic arc sources typically provide higher coating rates, but the cathode must be designed to dissipate the heat generated by the arc. Because the heat is concentrated in a small spot, direct water cooling is usually required. This leads to difficulty in changing cathodes and limits the use of some low thermal conductivity materials. In addition, arc confinement is essential, because damage to support components and contamination of the coating can occur if the arc spot leaves the cathode surface. More details on arc initiation, confinement, and other aspects of cathodic arc source design are provided in Ref 1, 2, and 3.

The cold cathodic arc source typically produces droplets of cathode material (macroparticles). These macroparticles result from the extreme localized heating of the cathode, which is due to the high current densities that are found in cold cathode arcs (10^4 to 10^8 A/cm^2). Unless the macroparticles can be removed from the plasma stream, they become lodged in the coating and are usually considered to be defects.

Macroparticle Filtering. An extensive body of knowledge that describes the filtering of these macroparticles in cases where such defects are unacceptable is now available. Two useful sources are Ref 5 and 6. Although the design of macroparticle filters is also beyond the scope of this article, one example is shown in Fig. 1. Briefly, this approach uses magnetic fields in order to constrain arc-produced electrons to follow a curved path from cathode to workpiece. This sets up an electrostatic field that channels the ions through the filter. The macroparticles, however, follow straight-line trajectories into baffles and are stopped. Although there are numerous designs for such filters, they all lose at least half of the desired coating material during transit through the filter, which leads to a corresponding decrease in deposition rate.

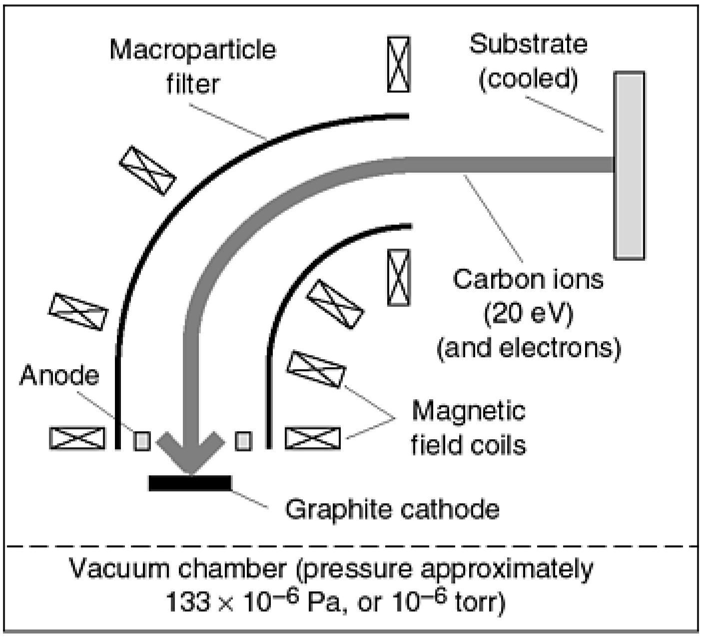

Fig. 1 Generic filter for removing macroparticles from a cathodic arc

A second general approach, which is appropriate in cases where a small number of macroparticles can be tolerated, is given by Coll (Ref 7). The cathode is placed behind a magnet structure that focuses the ion stream strongly at the coil location and then diverges outwardly toward the workpiece location. Arc confinement is provided by the magnetic field from the focusing coil (Fig. 2). The focusing action is thought to vaporize any macroparticles that pass through the plasma, reducing their number substantially. The source, however, requires a background gas pressure on the order of 1 Pa to operate, which can affect coating quality.

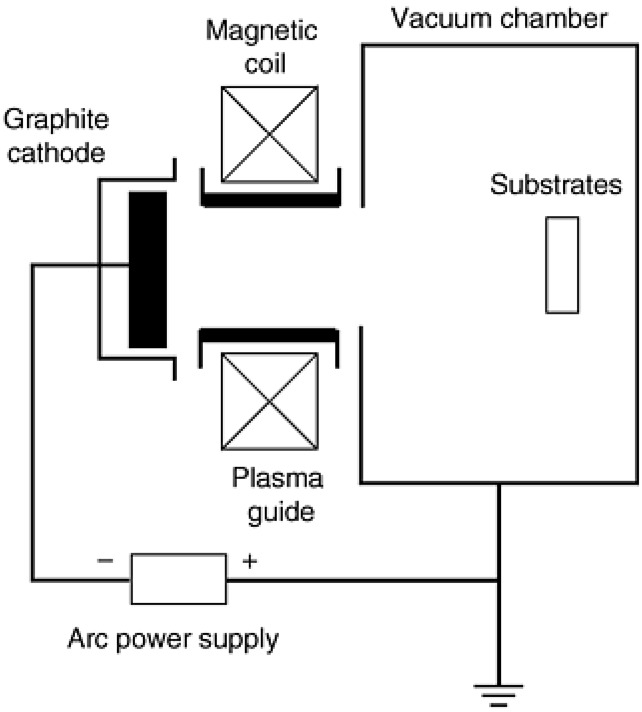

Fig. 2 Approach for reducing number of macroparticles from a cathodic arc

A third approach for avoiding macroparticles is to use an arc source that does not produce them. A broad class of such sources is based on a different type of arc, which is characterized by a much lower current density (~10 A/cm^2). This is about five orders of magnitude lower than that found in cold cathode arcs. The same arc currents are made possible because the arc is distributed over a much larger area of the electrode, which leads to the term ***distributed discharge arc*** (Ref 8). Although such distributed discharge arcs have been reported for both electrodes, most of the investigations to date have been on arcs that vaporize the positive electrode or anode.

Arc Source Types. Anodic arc sources can be classified according to the method by which ionization electrons are supplied (Ref 3). The sources can be hot filament (Ref 9), hollow cathode (Ref 10, 11, 12, 13), or cathodic arc (Ref 14, 15, 16). Typical configurations are shown in Fig. 3 and 4.

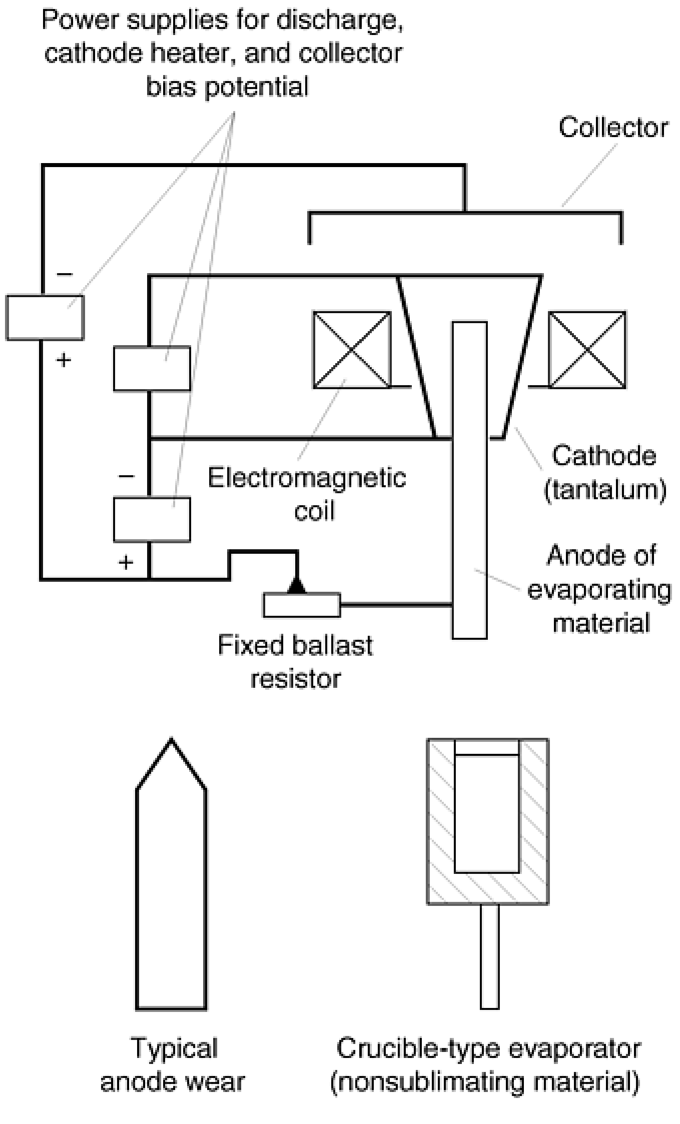

Fig. 3 Anodic arc device. Source: Based on Ref 11

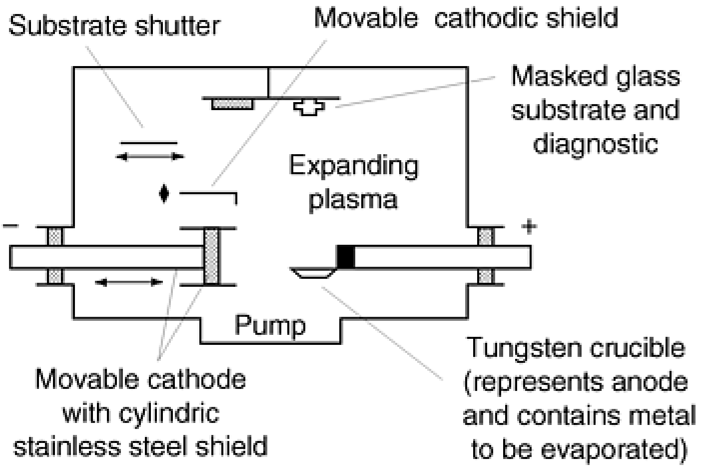

Fig. 4 Arc discharge apparatus. Source: Based on Ref 18

The hollow cathode arrangement described by Dorodnov (Ref 10, 11) operates as a self-sustaining arc (Fig. 3). The material to be evaporated, which forms the anode, is located within a hollow cathode. The anode material evaporates under a low-voltage (10-50 V), high-current (~100 A) electron beam, which, along with electrons trapped within the hollow cathode, ionizes the vapor (Ref 7). Because voltages are relatively low, sputtering of the cathode is minimized. Dorodnov reports using this source for chromium, carbon, magnesium, titanium, molybdenum, silicon, germanium, and copper (Ref 11). Saenko (Ref 13, 17) used this source to process substrates with diameters up to 150 mm (6 in.). Derkach and Saenko (Ref 12) incorporated a divergent plasma lens, which resulted in a 150 mm (6 in.) diameter copper vapor plasma with an ion-component beam uniformity of about 2%. The deposition rate was reported to be approximately 100 nm/s (4 μin./s).

The approach taken by Ehrich et al. (Ref 16) used a cathodic arc to supply ionization electrons to the vapor stream (Fig. 4). In this configuration, copper and zinc films were deposited at rates between 23 and 65 nm/s (0.9 and 2.6 μin./s) (below that reported by Dorodnov). The films were found to be homogeneous, with film purities up to 99.9% (Ref 14). The researchers determined an ion temperature of approximately 0.7 eV at plasma densities between 10^{15} and $10^{17}/m^3$ (Ref 18). These films were found to have densities that were lower than bulk material densities by 0 to 10%. Overall, this technique produced compact films with physical properties that were close to those of the bulk materials.

The use of shielding eliminated contamination of the deposited material that was due to cathodic bombardment (Fig. 4). This type of contamination, along with source contamination from the containment vessel, are issues that need to be addressed when designing this arc source. Dorodnov (Ref 11) suggests using a hearth made of the same material as that being evaporated. For vapors originating from sources that sublimate, such as carbon, actively cooled supports outside the heat-affected zone have been used. However, the relatively low evaporation rate (compared with the cathodic arc technique), short run times, and issues associated with filament lifetime have hindered the commercial development of the anodic arc source.

The utility of the anodic arc lies in its ability to generate a flow of predominant monocharged ions without macroparticles. This flow of single-charge-state ions facilitates deposition by allowing greater control of deposition energies. This can be contrasted with the cathodic arc, which produces multiple-charge-state ions. Deposition onto a biased substrate in the presence of multiple-charge-state ions may result in sputter damage to the substrate. Because the charge-state distribution in the anodic arc is nearly single valued, substrate sputtering can readily be controlled. Similarly, the monocharged nature of the anodic-arc-generated ions simplifies stream focusing and control. This facilitates usage in materials processing and as a plasma source in space research.

The rate of deposition, using arc technology in a laboratory environment can range from several angstroms/minute to 0.1 mm/s (4 mils/s) depending on the specific process chosen and the coating quality required. High-quality optical coatings of aluminum oxide and zirconium oxide have been produced using a cathodic arc with a macroparticle filter at rates of 35 μm/h and 20 μm/h, respectively (Ref 19).

Processing Parameters

Besides the typical processing variables that characterize other vacuum deposition processes, vacuum arc deposition offers additional control of the arrival energy of coating ions. In the case of conductive or semiconductive coatings, this bias can be controlled using a direct-current power supply. The level of bias is limited at the upper end by thermal considerations, because the part being coated is heated by condensing ions. Many of the trends that exist for other ion plating processes also apply to vacuum arc deposition. The main difference is ion composition. In the case of vacuum arc deposition, the ions are the particles that form the coating. With most other ion plating processes, the majority of ions involved are ionized gas molecules. This distinction can become important when coating parts that have complex shapes during a reactive process.

Properties of Deposited Materials

Vacuum arc deposited coatings tend to have compressive stress that is due to the impact energy of ions on the part being coated. Titanium nitride can be deposited on cutting tools at relatively low temperatures and still maintain excellent adhesion and cutting characteristics.

The deposition of carbon films by the cathode arc presents a particularly interesting example. The carbon films produced by the deposition of ions of roughly 20 eV energy have a hardness of 40 to 100 GPa (6 to 15 × 10^6 psi), a modulus of 300 to 500 GPa (45 to 75 × 10^6 psi), and an optical transmission of 0.5 to 50 μm. The coating is amorphous, with primarily sp^3 bonding characteristic of crystalline diamond. It has a low coefficient of friction, 0.02 to 0.1, and a hydrogen content of less than 0.1%. This is an example of a material that can only be produced by the condensation of energetic ions.

Process Advantages, Limitations, and Applications

One advantage of vacuum arc technology is the relative safety afforded by the low-voltage power supplies, compared with the high-voltage supplies necessary for sputtering and electron-beam evaporation. A second advantage is the relatively benign environmental impact of this technology, compared with competing means for depositing refractory metals, such as chemical vapor deposition.

All types of vacuum arc deposition processes share the same potential for making commercially valuable coatings. However, cold cathode sources produce macroparticles that may need to be removed in certain applications. Although hot sources avoid the macroparticle problem, they have other design constraints that must be evaluated, such as crucible reactions and heating and cooling cycle times.

As of 1994, the most important applications of coatings produced by the vacuum arc process involve the reactive deposition of nitrides for extending the useful life of cutting tools, reducing wear and friction in parts of machines, and providing a gold color in certain decorative applications. In particular, the cold cathode cathodic arc and one form of anodic arc have been used extensively in commercial environments for coating cutting tools with titanium nitride.

Future Trends

As with any emerging technology, the vacuum arc will displace existing approaches only when a compelling advantage can be demonstrated. Situations in which extremely good adhesion is desired can represent opportunities for the vacuum arc process. Adhesion of copper to glass with bond strengths sufficient to fracture the glass during a pull test have been reported (Ref 20). Applications that require an efficient process for rapidly depositing refractory metal coatings can be opportune for the cathodic arc. This technology should be particularly attractive in situations where the presence of a small number of macroparticles does not present difficulties. It may also be attractive for producing hard, amorphous diamond coatings for various tribological applications. There are also numerous potential applications for corrosion-barrier coatings. Examples include coatings on fibers used in metal-matrix composites and protective coatings for turbine blades (Ref 1). Filtered arcs can produce very high-quality ceramic coatings at high deposition rates (Ref 21) because of the high reactivity of the ions.

Ion Implantation

James K. Hirvonen, U.S. Army Research Laboratory; Bruce D. Sartwell, U.S. Naval Research Laboratory

Introduction

ION IMPLANTATION involves the bombardment of a solid material with medium-to-high-energy ionized atoms and offers the ability to alloy virtually any elemental species into the near-surface region of any substrate. This near-surface alloying can be performed irrespective of thermodynamic criteria such as solubility and diffusivity. These advantages, coupled with the additional possibility of low-temperature processing, have prompted explorations into applications in which the limitations of dimensional changes and possible delamination of conventional coatings are a concern. In almost all cases the modified region is within the outermost micrometer of the substrate, often only within the first few hundred angstroms (i.e., microinches) of the surface. Maximum. concentrations of several tens of atomic percent are usually achievable, although this depends on the ion-substrate combination.

During implantation, ions come to rest beneath the surface in less than 10^{-12} s. This rapid stopping time produces an ultrafast quench rate in the wake of the stopping ion. This allows many novel surface alloys or compounds unattainable by conventional (equilibrium) processing techniques to be produced at room temperature. These include substitutional solid solutions of normally immiscible or low-solubility elements. Such highly metastable and amorphous alloys often possess unique physical and chemical properties. Ion implantation has been used extensively in the semiconductor industry since the 1970s to introduce dopant atoms reproducibly into silicon wafers to modify electrical performance, and it is used routinely in several stages of integrated circuit production. It allows fabrication of electronic devices not producible by any other process, largely due to the highly reproducible control of dopant concentration levels over several orders of magnitude as compared to doping by thermal diffusion. Since the mid-1970s, the use of ion implantation and other closely related ion beam processes has expanded into a number of diverse application areas in the international research and development community. However, only relatively recently have applications in the industrial sector developed.

Research interests in metals have expanded from the initial friction and wear studies to include other areas, such as corrosion, oxidation, fatigue, and studies of basic metallurgical mechanisms (Ref 1, 2). In addition to metals, polymers and ceramics have been studied with the principal aims of increasing the conductivity of polymers (Ref 3) and improving the fracture toughness and tribological properties of ceramics (Ref 4).

On a commercial scale, the applications for ion implantation of metals continue to increase, at present mainly for antiwear treatment of high-value components. A large number of industrial trials have involved the implantation of nitrogen for improving the wear resistance of coated and uncoated tools and other precision components. Implantation appears to be an attractive technique for treating industrial components by stabilization of the microstructure (preventing a change in wear mode), by transformation to a wear-resistant mode, or by chemical passivation to prevent a corrosive wear mode (Ref 5).

Fundamentals of the Ion Implantation Process

Figure 1 shows a schematic view of the path of an individual ion as it loses energy in a material, thereby forming a shallow surface-modified region. As indicated in the figure, the ion does not travel in a straight path to its resting place, due to collisions with the target atoms. Target atoms are displaced from their lattice sites with sufficient energy that they

can themselves displace additional target atoms, resulting in a collision cascade. These individual collisions with lattice atoms within a single collision cascade are shown in the insert at the bottom of Fig. 1.

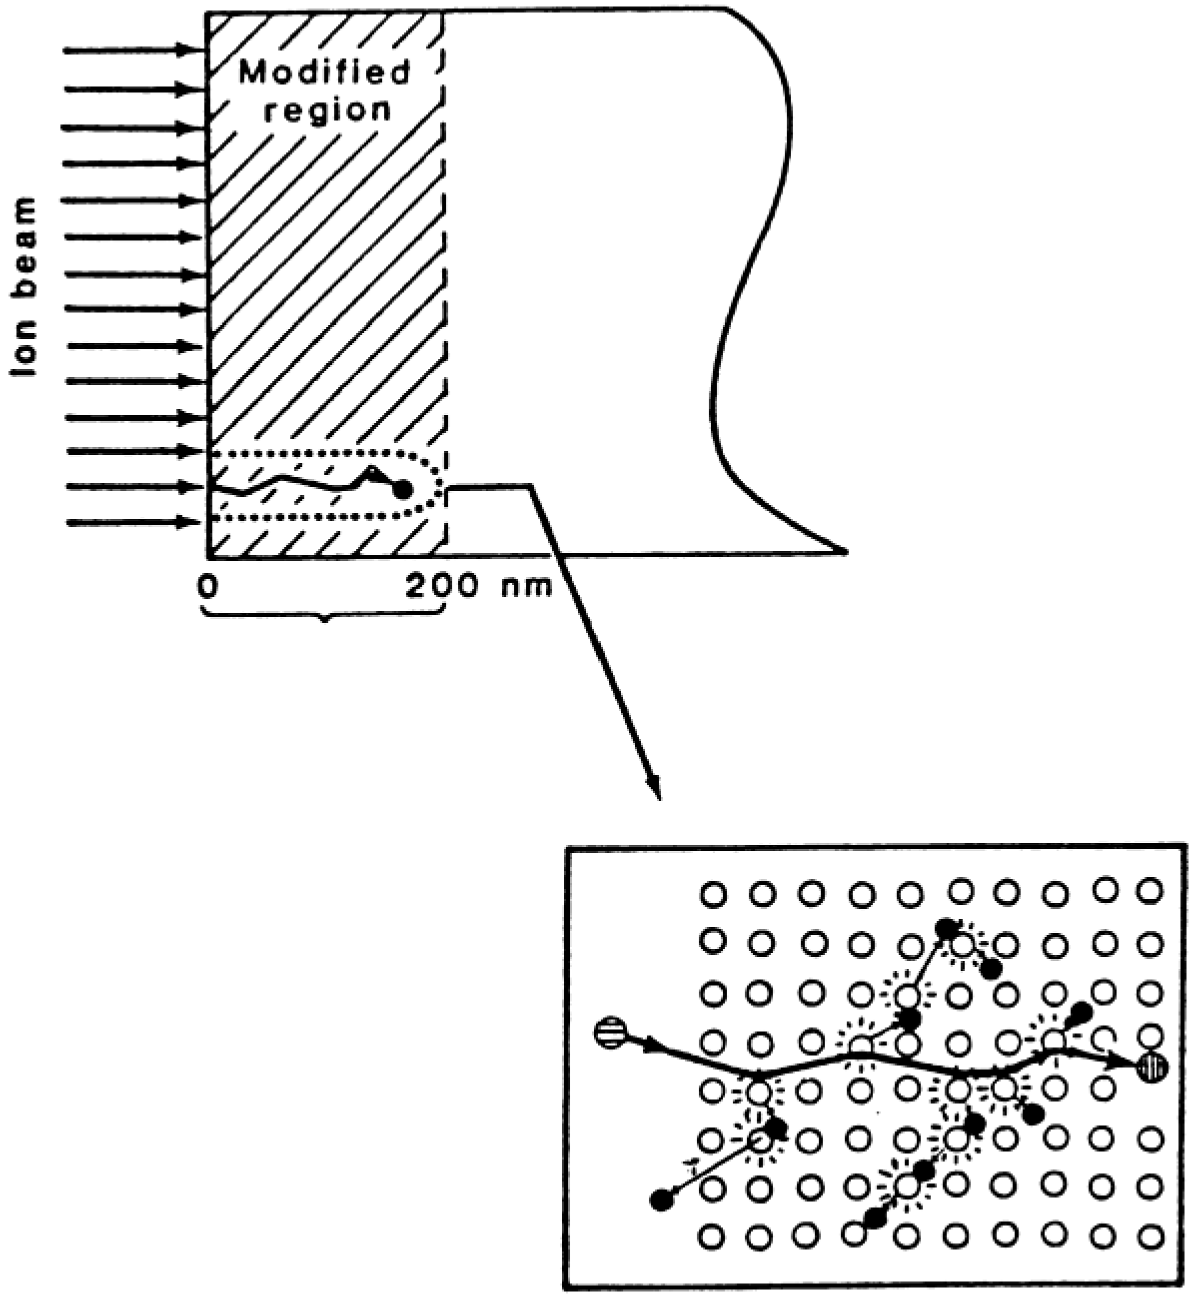

Fig. 1 Schematic view of ion implantation process (top) and depiction of the interactions with substrate atoms in a single collision cascade (bottom). Source: Ref 6

The actual integrated distance traveled by the ion is called the range, *R*. The net penetration of the ion into the material, measured as projected onto the original trajectory, is called the projected range. Ion implantation is a random process, normally producing a Gaussian-shaped impurity depth profile whose centroid is defined as the average projected range, R_p. The statistical nature of the scattering process gives rise to a distribution of ions around the projected range depth. The average fluctuation (standard deviation) in the projected range is called the range straggling, ΔR_p.

The ion energy directly affects both the range and the distribution of the implanted ions in a given substrate. At higher energies a greater spread in the ion distribution (a greater ΔR_p) is realized for a given dose, which is the number of implanted ions per unit area of the surface of the material (areal density), usually expressed as ions/cm^2. The areal dose (also called fluence) is a convenient unit of ion implantation because the actual volume concentration associated with an

implantation is a function of ion species, ion energy, and substrate material. For metals, beneficial doses can span the range of 10^{15} to 10^{18} ions/cm^2, depending on the application (see the section "Applications" in this article). The determination of the implanted atomic concentration (atoms/cm^3) requires relating the areal density of implanted atoms to their spatial extent. At low ion doses, the implant profile can normally be approximated as a Gaussian distribution centered about the projected range. Accordingly, the width of the distribution can be expressed by the standard deviation of the Gaussian distribution, ΔR_p. The expression for the peak concentration (N_p) of a Gaussian distribution is given in terms of the applied dose (N_A) and range straggling as:

$$N_p(atoms/cm^3) = \frac{N_A(atoms/cm^2)}{\sqrt{2}p\Delta R_p(cm)}$$

Figure 2 shows the projected range and range straggling for nitrogen ions implanted into iron versus the initial ion energy. The range distribution is shown as a Gaussian distribution with R_p and ΔR_p characteristic of the ion energy. For a given energy, a lighter ion such as nitrogen will penetrate farther and will undergo more large-angle scattering (leading to a broader distribution) than would a heavier ion such as chromium. Each implanted ion can displace hundreds to thousands of lattice atoms as it travels into the substrate surface. This results in a net damage distribution that is also normally Gaussian-shaped but is situated closer to the surface than the range distribution, because each ion creates damage between the surface and its final resting place in the lattice. This lattice damage can render ionic or covalently bonded lattices amorphous during implantation, whereas a nondirectionally bonded (metal) substrate can either self-anneal, with no residual damage, or else can retain point defects or extended defects (e.g., dislocations) resembling those of a heavily work-hardened metal or alloy. Ion implantation of certain species (e.g., phosphorus in iron) can stabilize amorphous structures in metals in a manner analogous to bulk rapid quench techniques such as splat cooling.

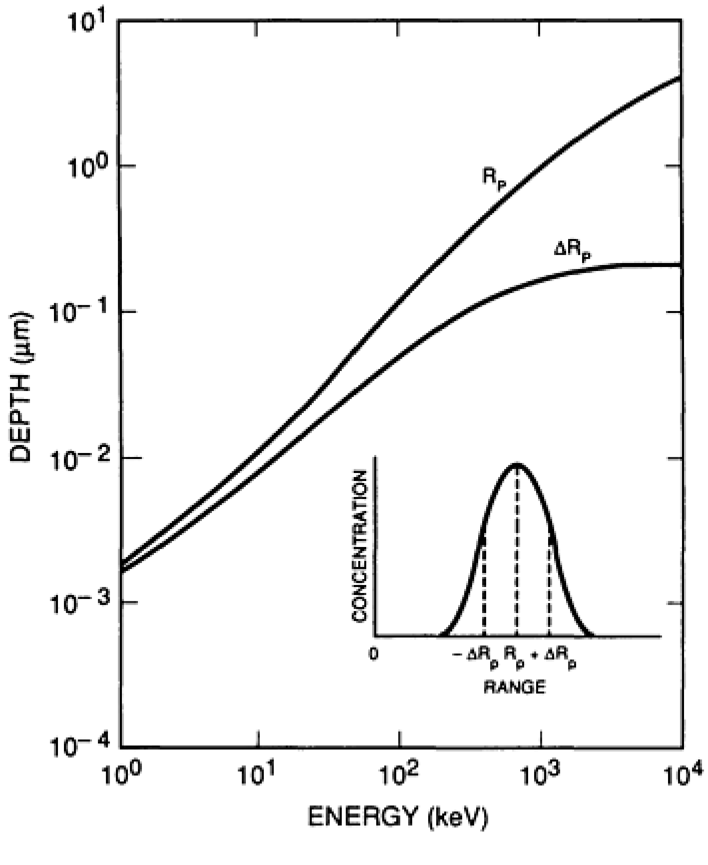

Fig. 2 The projected range, R_p, and range straggling, ΔR_p, of nitrogen ions implanted into iron vs. the initial ion energy. Source: Ref 6

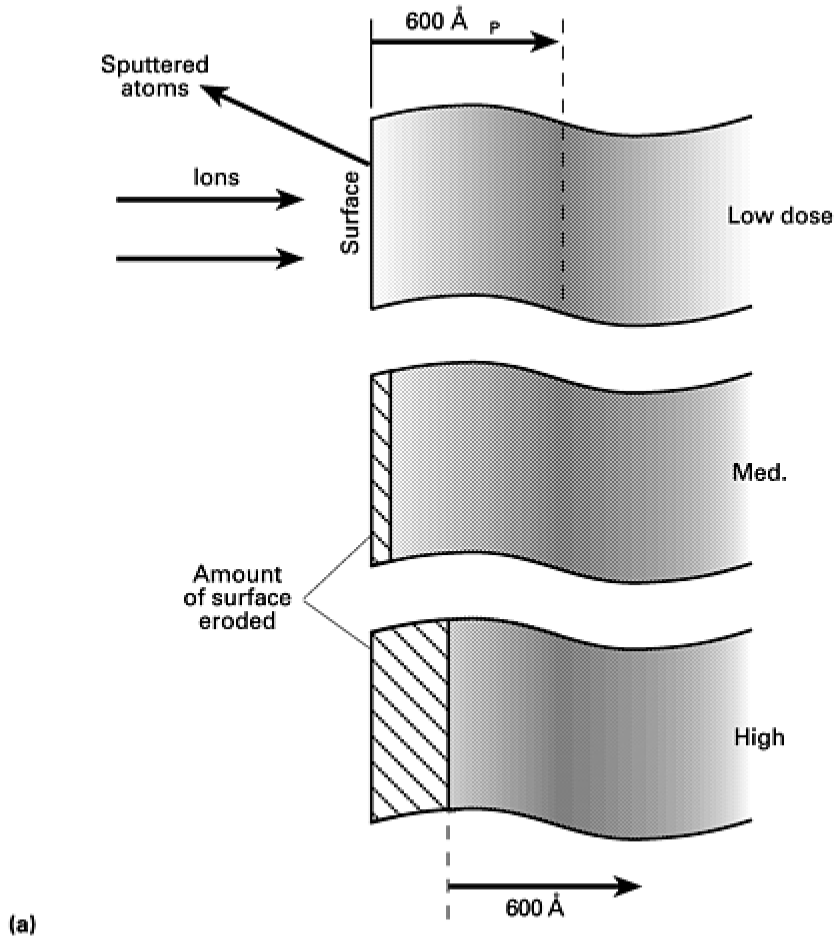
As an ion penetrates a material, there is a certain probability that a surface atom will be ejected from its lattice site, because there is some momentum directed back toward the surface in a collision cascade that allows an atom to receive sufficient energy to overcome its surface-binding energy. This phenomenon is called sputtering and is analogous to the

erosion of materials by the impact of high-velocity particles. The ratio of the number of substrate atoms ejected per incident ion is commonly termed the sputtering coefficient, *S*. As a general rule, for a given substrate material, *S* will increase with increasing ion mass and will increase sharply at more oblique angles of incidence. For a given ion at normal incidence, *S* depends principally on the surface binding energy of the material, which can be related to its heat of sublimation. Therefore, for a given ion, *S* will decrease with increasing heat of sublimation for the substrate material. Values for *S* can range from less than 1 for the case of a light ion incident on a heavy substrate (e.g., nitrogen implanted into iron) to greater than 10 for very heavy ions in a lighter substrate (e.g., tantalum ions implanted into iron).

Figure 3(a) shows a schematic view of the evolution of the concentration depth profile of an implanted element for the case where *S* is greater than unity. In this particular example, the projected range of ions is shown as being 600 Å. This closely represents the implantation of 200 keV chromium ions into steel (or iron). At a low dose, the distribution is essentially Gaussian, as discussed earlier, and there is a low concentration of implanted atoms at the surface. However, as the dose increases and the surface is eroded, an increasing number of previously implanted atoms are exposed on the surface, and these near-surface atoms are subject to sputtering just as the target atoms are.



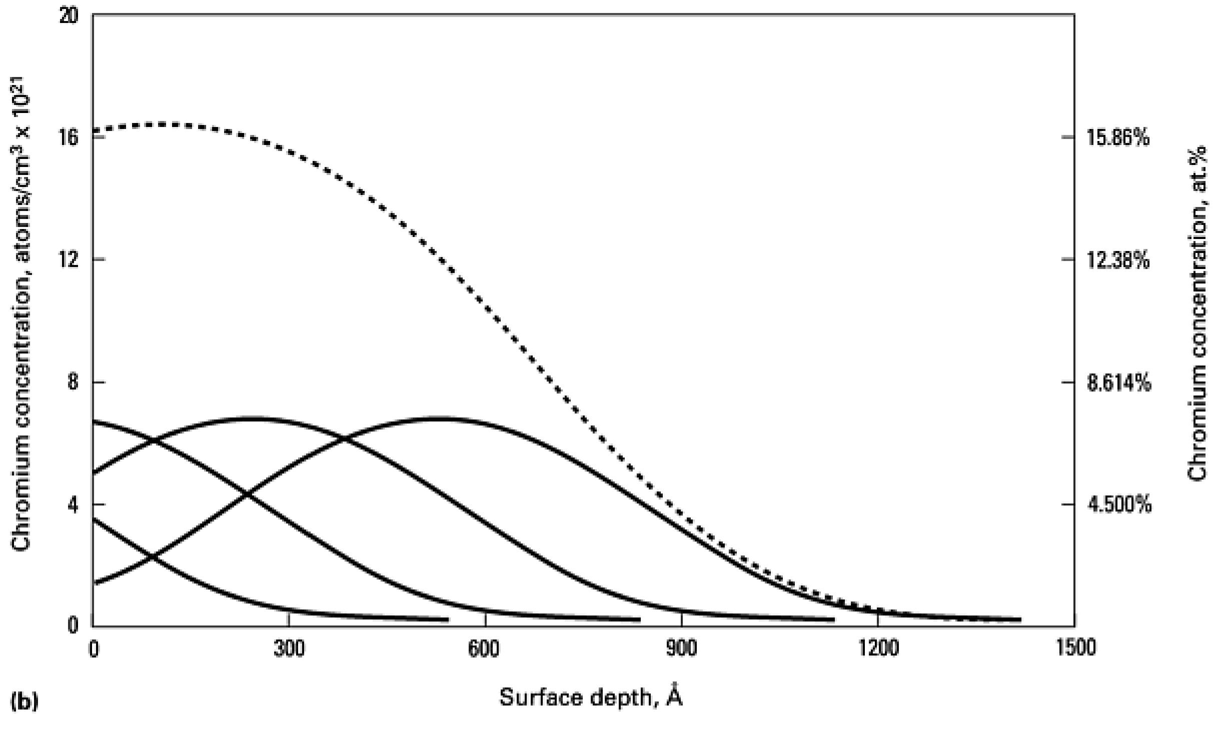


Fig. 3 (a) Schematic view of the development of implanted impurity profiles from low to high doses. Source: Ref 6. (b) Computer simulation of four consecutive 5 × 10^{16} Cr/cm^2 implantations at 200 keV energy into iron, accounting for sputter erosion of the surface for each implantation. The sum of the four individual profiles (the curve of dark squares) yields a distribution with a maximum near the receded surface. Source: Ref 7

At a particular dose level, called the saturation dose, a steady-state situation is established whereby the rate of removal of previously implanted atoms is equal to the arrival rate of energetic ions. The peak concentration of the implanted element distribution approaches the surface, as shown in Fig. 3(b), as the implanted dose increases and approaches the saturation dose. Generally, the maximum surface concentration of the surface element is equal to 1/(*S* + 1). For the example of 200 keV chromium ions in iron, *S* has a value of about 5 atoms/ion, so the maximum surface concentration of chromium would be about Å or 16 at.%. In this case, the steady-state dose would be approximately 2×10^{17} ions/cm^2. This behavior is quantitatively predicted by analytic models, as shown in Fig. 3(b), which illustrates the sputter removal of the surface and the surface enrichment of the implanted species resulting from successive (lower-dose) implantations.

For certain ion-substrate combinations and concentrations, chemical reactions with molecular species present in the vacuum chamber can be induced. An excellent example of this is titanium implantation into steel. At high titanium doses, highly reactive titanium atoms become exposed on the surface and react with the residual CO and CO_2 hydrocarbon molecules normally present in the vacuum chamber. When the partial pressure of carbon-containing molecules is 1×10^{-6} torr or higher, the implantation results in the formation of an amorphous Fe-Ti-C surface layer that has been shown to reduce friction and wear greatly (see the section "Applications" in this article). When the background pressure in the chamber is less than 10^{-6} torr, there are insufficient carbon-containing molecules to produce the carburized surface layer. A consequence of these surface chemical reactions is a considerably reduced sputtering yield because of the increase in the surface binding energy due to compound formation. This phenomenon has been exploited by deliberately introducing gases into the vacuum chamber during implantation. For example, for tantalum implantation into steel, where normally *S* is approximately 10, the introduction of oxygen into the chamber to 1×10^{-5} torr (partial pressure) reduces the sputtering by more than a factor of three, due to the formation of an almost pure Ta_2O_5 layer at the surface for a tantalum dose of 2×10^{17} ions/cm^2.

Advantages and Limitations of the Ion Implantation Process

Table 1 gives the advantages and limitations of the implantation process for surface modification.

Table 1

Advantages	**Limitations**
Produces surface alloys independent of thermodynamic criteria	Limited thickness of treated material
No delamination concerns	High-vacuum process
No significant dimensional changes	Line-of-sight process
Ambient-temperature processing possible	Alloy concentrations dependent on sputtering
Enhance surface properties while retaining bulk properties	Relatively costly process; intensive training required compared to other surface treatment processes
High degree of control and reproducibility	Limited commercial treatment facilities available

The ability to use ion implantation to inject alloying species forcibly into the near-surface region of virtually any material, independent of thermodynamic criteria such as solid solubility and diffusivity, is an important feature for applying the process to basic metallurgical studies. For example, one can prepare supersaturated or metastable systems and study their return to equilibrium by suitable thermal annealing and observation of their microstructure. This application of ion implantation technology has been exploited to measure low-temperature diffusion, solid solubility, and trapping phenomena in alloys (Ref 8).

Because implanted near-surface layers are an integral part of the substrate, without an interface, they can sustain very high stresses without the occurrence of the delamination that plagues certain types of coatings, especially those deposited at low temperatures.

Strictly speaking, ion-implanted surfaces do experience a dimensional change, albeit on a microscopic level (typically less than 0.1 μm, or 4 μin.), due to erosion caused by sputtering. In addition, at doses greater than 10^{17} ions/cm^2 some degree of surface roughening may occur due to sputtering effects. The accumulation of insoluble implanted gaseous species may also cause surface blistering. However, from a practical engineering perspective it is normally accurate to portray implantation as a process that does not significantly affect substrate dimensions or topography.

Implantation processing can be carried out at near-ambient temperatures, but this depends on the thermal mass of the substrate, the relative ion beam power (W/cm^2) being delivered to the substrate, and, critically, the ability to conduct heat away from the substrate, because radiative cooling is negligible at desired processing temperatures. The latter factor depends on the thermal conductivity between the substrate and the fixturing to which it is attached in the vacuum chamber.

The limited thickness of the implanted layer (typically less than a micrometer) is an intrinsic limitation of the ion implantation process and is dictated by the physics of the energy loss processes. For applications requiring thicker surface-modified regions, it may be desirable to employ hybrid ion beam/coating processes. See the article "Ion-Beam-Assisted Deposition" in this Volume.

Ion implantation is intrinsically a vacuum process requiring background pressures of 10^{-5} torr or less. Manipulation of components, through the use of vacuum-compatible fixtures, and thermal heat sinking are often required to ensure both uniform dosage and adequate cooling to dissipate the imposed heat load on the component due to the energetic ion beam. This requirement poses some limitations on the types of substrates that can be implanted.

Directed beam ion implantation is a line-of-sight process. It lacks the so-called throwing power of certain other plasma-based coating processes, which can better treat irregular surface features due to multiple scattering of atoms (ions) within the higher-pressure plasma.

As discussed previously, implanted atoms are always in an intimate mixture with atoms of the original substrate, thus forming a surface alloy. However, because of sputtering, desired alloy concentrations may be unattainable for many ion-substrate combinations.

Equipment and Processing Times

As of 1994, ion implantation processing technology is still a relatively specialized process compared to many conventional surface treatment techniques. Most implanters in use today for metals applications require highly trained operators because they were originally built for processing silicon wafers, which required very rigorous process control, Such implanters have been subsequently modified for more general use. Typically, the cost of processing components in these types of systems is higher per unit area than for conventional coatings or surface modification techniques.

Figure 4 is a schematic of a typical medium-current semiconductor implanter adapted for metals implantation. This implanter uses a versatile ion source capable of producing heavy metal ion beams of most elements by introducing metal vapor or a volatile compound of the element into the plasma discharge of the ion source. After the positive ions are

extracted from the ion source, they are mass analyzed by being passed through a 90° sector magnet. They are subsequently accelerated to their ultimate energy (typically 30 to 200 keV), then directed and scanned over the target.

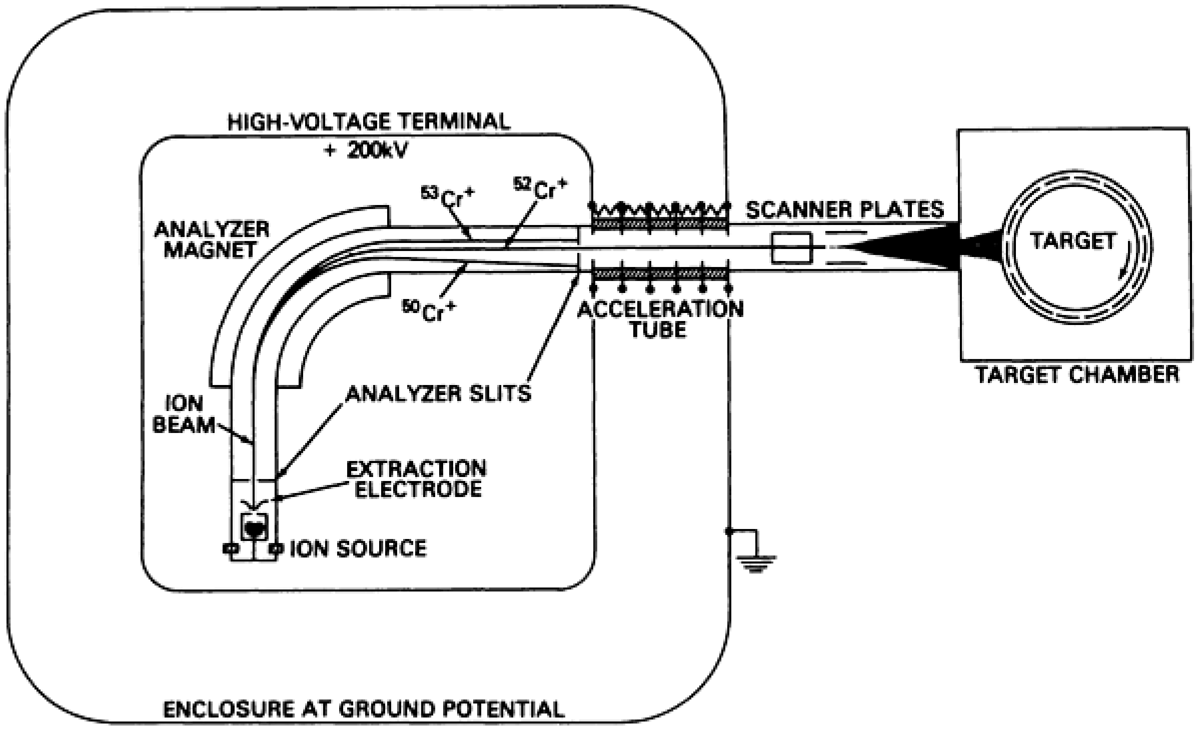

Fig. 4 Schematic of Naval Research Laboratory implantation facility for surface alloying. Mass analyzed $^{52}Cr^+$ beam being transported for the implantation of bearing components to improve their corrosion resistance. The footprint of this machine is about 2.5 × 4 m. Source: Ref 9

An implanter of this design can produce from 1 to 10 mA (6 to 60 × 10^{15} ions/s) of positive ion beam, depending on the size and design of the ion source. At an energy of 100 keV, this beam current corresponds to energy densities of 100 to 1000 W in the envelope of the beam. It is therefore imperative to either spread this beam energy over a large area or to ensure good thermal conductivity of the substrates to a heat sink in order to limit beam heating. Both of these approaches are used in practice. The actual processing times can be determined by knowing the area to be treated, the ion current intensity, and the geometrical factors involving manipulation of the substrates through the beam to ensure uniform surface coverage. For a stationary substrate, an average beam current of 1 mA will deliver 10^{17} ions in about 15 s, a typical ion dose required for each square centimeter of the substrate. The actual implantation time will therefore depend on the area over which the beam is scanned to ensure both dose uniformity and adequate cooling. Larger batch sizes help reduce beam heating and improve the economics of processing.

Several approaches have been taken to simplify and reduce the cost of implantation treatments, such as using alternative ion source designs when using mass analysis (Ref 10). Large-scale dedicated systems have also been built without mass analysis to implant nitrogen into fairly massive components. One such unit in the United Kingdom has a processing chamber that is more than 2 m in diameter and 2 m in length and has been used to implant components such as automobile camshafts, dies, and plastic molds weighing more than 500 kg. A similar system has been constructed in the United States (Ref 11). Another large-scale non-mass-analyzed unit, which has a target platen 2 ft in diameter, has been built and installed in a U.S. Army Aviation Depot for high-current (25 mA) nitrogen implantation of metal cutting tools (Ref 12).

A second approach, called plasma immersion ion implantation (PIII) or plasma source ion implantation (PSII) (Ref 13, 14), involves immersing the object to be implanted in a plasma and pulsing it to a high negative voltage (50 to 100 kV), thereby extracting the ions from the plasma. Because the plasma completely surrounds the component(s), the line-of-sight restriction of conventional ion implantation is greatly alleviated, with the result that more complex geometries can be implanted and/or less complicated fixturing can be used. A current restriction to this technique, however, is that it is limited to readily ionized plasma species (mainly gaseous elements such as nitrogen) and conducting substrates.

A third approach is to produce heavy ion beams from solids by using a metal vapor vacuum arc (MEVVA) discharge in a pulsed mode (Ref 15), yielding non-mass-analyzed ion beams extracted from a broad beam source (up to 50 cm in diameter). These sources have been demonstrated to produce up to 100 mA currents of metals. The commercial development of this source has been projected to yield low unit costs and high production throughput (Ref 16).

Applications

Table 2 outlines some of the research and development applications that have been pursued using directed beam ion implantation technology. Of the properties listed, the tribological aspects of ion implantation have received the most attention (Ref 17). In spite of the relatively shallow penetration of implanted ions (typically nitrogen), implanted surfaces have often demonstrated a high degree of resistance to wear under mild abrasive or lubricated sliding conditions. This wear resistance is especially noteworthy in alloy surfaces that contain elements forming stable nitrides. Titanium and Co-Cr alloy orthopedic prostheses for hips and knees are among the most successful commercial applications of ion implantation components for wear resistance. In use, these components, shown in Fig. 5, articulate against an ultrahigh-molecular-weight polyethylene mating surface. Tests at several laboratories have indicated that wear reductions of 10× to 100× may be realized by the implantation of nitrogen ions into the alloy. To date tens of thousands of such components have been ion implanted prior to surgical implantation.

Table 2

Surface properties modified	**Substrates studied**	**Ions species used**	**Comments, references**
Wear	Steels, WC, Ti, Co/Cr alloys, TiN coatings, electroplated Cr	N, C 10-20 at.% $\geq 10^{17}$ ions/cm^2	Ti, Co/Cr alloys largest use commercially in orthopedic devices (Ref 5, 9, 17)
Friction	Steels	Ti plus C implants $\geq 10^{17}$ ions/cm^2	Dual implants give amorphous surface layer (Ref 18)
Fatigue	Ti alloys, steels	N, C $\geq 10^{17}$ ions/cm^2	Implantation effective for surface initiated fatigue (Ref 5)
Fracture toughness	Ceramics: Al_2O_3, TiN	Ar 10^{15}-10^{17}	Radiation damage critical, ion induced compressive stress helpful (Ref 4, 19)

		ions/cm^2	
Aqueous corrosion catalysis	Steels, Ti alloys, Pt	Cr, Ta, Cr plus P $\geq 10^{17}$ ions/cm^2	Ion implant can mimic "normal" alloys; amorphous and unique surface alloys possible (Ref 20)
Oxidation	Superalloys	Y, Ce $\geq 10^{15}$ ions/cm^2	Low effective doses; implanted species stay at metal-oxide interface (Ref 21, 22)
Electrical conductivity	Polymers	Ar, F 10^{12}-10^{17} ions/cm^2	Permits chain scissoning, doping; conductivity approaches disordered metal levels (Ref 3, 23)
Optical: Refractive index	Glasses, electrooptics	Li, Ar 10^{15}-10^{17} ions/cm^2	Chemical doping and lattice disorder both important (Ref 24, 25)

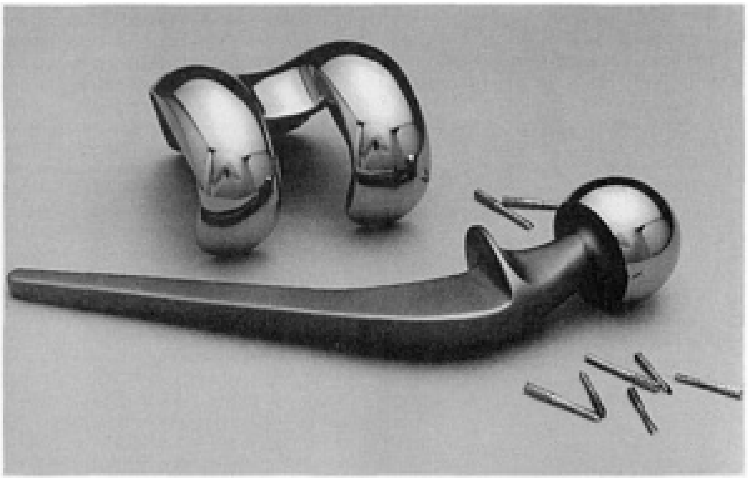

Fig. 5 Surgical prostheses of Ti-6Al-4V alloy of types being commercially ion implanted for wear benefits

Ion implantation is also being investigated as a means of improving the performance of certain types of coatings. Two examples are the implantation of nitrogen ions into (a) physical vapor deposited TiN coatings, such as on cutting inserts to increase their lifetimes, and (b) electroplated chromium to produce a CrN surface layer that inhibits the formation of microcracks, thus increasing the useful life of the electroplate. The latter use is of particular interest because of steadily increasing environmental concerns.

Health and Safety

Ion implantation of gaseous elements, whether using conventional ion implantation or the PSII process, does not involve the use of any toxic or hazardous material and produces no effluent that requires special precautions. Semiconductor applications typically do use toxic gases for production of ion beams, and chlorine gas is sometimes used for producing heavy metal ion beams. However, implanters using a MEVVA, high-temperature, or sputtering heavy ion source do not require the use of toxic gases. The use of high voltages for ion acceleration and ion beam handling requires adequate training of personnel and proper design of equipment for shock protection and reduction of x-ray levels to within acceptable limits.

Future Trends

Commercial ion implantation processing is presently a service business directed toward high-value components whose lifetime extension warrants the processing costs. The largest markets are presently orthopedic devices and specialized tooling. However, a growing body of research and develoment workers are exploring the PIII process because of the attractive scaleup possibilities for large objects with complicated shapes. The ongoing development of high-current, heavy ion sources is also expected to open up new process applications. These include both high-temperature, versatile heavy ion sources (Ref 10) and MEVVA sources (Ref 15, 16) for applications not requiring mass analysis. The potential for scaleup must continue to be guided by the intrinsic depth limitations of this technique, which will proscribe applications subject to severe abrasion or erosion.

Diffusion Coatings

Introduction

DIFFUSION COATINGS are deposited either by heating the components to be treated in contact with the powder coating material in an inert atmosphere (solid-state diffusion) or by heating them in an atmosphere of a volatile compound of the coating material (out-of-contact gas-phase deposition, or chemical vapor deposition). Solid-state diffusion methods include pack cementation, which is the most widely employed diffusion coating method and the process described in most detail in this article, and various slurry or powder-paint methods of coating metal parts and assemblies. The most widely

used coatings are those based on aluminum (aluminizing), chromium (chromizing), and silicon (siliconizing). Substrate materials include nickel- and cobalt-base superalloys, steels (including carbon, alloy, and stainless steels), and refractory metals and alloys.

This article is divided into two major Sections. The first Section describes the widespread use of diffusion coatings for elevated-temperature protection of turbine components for aircraft engines or ground- or marine-based gas turbines. The second Section reviews diffusion-coated ferrous alloys.

High-temperature oxidation-resistant diffusion coatings for molybdenum, niobium, tantalum, and tungsten substrates are described in the article "Surface Engineering of Refractory Metals and Alloys" in this Volume. In addition, information on the use of diffusion coatings for wear resistance, for example, coatings based on boron (boronizing) via pack cementation or complex carbides (vanadium carbide, chromium carbide, and niobium carbide) deposited from salt baths, can be found in *Heat Treating,* Volume 4 of the *ASM Handbook;* see the articles "Boriding (Boronizing)" and "Thermoreactive Deposition/Diffusion Process," respectively.

Diffusion Coatings for Gas Turbine Engine Hot Section Parts

G. William Goward, Consultant; Leslie L. Seigle, State University of New York at Stony Brook

---

Blades and vanes made from nickel- and cobalt-base superalloys that are used in the hot sections of all gas turbine engines are coated to enhance resistance to hot corrosion. The most widely used coatings are those based on the intermetallic compounds NiAl and CoAl, which are formed by the diffusion interaction of aluminum with surfaces of the nickel and cobalt alloys, respectively. Diffusion chromium coatings are also used to protect against certain forms of molten salt hot corrosion. The majority of these diffusion coatings are manufactured by pack cementation and related "gas phase," or out-of-contact, processes.

The first public descriptions of pack cementation aluminizing were by Van Aller in a U.S. patent filed in 1911 (Ref 1) and in a technical paper by Allison and Hawkins in 1914 (Ref 2)--both from the General Electric Research Laboratories. The process consisted of embedding pieces to be coated in powder mixtures of aluminum, ammonium chloride, and graphite, and heating the assembly at 450 °C (840 °F) for two hours. A few years later, Gilson, of the same laboratory, patented the use of alumina, or aluminum oxide (Al_2O_3), as a substitute for graphite in the mix (Ref 3). The first known use of pack cementation aluminizing of gas turbine parts was for stationary cobalt superalloy vanes in about 1957 (Ref 4). Rotating nickel superalloy turbine blades may have been first aluminized by hot dipping in molten aluminum (Ref 5). Kelley (Ref 6) described his invention of pack cementation chromizing of steels in 1923. Comprehensive reviews of chromide coatings on steels were published in 1951 and 52 (Ref 7, 8). Aluminide coating of chromized steels to further improve high-temperature oxidation resistance was patented in 1953 (Ref 9). The time of first widespread use of chromide coatings on gas turbine parts is obscure but probably occurred in Europe in the early 1960s (Ref 10, 11).

Pack cementation siliconizing of iron and steels with powder mixtures of ferrosilicon, ammonium chloride, and alumina was described in 1954 (Ref 12). Siliconizing of nickel and cobalt superalloys does not produce practically useful coatings because of the formation of low-melting, brittle silicide phases (Ref 13). Minor additions of silicon to aluminide coatings on superalloys do enhance hot corrosion resistance.

Major developments in diffusion coatings for superalloys (and steels) over the last two decades include modifications of aluminide diffusion coatings with chromium (Ref 14), platinum (Ref 15), and to a lesser extent, silicon. The theory of codeposition of combinations of aluminum, chromium, silicon, and the so-called reactive metals (yttrium, rare earths, hafnium, etc.) has been refined and straightforward processes have been developed (Ref 16). Out-of-contact gas-phase coating (chemical vapor deposition, or CVD) has gained in use, not only for coating complex air-cooling passages, but as an overall versatile, environmentally friendly, cost-effective technology (Ref 17, 18, 19). It is estimated that more than 90% of all coated gas-turbine hot-section blades and vanes are coated by pack cementation and related processes.

Principles of Pack Diffusion Coating

Aluminizing. Pack diffusion coating may be considered as a CVD process carried out with the aid of a powder mixture (pack), in or near which the part to be coated (substrate) is immersed or suspended, containing the element or elements to be deposited (source), a halide salt (activator), and an inert diluent such as alumina (filler). When the mixture is heated, the activator reacts to produce an atmosphere of source element(s) halides which diffuse in the pack and transfer the source element(s) to the substrate on which the coating is formed.

Figure 1 presents schematic diagrams of the diffusion zones in a series of packs used for the production of aluminide coatings on nickel- and cobalt-based superalloys, in which the source is aluminum or an aluminum alloy and the activator an ammonium or sodium halide. Upon heating, the activator reacts with aluminum to form H_2(g) or Na(g) and a series of volatile aluminum halides. The nature and partial pressures of the major constituents in the gas phase in equilibrium with aluminum at high activity in the pack, and at lower activity at the surface of the coating, can be calculated when the free energies of formation of the halides and the activity versus composition relationship for aluminum in the source alloy and coating are known. In the presence of a high aluminum activity, no significant amounts of the halides of other metals in the source or superalloy appear in the gas phase, and these metals are, therefore, not transported in packs of this type. Alloying is used simply to control the activity of aluminum in the source in order to obtain a desired concentration of aluminum at the surface of the coating.

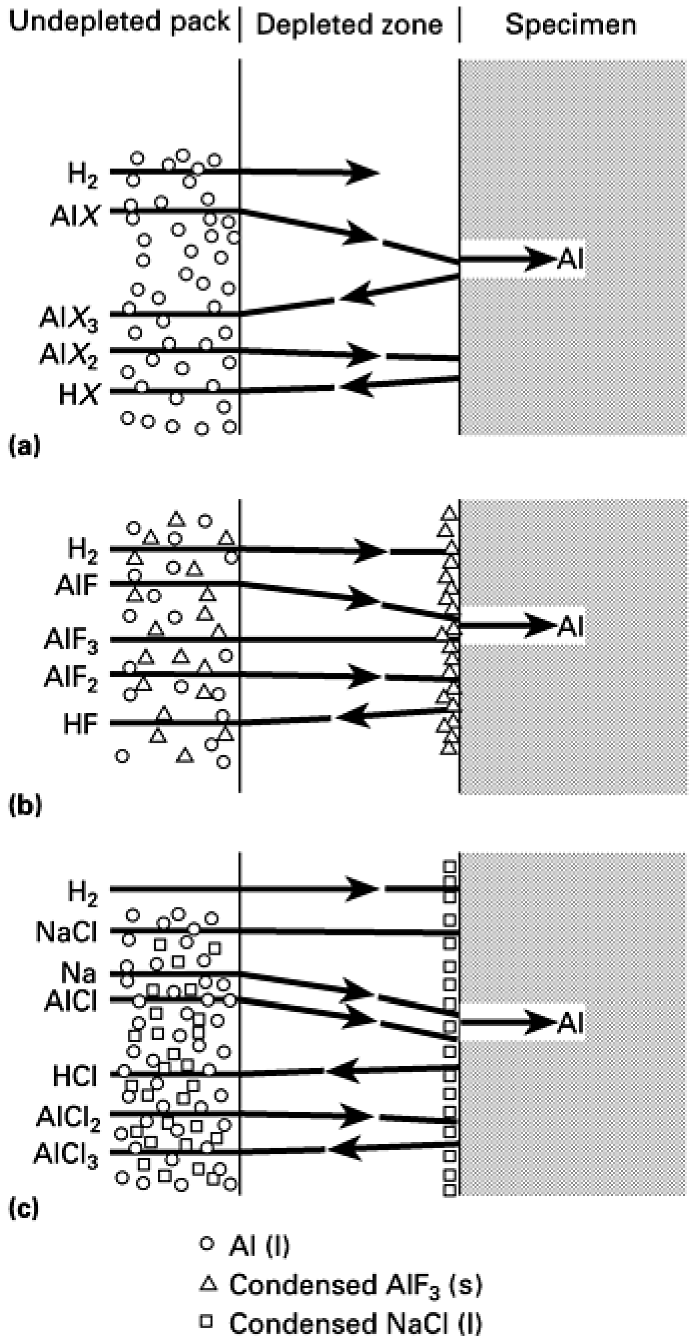

Fig. 1 Schematic diagrams of the fluxes of the major diffusing gaseous species in aluminizing packs activated with (a) NH_4X (X = Cl, Br, or I), (b) NH_4F, and (c) NaCl. Source: Ref 20, 21

Diffusion of the gaseous halides takes place across an aluminum-depleted zone which forms as a result of transport of aluminum into the coating under the action of the partial pressure gradients which exist between the pack and the coating surface (Ref 20, 21). The rate of diffusion of constituent *i* is proportional to:

$$D_i(P_i-P_i') = D_i\Delta P_i$$

where D_i is the interdiffusion coefficient of *i* with the residual gas in the system, and P_i and P_i' the partial pressures of *i* in the bulk pack and at the surface of the coating, respectively. The instantaneous rate of transport of aluminum from the pack to the coating, obtained by summing the contributions from each of the diffusing aluminum halides, can be expressed as:

$$J_{Al} = (\varepsilon/dRT) \sum \alpha_i N_i D_i \Delta P_i$$

where J_{Al} is the rate of transport of aluminum in moles/cm^2 · s; d is the effective diffusion distance in cm; ε is a constant to correct for the porosity of the pack; α_i is a factor to correct for the possible condensation of activator (to be discussed later); N_i is the number of gram atoms of aluminum in the ith species; D_i is diffusion coefficient of constituent i in cm^2/s; P_i is the partial pressure of constituent i in atm; R is the gas constant in cm^3 · atm/mole· deg; and T is temperature in degrees Kelvin, K. For the case of aluminization in a static pack with a high aluminum source, after a short period of time the aluminum concentration at the surface of the coating reaches a constant value, different from that in the source. Under this condition the weight of aluminum W_g (g/cm^2· s) transported to the substrate in t (s) is given by a parabolic expression (Ref 22):

$$W_g^2 = K_g t$$

where

$$K_g = (2\rho\varepsilon M/RT) \sum \alpha_i N_i D_i \Delta P_i$$

in which ρ is the pack aluminum concentration in g/cm^3, and M is the gram-atomic weight of aluminum. The diffusion of aluminum into the coating is also governed by a parabolic expression:

$$W_s^2 = K_s t$$

where K_s is the rate constant for diffusion in the solid, which can be evaluated if diffusion coefficients are known for the phases in the coating. Both K_g and K_s are functions of the surface composition of the coating, and this unknown composition can be determined from the condition that at steady state $K_g = K_s$.

Figure 1(a) shows, in order of increasing partial pressure, the principal diffusing species in a pack activated with NH_4X (X = Cl, Br, or I), and the direction of diffusion of each species. The thermodynamic calculations indicate that ΔP_i is greater for AlX(g) and AlX_3(g) than for the other halides (Table 1). Since, furthermore, the diffusion coefficients of the halides decrease with increasing molecular weight, it can be deduced that in packs activated with ammonium chloride, iodide, or bromide, aluminum is transported mainly by the diffusion of AlX(g) to the coating surface where the reaction:

$$3AlX(g) = 2Al(s) + AlX_3(g)$$

occurs. The Al(s) diffuses to form the coating while AlX_3(g) diffuses back and reacts with Al(l) in the pack to regenerate AlX(g). Moreover, since the value of ΔP_i for AlCl is greater than those for AlBr and AlI, it is expected that ammonium chloride should be a better activator than the bromide or iodide.

Table 1 Values of ΔP_i for the major diffusing gaseous species in variously activated aluminizing packs at 1093 °C (2000 °F)

Activator	ΔP at 1093 °C (2000 °F), atm						
	AlX	**AlX_2**	**AlX_3**	**NaX**	**Na**	**HX**	**H_2**
NH_4Cl	1.27×10^{-1}	1.59×10^{-2}	-0.93×10^{-1}	. . .	. . .	-5.35×10^{-3}	4.41×10^{-2}
NH_4Br	7.66×10^{-3}	. . .	-3.70×10^{-3}	. . .	. . .	-1.93×10^{-5}	1.52×10^{-5}

NH_4I	1.38×10^{-3}	. . .	-3.01×10^{-4}	. . .	. . .	-3.21×10^{-4}	2.21×10^{-5}
NH_4F	1.96×10^{-1}	1.40×10^{-2}	0	. . .	. . .	-3.38×10^{-4}	0.2108
NaF	7.85×10^{-2}	1.94×10^{-3}	-3.15×10^{-3}	0	8.22×10^{-2}	$-1.81 \times 10^{-4,}$	. . .
NaCl	4.34×10^{-3}	2.21×10^{-5}	-0.69×10^{-6}	0	3.74×10^{-3}	-1.51×10^{-4}	. . .
NaBr	1.71×10^{-3}	. . .	6.79×10^{-6}	0	9.95×10^{-4}	. . .	. . .
NaI	4.52×10^{-3}	. . .	4.9×10^{-9}	0	3.53×10^{-3}	-5.12×10^{-5}	. . .

Note: a_{Al} in the pack = 1; a_{Al} at the coating surface = 0.01. Values for NH_4Br, NH_4I, and NaBr activated packs taken from Ref 20.

In packs activated with NH_4F (or AlF_3) (Fig. 1b), AlF_3 appears as a solid at the operating temperature, and its vapor pressure is uniform throughout the pack. This constituent, therefore, does not diffuse in the gas phase. As indicated by Fig. 1(b) and the ΔP_i values in Table 1, aluminum is transported primarily by the diffusion of AlF(g) to the coating surface where deposition takes place by the reaction:

$$3AlF(g) = 2Al(s) + AlF_3(s)$$

The AlF_3(s) which is formed deposits as crystalline solid at the surface, some of which may adhere to the coating. The supply of AlF(g) is maintained by the reverse reaction in the pack.

In packs activated with a sodium halide such as NaCl (Fig. 1c), Na*X*(l) appears as a condensed phase in the pack. Aluminum deposition occurs mainly by the diffusion of Na(g) and Al*X*(g) to the coating surface where a reaction of the type:

$$AlX(g) + Na(g) = Al(s) + NaX(l)$$

occurs with the deposition of Na*X*(l) at the surface. The flux of Al*X*(g) is maintained by the reverse reaction in the pack. Due to the presence of solid or liquid activator, the operating characteristics of packs containing a condensed halide phase differ from those of packs activated with ammonium chloride, bromide, or iodide in the following ways:

- The condensed activator phase serves as a reservoir whose evaporation compensates for leakage of halide vapors out of "semisealed" coating chambers, resulting in more stable pack behavior over time
- The halide partial pressures and, therefore, the rate of aluminum deposition, increase much more rapidly with temperature, since they vary with the vapor pressure of the condensed phase, which increases rapidly with increasing temperature
- Activator as well as aluminum is transported to the coating surface

The expression given for K_g indicates that the instantaneous flux of gaseous halides will increase with an increase in the density (g/cm^3) of aluminum in the pack. The increase would not be directly proportional to ρ, however, since increasing the flux of aluminum would increase the aluminum concentration at the surface of the coating and, therefore, have a complex effect on the aluminum transfer rate as a whole.

Codeposition of Aluminum and Other Elements. For successful codeposition, the thermodynamic equilibrium between the source elements in the pack and halides in the gas phase must permit the attainment of sufficiently high

partial pressures for the halides of all elements desired to be transferred (Ref 16). The partial pressures are functions of the free energies of formation of the halides and activities of the elements in the source alloy. As illustrated by the curves in Fig. 2, the partial pressures of chromium and silicon halides in a pack in which aluminum, chromium, and silicon are present at equal activity are orders of magnitude below those of the aluminum halides, and too low to support the codeposition of an appreciable amount of these metals. An estimate of the general conditions under which codeposition is possible can be obtained by considering the equilibrium constant K for the simple reaction involving a source alloy of two metals A and B and the volatile halides A*X* and B*X:*

$$\mathrm{A}X(\mathrm{g}) + \mathrm{B}(\mathrm{s}) = \mathrm{B}X(\mathrm{g}) + \mathrm{A}(\mathrm{s})$$

where

$$\mathrm{K} = (P_{\mathrm{B}X}/P_{\mathrm{A}X})(a_{\mathrm{A}}/a_{\mathrm{B}})$$

or

$$\mathrm{K} = \exp(-\Delta G^0/RT)$$

and

$$\Delta G^0 = \Delta G_{\mathrm{f,B}X} - \Delta G_{\mathrm{f,A}X}$$

The activity ratio at which $P_{\mathrm{A}X} = P_{\mathrm{B}X}$ is given by:

$$a_{\mathrm{A}}/a_{\mathrm{B}} = \exp\,(-\Delta G^0/RT)$$

If A*X* is more stable than B*X,* the sign of ΔG^0 will be positive and $a_{\mathrm{A}}/a_{\mathrm{B}} < 1$. The activity ratio varies rapidly with ΔG^0. For example, at T = 1300 K, when ΔG^0 = 50,000 J/mole, $a_{\mathrm{A}}/a_{\mathrm{B}} = 9.8 \times 10^{-3}$, and when ΔG^0 = 100,000 J/mole $a_{\mathrm{A}}/a_{\mathrm{B}} = 9.6 \times 10^{-5}$. Conversion of the activity ratio to a composition ratio requires a knowledge of the thermodyamic properties of the source alloy. If this behaves as an ideal solution, the calculations suggest that codeposition is unlikely to occur if the free energies of formation of the source alloy halides (per gram-atom of Cl) differ by more than 50,000 J/mole. The codeposition of chromium with aluminum has been achieved by using chromium-rich source alloys containing 5-10 wt% aluminum (Ref 16, 24, 25). In this case the large negative deviation from ideality of the chromium-aluminum alloys (Ref 26) helps to compensate for the large formation free energy difference between the aluminum and chromium halides.

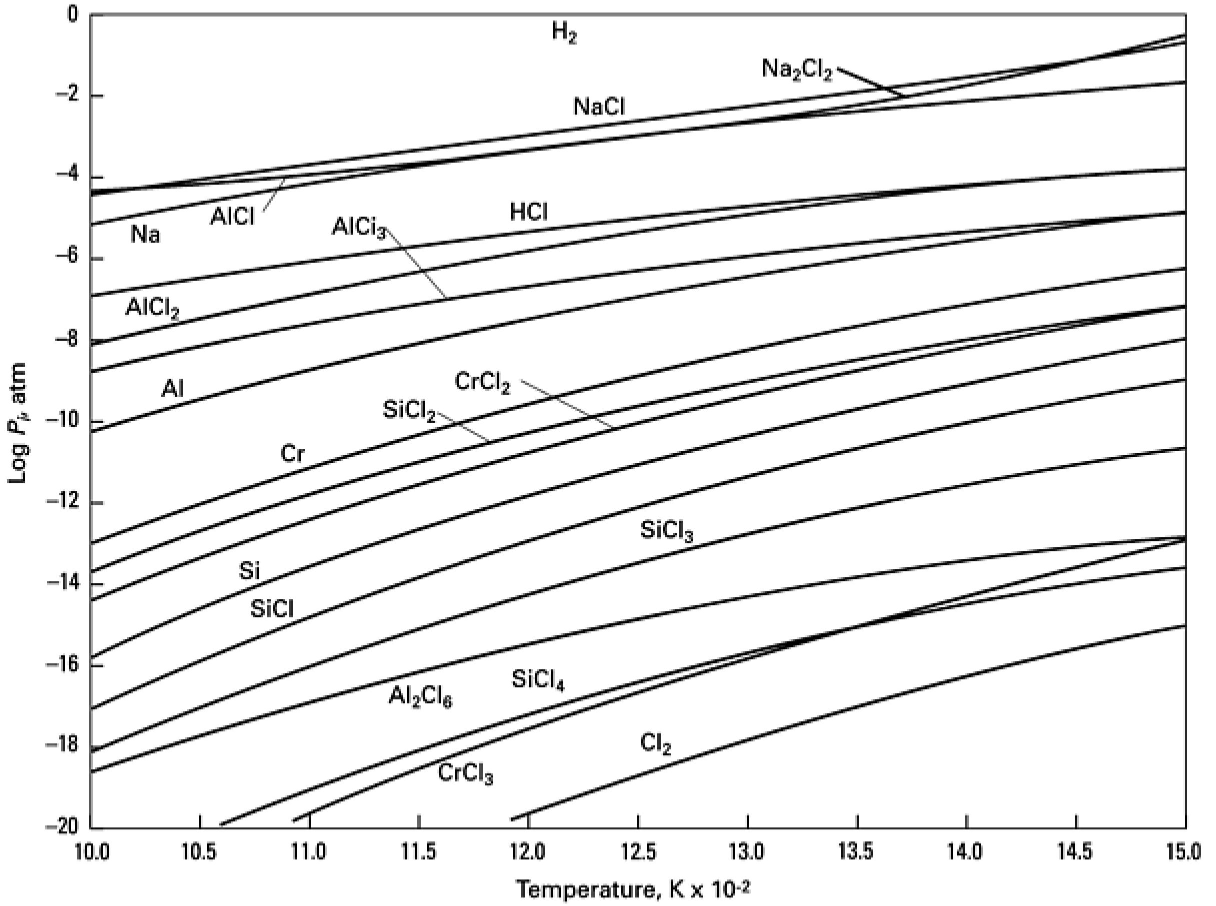

Fig. 2 Equilibrium partial pressures of gaseous species in a NaCl-activated pack containing pure aluminum, chromium, and silicon and a residual atmosphere of H_2. Source: Ref 23, 24

Chromizing. Although many of the same principles apply to chromizing as to aluminizing packs, the fact that chromium halides are less stable than aluminum halides introduces several new factors (Ref 27, 28). In ammonium halide activated chromizing packs, $CrX_2(l)$ appears as a condensed phase. The major constituents in the gas phase in equilibrium with chromium in the pack are $CrX_2(g)$, $CrX_3(g)$, $HX(g)$, and $H_2(g)$. The partial pressure of $HX(g)$ is high enough so that hydrogen reduction according to the reaction:

$$CrX_2(g) + H_2(g) = Cr(s) + 2\ HX(g)$$

at the coating surface is an important mechanism for the deposition of chromium. Since the free energies of formation of FeX_2 and CrX_2 are comparable, if the substrate is an iron-base alloy the exchange reaction

$$CrX_2(g) + Fe(s) = Cr(s) + FeX_2(g)$$

also occurs. The $FeX_2(g)$ diffuses back into the pack where the reverse reaction leads to the deposition of Fe(s) on the particles of the source alloy, thus changing its composition, while the Cr(s) diffuses into the coating. In this case, the weight of the substrate does not change significantly since it loses one atom of iron for every atom of chromium gained. The exchange reaction does not occur to an appreciable extent when nickel- or cobalt-base alloys are chromized, since the halides of these elements are sufficiently less stable than those of chromium so that significant concentrations of these halides do not appear in the gas phase. The replacement of hydrogen with argon as a protective atmosphere, such as would be possible if $CrX_2(s)$ were used as an activator, would significantly change the deposition rate because of elimination of the hydrogen reduction reaction.

Siliconizing. In packs activated with NH_4Cl, the principle constituents in the gas phase in equilibrium with pure Si(s) below 1500 K are $SiHCl_3$(g), $SiCl_4$(g), $SiCl_3$(g), HCl(g), and H_2(g) (Ref 28). Free energy considerations indicate that concentrations of the halides of nickel, cobalt, molybdenum, and tungsten in the gas phase would be very small, and these elements would therefore be immobile in such a pack. Hydrogen reduction of $SiHCl_3$(g) and $SiCl_4$(g) are predicted to be the most probable silicon deposition reactions at the coating surface when the substrate is a nickel- or cobalt-base superalloy, or pure tungsten or molybdenum:

$$SiHCl_3(g) + H_2(g) = Si(s) + 3HCl(g)$$

$$SiCl_4(g) + 2H_2(g) = Si(s) + 4HCl(g)$$

In a pack for the coating of these metals activated with $SiCl_4$(l), in which $SiHCl_3$, HCl, as well as H_2 would be absent, silicon deposition would presumably occur mainly via the disproportionation reaction:

$$2SiCl_2(g) = Si(s) + SiCl_4(g)$$

and, to a smaller extent, by:

$$4SiCl_3(g) = Si(s) + 3SiCl_3(g)$$

Formation free energy values indicate that various amounts of iron, chromium, and titanium chlorides will appear in the gas phase, and these substrate elements will exhibit varying degrees of mobility in a chloride activated siliconizing pack. In this case, exchange reactions such as:

$$SiCl_4(g) + 2M(s) = 2MCl_2(g) + Si(s)$$

and

$$SiCl_2(g) + M(s) = MCl_2(g) + Si(s)$$

may play a significant role in the deposition process. Finally, since for the reaction:

$$3/2SiCl_4(g) + Al_2O_3(s) = 3/2SiO_2(s) + 2AlCl_3(g)$$

where ΔG^0 = -15,400 cal at 1300 K, alumina is evidently not inert in a siliconizing pack, and the use of a different filler such as silica, or silicon dioxide (SiO_2) is advisable.

Properties of Diffusion Coatings on Superalloys

Coating Formation Mechanisms. Diffusion aluminide coatings on superalloys are classified by microstructure as being of the "inward diffusion" or "outward diffusion" type according to the seminal work of Goward and Boone (Ref 29). The classification was derived from studies of aluminide coating formation on a typical nickel superalloy, Udimet 700, which has a nominal composition of Ni-15Cr-17Co-5Mo-4Al-3.5Ti. It was observed that for pack mixes containing pure aluminum (unit or "high" activity), coatings formed by predominant inward diffusion of aluminum through Ni_2Al_3, and deeper in the coating, through aluminum-rich NiAl (for pure nickel, by inward diffusion through Ni_2Al_3 only). The diffusion rates are abnormally high--practical coating thicknesses can be achieved in a few hours at 760 °C (1400 °F). A typical as-coated microstructure is shown in Fig. 3(a). Upon further heat treatment at, for example, 1080 °C (1975 °F) for four hours, the microstructure shown in Fig. 3(b) is formed--the coating matrix is now NiAl. The single-phase region in the center of the coating is nickel-rich NiAl grown by predominant outward diffusion of nickel from the substrate alloy to react with aluminum from the top layer. The inner layer, or so-called interdiffusion zone, consists of refractory metal (tungsten, molybdenum, tantalum, etc.) carbides and/or complex intermetallic phases in a NiAl and/or Ni_3Al matrix, formed by the removal of nickel from the underlying alloy, thereby converting its Ni-Ni_3Al structure to those phases. Conversely, if the activity of aluminum in the source is reduced by alloying with, for example, nickel or chromium, to a level where nickel-rich NiAl is formed at the surface, the coating, shown in Fig. 3(c), grows by predominant outward diffusion of nickel from the substrate to form NiAl by reaction with aluminum from the source. The lower layer of this coating is formed as previously described. Diffusion rates are relatively low so the coating process must be carried out at higher temperatures--usually greater than 1000 °C (1830 °F). These mechanisms are consistent with those observed by Janssen and Rieck (Ref 30) and later by Shankar and Seigle (Ref 31) during studies of diffusion in the simple nickel-aluminum system. Figure 4 shows the ratios of diffusion rates of nickel and aluminum across the range of stoichiometry of NiAl (Ref 31). At the high aluminum limit of NiAl, diffusion is by predominant motion of aluminum, confirming the earlier postulate of Goward and Boone (Ref 29). A coating with a matrix of NiAl formed by this diffusion mechanism is shown in Fig. 3(d). Upon further heat treatment, this coating will stabilize with a structure similar to that shown in Fig. 3(b).

Ni_2Al_3 (and aluminum-rich NiAl). (b) Same as (a) but heat treated at 1080 °C (1975 °F). (c) Outward diffusion of nickel in nickel-rich NiAl. (d) Inward diffusion of aluminum in aluminum-rich NiAl. Source: Ref 29

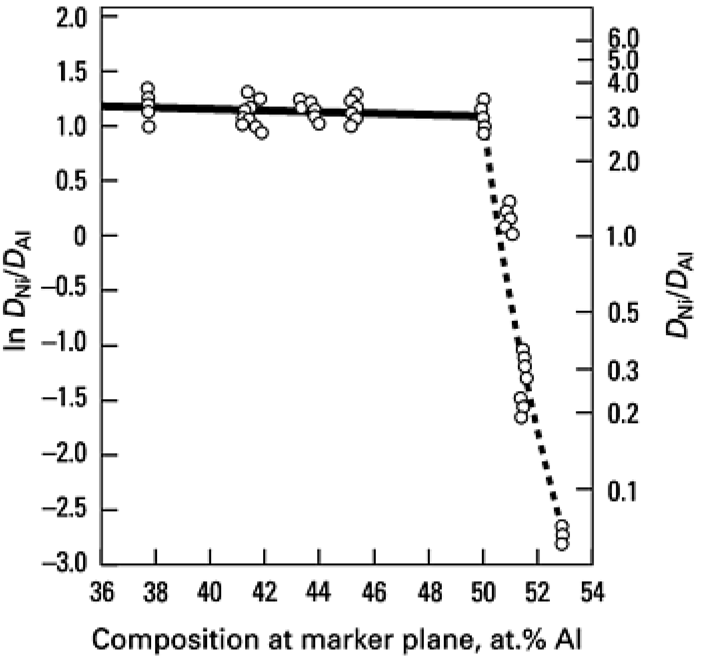

Fig. 4 Ratio of diffusion coefficients of nickel and aluminum as a function of aluminum in NiAl. Source: Ref 31

The above mechanisms apply equally to those coatings formed by out-of-contact or CVD processes, from slurry "slip packs" (Ref 32), and from aluminum alloy powders deposited on superalloys by slurry spraying or by slurry electrophoresis (Ref 33). Coatings applied by spraying (Ref 34, 35) or electrophoretically depositing (Ref 33) pure aluminum or low-melting aluminum alloys, for example, Al-10Si, and then heat treating, form by dissolution of the superalloy into the melt until the melt solidifies, followed by diffusion of aluminum similar to that described above.

All known aluminide-based coatings on nickel superalloys, including those modified by chromium, platinum, and silicon, have one of the archetypical microstructures described above. For pure nickel and nickel alloys containing no aluminum, (or <0.2% Al), the interdiffusion zone does not form. For pure nickel, Kirkendall voids and alumina, from oxygen in the nickel, form at the coating/substrate interface (Ref 29). For nickel alloys containing no aluminum, voids, refractory metal layers, and alumina form at the interface (Ref 29). The adherence of the resulting coatings is compromised and they may not be practically useful. It is anticipated that similar mechanisms apply to the coating of cobalt superalloys. Again, the absence of aluminum in many of these alloys precludes the formation of the interdiffusion zone common to most nickel superalloys. Rather, a refractory metal (tungsten, chromium) carbide forms at the juncture to the base alloy (Ref 40). As described for similar nickel-base alloys, this refractory metal carbide and alumina formed from oxygen in the aluminum-free alloys, can also compromise the adherence of these coatings. Special processing conditions, involving slow coating growth at high temperatures (up to 1095 °C, or 2000 °F) from relatively low aluminum activity sources, can sometimes be used to achieve satisfactory coating adherence. Minor additions of aluminum (1 to 2%) to cobalt superalloys completely obviate these problems--stable interdiffusion zones then form analogous to those on most nickel superalloys (Ref 36).

Diffusion chromide coatings formed on a nickel superalloy by pack cementation and out-of-contact processes are illustrated in Fig. 5. The coating deposited by pack cementation is overlaid with a thin layer of alpha-chromium as shown in Fig. 5(a). Users generally require that this phase be absent. It must then be removed chemically, or alternatively the coating applied by an out-of-contact process to produce the structure shown in Fig. 5(b). These coatings usually then contain chromium to the extent of 20 to 25% at the outer surface. Coating formation, from chromium-alumina-activator (usually ammonium chloride) packs or from out-of-contact sources (powders or chromium granules as described in Ref 18) involves approximately equal rates of interdiffusion of chromium and nickel. Significant depletion of titanium and aluminum from the alloy surface occurs because the sources do not contain these elements. The desired coatings are thus solid solutions of chromium in the remaining nickel-base alloy. Internal oxides of aluminum and titanium can form because the oxygen potential of the sources is normally sufficient to cause internal oxidation. This can be avoided by

adding aluminum to the sources in amounts just below that which would cause aluminizing rather than chromizing (Ref 38).

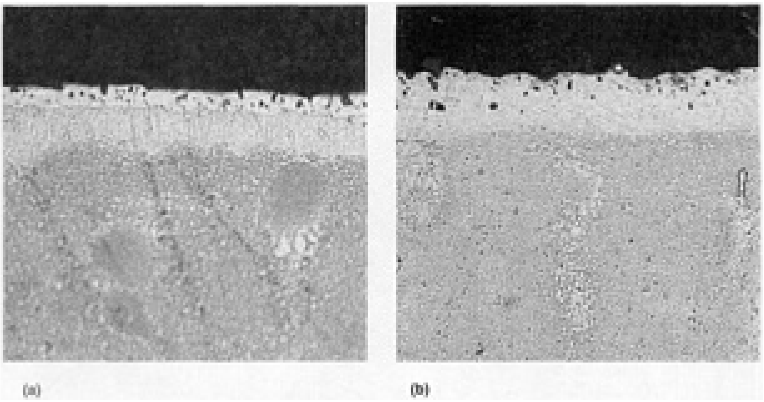

Fig. 5 Chromium diffusion coatings on a nickel superalloy by (a) pack cementation and (b) out-of-contact gas-phase processing. Both at 500×. Source: Ref 37

Rapp and co-workers (Ref 16) have refined the theory of codeposition of aluminum, chromium, silicon, and reactive elements (yttrium and hafnium) by pack cementation and related processes and have demonstrated the benefits derived therefrom. These processes and coatings should find practical applications in the near future.

Coating Protection and Degradation. Simple aluminide coatings resist high-temperature oxidation by the formation of protective layers of alumina and can be used up to about 1150 °C (2100 °F). The coatings degrade by loss of aluminum due to spalling of oxides under thermal cycling conditions. Incorporation of reactive elements, such as yttrium and hafnium, by codeposition during aluminizing (Ref 16) can significantly improve adherence of the protective alumina scales and therefore extend coating life. At temperatures above about 1000 °C (1830 °F) interdiffusion of the coatings with substrates contribute significantly to degradation (Ref 39). Practical coating service lives are limited to operating temperatures of 870 to 980 °C (1600 to 1800 °F) with only short excursions at the highest temperatures.

Chromium modifications, made by diffusion chromizing prior to aluminizing (Ref 14) or by codeposition of aluminum and chromium (Ref 16, 41, 42), have enhanced resistance to various forms of molten-salt hot corrosion. Electroplating with a thin layer of platinum (and possibly rhodium) followed by aluminizing (Ref 15) forms a coating with substantially improved resistance to both oxidation and high-temperature (Type I) molten-salt corrosion. Additions of up to about 5% Si improve both oxidation and hot corrosion resistance (Ref 13). Silicon can be codeposited with aluminum by pack cementation (Ref 16, 43) and related out-of-contact processes. So-called slurry processes wherein a liquid suspension of aluminum and silicon powders is applied to the alloy surface, then dried and fired at elevated temperatures, can also be used to incorporate silicon (Ref 35).

The oxidation and hot corrosion resistance of these coatings are more or less influenced by the composition of substrate alloys. Tantalum and hafnium improve cyclic oxidation and hot corrosion resistance, the latter element by improving the adherence of the protective layer of alumina (Ref 44). Molybdenum and tungsten compromise hot corrosion resistance.

Because of the brittle fracture behavior of NiAl up to temperatures of 650 to 775 °C (1200 to 1400 °F), all aluminide coatings exhibit such fracture below these temperatures while above these limits ductile behavior occurs (Ref 45). This behavior can either compromise or enhance thermal fatigue resistance of substrate alloys depending on such complex factors as the exact nature of the thermal cycle and the structure--equiaxed, directionally solidified, or single crystal--of the alloys (Ref 46). If these effects are limiting, designers may require use of more expensive overlay coatings of the MCrAlY (M = Co and/or Ni) and/or thermal barrier (zirconia) types.

Manufacturing Technology

A flow path for a typical production-scale pack cementation process is shown in Fig. 6. Practical manufacturing aspects of the various steps of the process are described below.

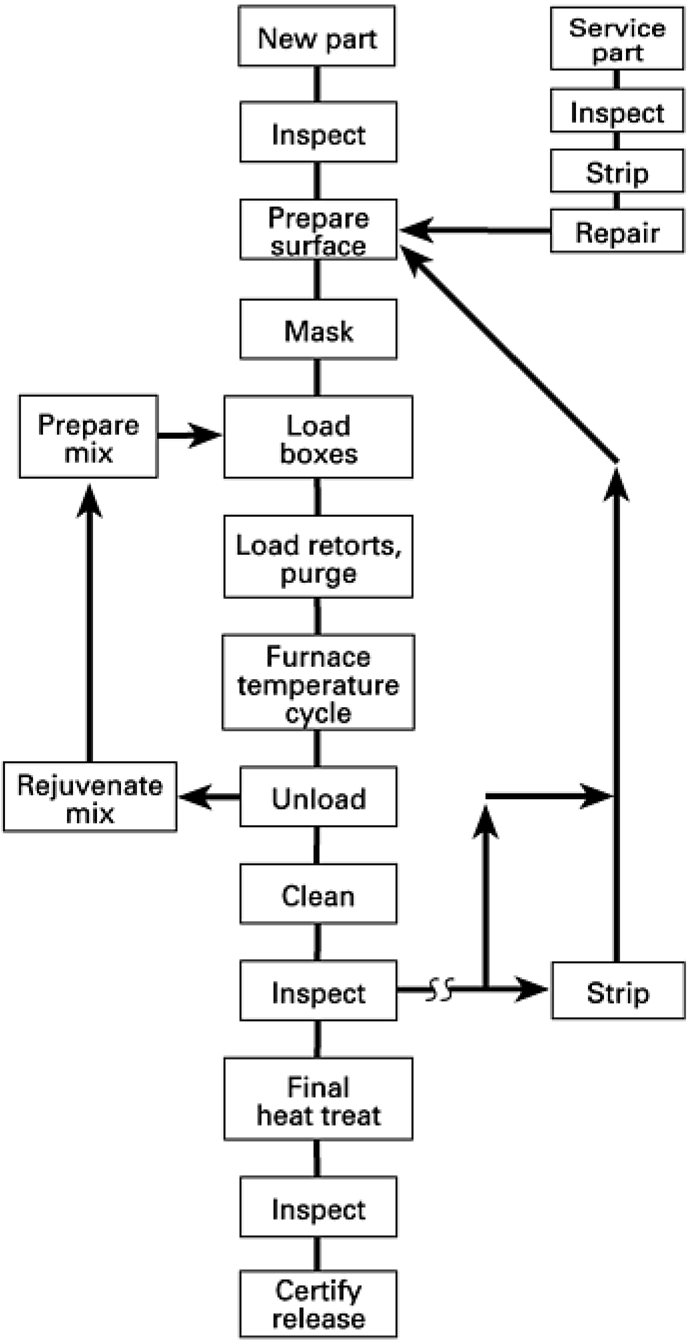

Fig. 6 Flow diagram for typical pack cementation processes. Source: Ref 37

Inspection. Visual and flow inspection of cooled airfoils before coating affords the last opportunity to determine if all surfaces are suitable for the intended use. Oxidized surfaces and the remains of investment casting core and shell materials can interfere with coating deposition and compromise useful service lives.

Surface Preparation. Surface preparation to remove superficial oxides is usually accomplished by grit blasting with intermediate sized alumina grit. Grit blasting with silicon carbide is avoided because any entrapped grit forms low-melting eutectic phases with superalloys. Vibratory finishing is used where a surface finish is specified to achieve aerodynamic design intent. Removal of oily residues from machining by vapor degreasing or low temperature burnout may be required.

Masking to prevent coating on critical mechanical contact surfaces, such as blade roots, may be required. This can be accomplished with mechanical, oxide barrier, or chemically reactive masks. Complete exclusion of coating by mechanical masks is difficult for processes with high throwing power, a property common to those run at higher temperatures, for

example, >870 °C (1600 °F). Chemically reactive masks containing elemental or alloy powders which react with the coating species to prevent coating deposition on the surface are more effective at higher processing temperatures. Coating before machining, to obviate expensive masking requirements, is strongly recommended.

Pack Mix (Source) Preparation. Preparation of pack mixes requires the use of large-scale powder handling equipment designed for effective mixing, storage, and dispensing. Examples of mix (source) compositions are given in Table 2. Closed handling systems are now required for health and safety reasons. The possibility of explosive burning of metal powders must be excluded. In general, various chemical engineering technologies are applicable.

Table 2 Examples of pack mixes/sources and processing parameters for various coatings on nickel and cobalt superalloys

Coating type	Source composition	Processing parameters
Pack aluminizing, inward diffusion in Ni_2Al_3 in nickel alloys[(a)]	5-20% Al (Al-10Si), 0.5-3% NH_4Cl, balance Al_2O_3 powder	1 to 4 h at 650 to 680 °C (1200 to 1255 °F) in air, argon, H_2; heat treat 4 to 6 h at 1095 °C (2000 °F) in argon
Pack aluminizing, inward diffusion in NiAl in nickel alloys[(b)]	44% Al, 56% Cr NH_4Cl balance Al_2O_3 powder	5 to 10 h at 1040 °C (1900 °F) in vacuum (argon, H_2)
Pack aluminizing, outward diffusion in NiAl in nickel alloys[(c)]	2-3% Al, 20% Cr, 0.25% NH_4HF_2, balance Al_2O_3 powder	25 h at 1040 °C (1900 °F) in argon
Pack aluminizing of cobalt alloys[(d)]	8% Al, 22% Cr 1% NH_4F, balance Al_2O_3 powder	4 to 20 h at 980 to 1150 °C (1800 to 2100 °F) in argon
Gas-phase aluminizing, outward diffusion in NiAl in nickel alloys[(e)]	10% Co_2Al_5, 2.5% NaCl, 2.5% $AlCl_3$, balance Al_2O_3 powder	3 h at 1095 °C (2000 °F) in argon
Gas-phase aluminizing, outward diffusion in NiAl in nickel alloys[(f)]	30% Al-70% Cr alloy granules, NH_4F	4 h at 1150 °C (2100 °F) in argon
Pack or gas-phase chromizing of nickel alloys[(g)]	15% Cr, 4% Ni, 1% Al, 10.25% NH_4Br or NH_4Cl, balance Al_2O_3 powder	3 h at 1040 °C (1900 °F) in argon

Loading Boxes and Retorts. Loading of parts, which consists of embedding parts in coating powder mixtures in controlled positions in coating boxes ("boats"), is labor intensive and environmentally unfriendly. Automation with robotics is theoretically possible but no such systems are known to be in use.

Furnace Temperature Cycle and Heat Treatments. Furnaces with specified temperature capability and uniformity and associated inert gas delivery systems are the most costly components of coating plants. For most processes, coating boxes are loaded into retorts constructed of high-temperature alloys, for example, Inconel 600 or 601, and are capable of being sealed (sand, glass, or water-cooled seals) to exclude air. Retorts for gas-fired or electrically fired pit furnaces can be as large as 1.2 m (4.0 ft) in diameter and 2.4 m (8.0 ft) tall. A supply of inert gas, argon or hydrogen is required to purge retorts free of air and moisture, and to maintain an inert environment during the coating cycle.

A coating cycle includes bringing the retort and contents to temperature, holding at temperature for several hours, and then cooling to ambient temperature while maintaining the inert gas environment. Coating temperatures range from 650 °C (1200 °F) for low-temperature inward diffusion aluminizing to as high as 1150 °C (2100 °F) for outward-diffusion aluminizing of nickel superalloys. Processing times range from 4 to 24, h respectively. Some examples of time-temperature cycles are given in Table 2. Temperature uniformity within the retort load during the holding period is usually required to be within 14 °C (25 °F) of nominal. Off-gases from the process, carried by the inert gas flow, contain environmentally harmful chemicals such as aluminum chloride, hydrogen chloride, aluminum fluoride, hydrogen fluoride, and chromium chloride. These must be captured by scrubbing and filtering before the inert gas is vented to the atmosphere, and then disposed of in accord with applicable environmental regulations.

Unloading the retorts and boxes, separating the parts from powders and masking devices, and cleaning the parts, including thorough water washing, are currently labor intensive. Blades and vanes may require further heat treatment to cause proper development of the coating and/or to obtain optimum mechanical properties of the substrate alloy. Such treatments require inert or vacuum environments with the same rigid temperature controls as the coating thermal cycle.

Source Rejuvenation. It is common practice to rejuvenate powder mixes by additions of coating elements and alloys, and activators. Chemical analysis of the used mixes facilitates control of critical constituents. For simple systems historical data can sometimes be applied empirically for these purposes. Disposal of used mixes is quite costly under current environmental regulations. Recovery and recycling of expensive metals is being practiced with increasing frequency.

Quality Control. The most widely accepted quality control practice requires coating of representative samples with each processing cycle and destructively evaluating these to determine accordance with user specifications for thickness (in the range of 25 to 100 μm, or 1 to 4 mils for most applications), and microstructure. Quantitative analysis by x-ray fluorescense or electron microprobe for elemental composition, for example, aluminum, chromium, and platinum content, may also be required. Complete coating coverage can be confirmed by contact thermocouple measurement or by heat tinting aluminized nickel alloys in air at 621 °C (1150 °F) for one hour--coated areas exhibit a gold color and uncoated areas a dark blue color. Procedures for nondestructive coating thickness measurements are available (Ref 47), but are not widely used for control of new coating production. There is increasing interest in measuring coating thickness and aluminum content to judge the remaining life of coatings on used parts (Ref 48).

If inspection reveals faulty coatings, parts may be overcoated using appropriate time-temperature cycles. In extreme cases the coatings are stripped in acid solutions, for example, nitric or hydrochloric acid for aluminide coatings, and subjected to another full coating cycle. This is to be avoided because aluminide coatings are formed by consumption of the nickel component of the alloy and removal of the coating can result in significant reduction in critical part dimensions. Increasingly, statistical process control is being used to avoid these problems.

Out-of-Contact Processes. When aluminizing and/or chromizing are to be accomplished by out-of-contact CVD processes, all preparation steps are as described previously. For simple static aluminizing or chromizing, parts may be

surrounded by suitable source material in the form of granules contained in baskets in a variety of coating box designs. A typical example is shown schematically in Fig. 7. Activator chemicals are simply sprinkled into the boxes which are then covered, placed in retorts, purged with inert gas and subjected to the usual time-temperature cycles. If coating of blade and vane cooling passages is required, a flow of the inert gas is used to carry the coating species through the passages (Ref 19). Alternatively, pressure can be lowered (Ref 49) or cycled (Ref 50) to accomplish internal passage coating. For so-called CVD processes, the coating species may be generated by passing reactive gases, based on hydrogen chloride or hydrogen fluoride in a carrier gas over the source material in a separate reactor with the gas stream directed into the main coating chamber to coat external or internal surfaces or both (Ref 17). In any case, all other items shown in Fig. 6 still apply. More detailed information on CVD processing can be found in the article "Chemical Vapor Deposition of Nonsemiconductor Materials" in this Volume.

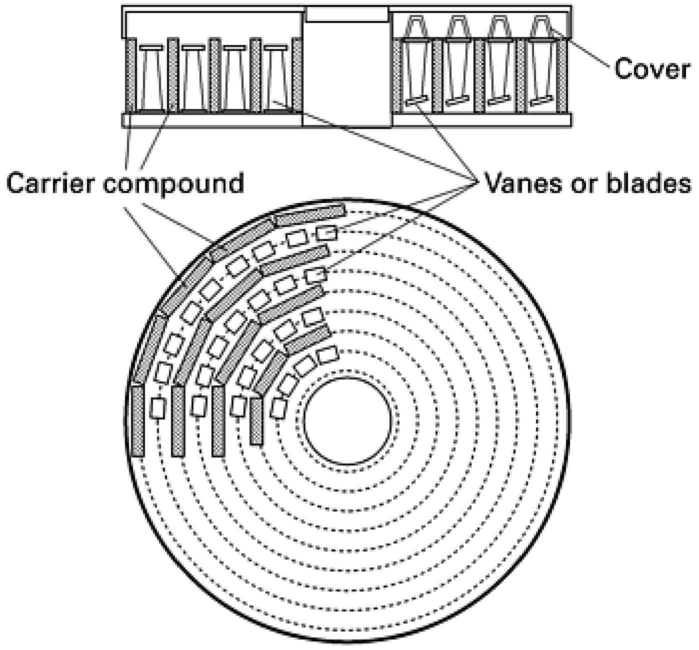

Fig. 7 Schematic of a coating chamber for an out-of-contact aluminizing process. Source: Ref 18

Repair. It is frequently possible to repair blades and vanes that have been in service for some time. To accomplish this, the first coating, now depleted during service, is removed by acid stripping. Parts are then repaired as appropriate, by welding, and/or brazing and re-machining (Ref 51). Suitable coatings are then re-applied as shown in Fig. 6.

Practical Applications

For aircraft gas turbine blades fabricated from moderately-corrosion resistant nickel alloys (those containing 12 to 15% Cr), simple aluminide coatings of the inward and outward diffusion types provide adequate protection for many contemporary engines. When alloys are more corrosion prone (those containing 7 to 10% Cr), current practice is to modify aluminide coatings by chromizing prior to aluminizing. Aluminizing should be by inward diffusion of aluminum to locate the higher chromium concentration in the outer layer of the coating (Ref 14). For more severe Type I hot corrosion resulting from exposure of engines to salt spray from marine environments, modification of aluminide coatings with silicon (or better, by platinum) can prove to be the more cost effective solution.

If more expensive structure modifications of nickel superalloys, such as single crystals, are used to full strength-temperature capabilities to enhance fuel efficiency, contemporary diffusion coatings may not meet design objectives for oxidation and/or thermal fatigue service lives of the turbine. For these conditions use of the more expensive MCrAlY overlay and/or ceramic (zirconia-based) thermal barrier coatings may be in order.

Ground-Based and Marine Gas Turbines. Achieving cost effective hot corrosion protection for ground- or marine-based gas turbines is a more complex problem because of wide variations in local environments with respect to air contaminants (salts, sulfur oxides, and other industrial pollutants) and fuel constituents (salts, sulfur, vanadium, etc.). Burgel (Ref 11) identified chromizing as one of the best solutions in ground-based engines subjected to severe Type II hot corrosion in the metal temperature range of 740 °C (1365 °F)--this in comparison to silicide, platinum-aluminide, and some MCrAlY type coatings. Chromide coatings are, however, not satisfactory above 800 °C (1470 °F). Platinum aluminides provide moderate protection at somewhat higher temperatures but may not be sufficiently resistant to lower temperature Type II hot corrosion. Similar considerations appear to apply for marine environments (Ref 52).

The trend for most ground-based gas turbines is toward the use of various modifications of MCrAlY type coatings, particularly those with higher chromium and perhaps silicon additions (Ref 53, 54). For the very latest machines operating at the higher temperatures for improved fuel efficiency, these coatings may be overaluminized (Ref 55, 56) and internal cooling passages simultaneously aluminized to resist increasingly severe oxidation conditions.

Future Development

Future development activity for pack cementation and related coatings, primarily for use in aircraft engines, will focus on more efficient automated and environmentally friendly manufacturing technology. In addition, means to incorporate additions of beneficial elements, such as hafnium and other oxygen-active elements, by codeposition with aluminum, should become practically available in the near future (Ref 16).

Pack Cementation Aluminizing of Steels

L. Keith Bennett and George T. Bayer, Alon Processing, Inc.

The pack cementation aluminizing process is used to improve the performance of steels in high-temperature corrosive environments. The complex aluminide intermetallic coatings formed during the process exhibit superior resistance to

oxidation, carburization, and sulfidation (Ref 57). Table 3 provides a partial listing of commercial applications for the pack aluminizing process. Typical applications include carbon steel heat exchanger tubes used in sulfuric acid plants, low-alloy steel pipes and fittings used in petroleum refinery heaters, type 304 stainless steel vessels used in flue gas desulfurization systems, and HK or HP cast tubing for ethylene pyrolysis units.

Table 3 Partial list of commercial applications of pack cementation aluminizing

Industry	**Component**	**Typical materials aluminized**
Hydrocarbon processing	Refinery heater tubes	$2\frac{1}{4}$% Cr-1% Mo steel
	Ethylene pyrolysis furnace tubes	Incoloy 802
	Hydrodesulfurizer furnace tubes	$2\frac{1}{4}$% Cr-1% Mo steel
	Delayed coker furnace tubes	9% Cr-1% Mo steel
	Catalyst reactor screens	347 stainless steel
	Catalyst reactor grating	Carbon steel
Sulfuric acid	Gas-to-gas heat exchanger tubes	Carbon steel
Industrial furnace components	Aluminum plant furnace parts	Carbon steel
	Heat treating pots	Carbon steel
	Structural members	High-nickel alloy steel
	Thermowells	Carbon and stainless steels
Steam power and cogeneration	Waterwall tubes	$2\frac{1}{4}$% Cr-1% Mo steel
	Fluidized bed combustor tubes	$2\frac{1}{4}$% Cr-1% Mo steel
	Waste heat boiler tubes	Carbon steel
	Economizer and air preheater tubes	$2\frac{1}{4}$% Cr-1% Mo steel

	Superheater tubes	$2\frac{1}{4}$% Cr-1% Mo steel
Aerospace[a]	Turbine blades	Nickel-base superalloy
	Turbine vanes	Nickel-base superalloy
Flue gas scrubbers	NO_x/SO_x removal units	304 stainless steel
Chemical processing	Reactor vessels and tubing	304/316 stainless steel
Cement	Cooler grates	Stainless steel, HP, HK

(a) Aerospace applications are described in the Section "Diffusion Coatings for Gas Turbine Engine Hot Section Parts" of this article.

Generalized Reaction Agents and Products

As described in the previous Section of this article which dealt with diffusion coatings for turbine blades and vanes, the pack cementation aluminizing coating process is performed in a pack consisting of the following mixture:

- Aluminum--in the form of a pure metal powder or alloy powder
- Filler--a ceramic powder phase, to prevent sintering of the mix during high-temperature processing. Usually aluminum oxide is used
- Activator--a volatile halide, usually an ammonium or sodium halide, to act as a chemical transfer medium for the aluminum

The precleaned steel parts to be pack aluminized are placed in a retort, or reactor vessel, with the pack mixture. Using ammonium halide ($NH_4X; X$ = F,Cl,Br,I) as the activator, the following sequence of high-temperature reactions occurs when aluminum is deposited on the surfaces of an iron-base alloy:

- Decomposition of NH_4X

$$NH_4X(s) = NH_3(g) + HX(g)$$

- Formation of volatile aluminum halides

$$6HX(g) + 2Al(pack) = 2AlX_3(g) + 3H_2(g)$$

$$AlX_3(g) + 2Al(pack) = 3AlX(g)$$

- Deposition of aluminum onto steel (substrate) surface

$$2AlX(g) + 3Fe(substrate) = 2AlFe(alloy) + FeX_2(g) \text{ (displacement reaction)}$$

$$3FeX_2(g) + 5Al(pack) = 3AlFe(alloy) + 2AlX_3(g) \text{ (displacement reaction)}$$

$$3AlX(g) + 2Fe(substrate) = AlX_3(g) + 2AlFe(alloy) \text{ (disproportionation reaction)}$$

$$2AlX(g) + 2Fe(substrate) = 2AlFe(alloy) + X_2(g) \text{ (decomposition reaction)}$$

$$2AlX(g) + H_2(g) + 2Fe(substrate) = 2AlFe(alloy) + 2HX(g) \text{ (reduction reaction)}$$

-

It is probable that deposition occurs principally by the disproportionation reaction, with replacement of Al*X* by the reaction $AlX_3(g) + 2Al(pack) = 3AlX(g)$. Rates of deposition are controlled by partial pressure gradients of reaction species between the source material and the coating surface.

Photomicrographs of the structure, including the diffusion zones, of pack aluminized low-carbon steel and type 304 stainless steel are shown in Fig. 8 (Ref 58). Comprehensive metallographic, x-ray, and electron microprobe analysis of the aluminum diffusion zone in stainless steels indicate an aluminum-rich surface (26-34 wt% Al) after undergoing this pack aluminizing process (Ref 59).

Processing Procedures

Cleaning. Prior to processing of parts, all surfaces should be cleaned to be free of oil, grease, mill scale, crayon, weld slag or spatter, and other foreign materials. A typical cleaning procedure might involve acid pickling to remove mill scale, removal of oil and/or grease by vapor degreasing, as well as abrasive or grit blasting. Grit blasting should be done using aluminum oxide abrasives (60 to 320 mesh, depending on surface finish) at 400 to 550 kPa (60 to 80 psi) from a 75 to 150 mm (3 to 6 in.) standoff. Residual grit should be blown off with a clean source of compressed air. From this point on until packing, parts should be handled with clean cotton gloves to prevent contamination.

Powder Blending. Depending on the material being processed and the desired aluminum activity of the pack, the aluminum pack cementation powder mix contains the following typical range:

- Aluminum (pure metal or ferroalloy): 4% to 25%
- Inert filler (Al_2O_3): 70% to 95%
- Halide activator: 0.5% to 4%

The two types of pack cycles are known as high activity and low activity (see the discussion on "Principles of Pack Diffusion Coating" in the previous Section of this article on "Diffusion Coatings for Gas Turbine Engine Hot Section Parts"). A high-activity pack contains a relatively high fraction of pure aluminum (Table 2) as the source material, a halide activator, and an inert diluent, usually alumina; the process is performed at lower temperatures (650 to 815 °C, or 1200 to 1500 °F). This type of pack generally requires a subsequent high-temperature heat treatment under an inert atmosphere in order to complete diffusion and obtain the required surface aluminum content and diffusion depth. A low-activity pack contains a lower fraction of aluminum, usually in the form of an alloy with iron or chromium, and is performed at higher temperatures (815 to 1150 °C, or 1500 to 2100 °F) with no subsequent heat treatment.

Packing. Retorts can be constructed from a variety of alloys ranging from plain carbon steel to nickel-base superalloys, depending upon desired service life and acceptable costs. Retorts should be fabricated to best accommodate the job being processed. The parts to be coated in the retort should be completely covered with pack mix and should not be allowed to touch each other or the walls of the retort. Prior to sealing the retort, it is advised to make sure that the pack mix is well settled. Low-temperature (high-activity) packs can be run in air, but with high-temperature (low-activity) packs, a protective blanket of hydrogen or inert argon gas is required. For obvious reasons, the use of argon is preferable for safety considerations. High-temperature retorts must be constructed with provisions for gas input/removal kept in mind.

Coating Cycle. Depending on the base material to be pack aluminized, processing temperatures can range from 650 to 1150 °C (1200 to 2100 °F), as measured from a thermocouple inside the retort. At specific process temperatures, a maximum of ±14 °C (±25 °F) must be maintained. Process cycle times can range from 3 to ≥40 h, depending on process temperature and base material to be processed. Transport of aluminum as aluminum chloride through the pack and solid state diffusion of aluminum through the base material is more influenced by process temperature than process time. Although higher process temperatures generally increase surface aluminum content and overall diffusion depth, in some cases the higher processing temperatures can have undesirable effects on the mechanical properties of the base material. In these cases, parts are processed at lower temperatures for longer periods of time.

Finishing. Retorts should be cooled to below 95 °C (200 °F) before opening. Parts should be removed and cleaned by brushing or by a light wet or dry abrasive blast. Certain alloys require controlled cooling cycles to maintain mechanical properties.

Classification of Materials

Pack compositions, process temperatures and process times depend on the type of base material to be aluminized. Materials fall into one of the following general classifications:

- Class I: carbon and low-alloy steels and copper
- Class II: ferritic and martensitic stainless steels and austenitic stainless steels with less than 20% Ni
- Class III: austenitic stainless steels with 21-40% Ni and iron-base superalloys

- Class IV: nickel-and cobalt-base superalloys

As a general rule, overall aluminum diffusion is slower as the nickel, chromium, and cobalt contents increase. Therefore, higher temperatures and longer process times are required to produce greater aluminum diffusion thicknesses as the base material goes from Class I to Class IV. (The Class IV materials are covered in the Section "Diffusion Coatings for Gas Turbine Engine Hot Section Parts" of this article.)

Quality Control

Process quality is monitored by testing of coupons or test pieces which are run in the retort with the production materials during the process cycle. These test pieces are used to determine quality and depth of aluminum diffusion, and should be of the same or similar base material as the production parts. These pieces should be located in the hottest and coldest sections of the furnace loads. These locations should be determined prior to actual processing of parts through furnace surveys.

After the processing has been completed, the test pieces are removed from the retort and examined according to ASTM C 664-87, "Standard Test Methods for Thickness of Diffusion Coating." There are two procedures for measuring the thickness of diffusion coatings. Method A is the determination of the dimensional-change thickness, defined as the difference in the part before and after coating. This method employs a micrometer. Method B is the determination of total coating thickness, defined as the distance between the observably unaffected substrate and the exterior surface of the coating. This method employs standard metallographic specimen preparation equipment for mounting, polishing, and etching as well as a metallographic or optical microscope for observation of the diffusion layer at 100× and 500×.

Quality control reporting should include the maximum, minimum, and average coating thickness (in mils) of the individual measurements made on a specific part of the specimen surface. If Method B is used, a photomicrograph showing the bounds of a typical area of the coating is recommended. Depending on base materials and processing conditions, thicknesses from 1 to ≥40 mils (25 to 1000 μm) can be produced.

Additional mechanical testing may also be appropriate for processed materials which may undergo mechanical property changes due to the temperatures encountered in the process cycle. This testing could include hardness/microhardness measurements, as well as tensile testing to determine yield strength, ultimate tensile strength, and percent elongation.

Properties of Pack Aluminized Steels

Oxidation Resistance. The action of pack aluminized steels under heat is similar to that of unprocessed stainless steels. Stainless steels owe their oxidation resistance to the formation of a thin chromium-rich oxide (Cr_2O_3) film which protects the underlying steel. A similar reaction occurs with aluminized steels, which form an even more protective oxide. Al_2O_3, from the aluminum in the coating. This oxide grows at a lower rate than Cr_2O_3 and does not exhibit volatility in the presence of oxygen above about 927 °C (1700 °F) as does Cr_2O_3. While a type 304 stainless steel scales excessively at temperatures of ≥870 °C (≥1600 °F) in an oxidizing environment, a pack aluminized carbon steel exhibits only slight discoloration of the surface under these conditions. Figure 9 compares aluminized carbon steel with bare carbon steel, 5% Cr steel, 12% Cr steel, and 18Cr-8Ni steel with respect to the temperature at which scaling is less than 10 mg/cm^2 for oxidation in air. High-strength, highly alloyed stainless steels are also frequently aluminized to improve their oxidation resistance in elevated-temperature applications.

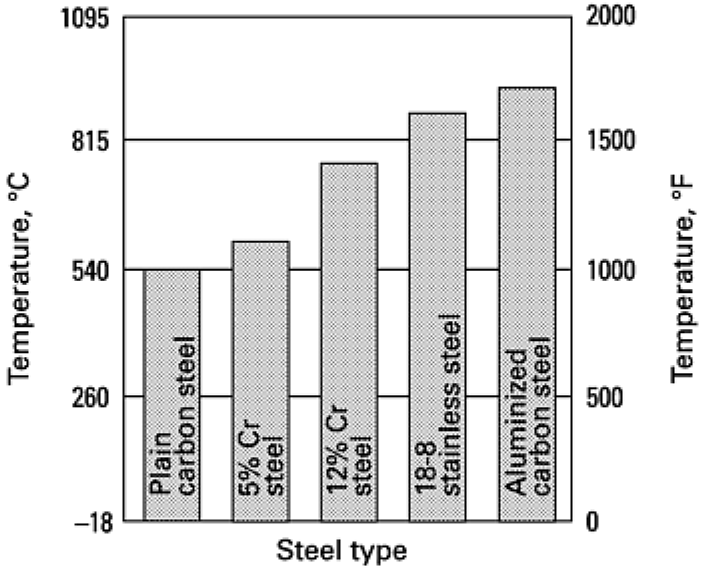

Fig. 9 Oxidation of steels in air at the temperature at which scaling is less than 10 mg/cm^2. Source: Ref 60

Sulfidation Resistance. Pack aluminized steels have remarkable resistance to the corrosive attack of gases such as hydrogen sulfide (H_2S), sulfur dioxide (SO_2), and sulfur trioxide (SO_3) as well as many other sulfur-bearing atmospheres at temperatures exceeding 230 °C (450 °F). The diffusion zone typically contains a minimum of 20% Al while the alloy surface is about 50 at.% Al and is far more resistant to high-temperature sulfide corrosion than stainless steels containing as much as 28% Cr. The maximum temperature at which these materials can be used in sulfur-bearing environments is limited by the high-temperature mechanical properties of the base steel. Figure 10 provides experimental data on the relative corrosion rates of bare and aluminized 9Cr-1Mo steel in H_2S environments.

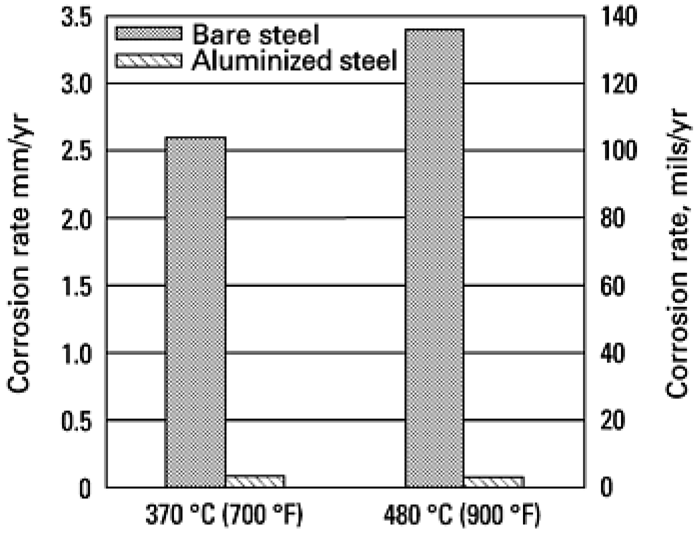

Fig. 10 Relative corrosion rates of 9Cr-1 Mo alloy steel in 5 mol% H_2S at 3550 kPa (515 psi) for 300 h. Source: Ref 61

Carburization Resistance. When exposed at high temperatures to carbon-rich atmospheres, both stainless and alloy steels will carburize, become extremely brittle, and lose their heat- and corrosion-resistance properties. In certain environments, metal dusting associated with carburization will rapidly destroy the steel. Pack aluminized steels, however, suffer negligible deterioration from either carburization or metal dusting in high-temperature, carbon-rich atmospheres,

thus greatly lengthening the service life of the steels in these environments. Figure 11 compares the carburization resistance of bare and pack aluminized austenitic stainless steels.

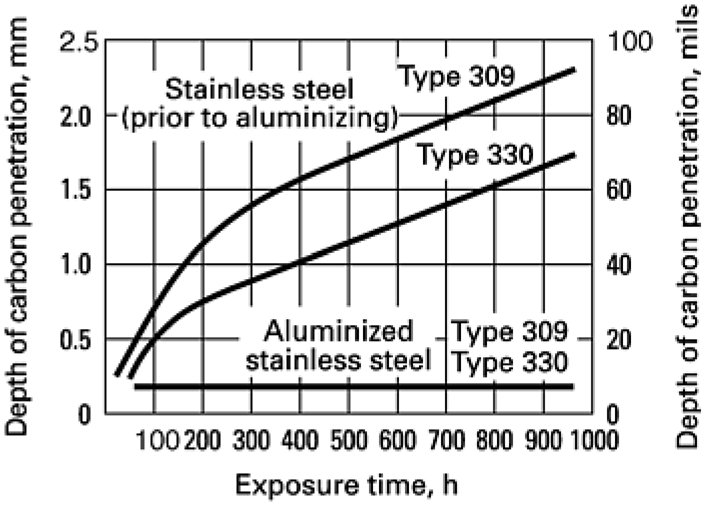

Fig. 11 Carburization resistance of bare and aluminized stainless steels at 925 °C (1700 °F). Source: Ref 62

Pulsed-Laser Deposition

James S. Horwitz, Naval Research Laboratory

Introduction

PULSED-LASER DEPOSITION (PLD) is a physical vapor deposition (PVD) technique that has gained popularity for the growth of high-quality multicomponent oxide thin films (Ref 1, 2, 3). Conceptually, PLD is an extremely simple PVD technique. The output of a short laser pulse (10 to 30 ns) is focused onto a solid target. The laser rapidly raises the surface temperature of a small portion of the target well beyond the vaporization temperature. A plume of evaporated material is ejected from the target and is collected on a nearby substrate. The congruent non-equilibrium evaporation of multicomponent materials and the transfer of the target composition to the deposited film make available high-quality thin films of materials that could not be deposited by other PVD techniques.

Much of the current research on PLD is due to the success realized with high-temperature superconductor (HTS) materials. In 1986 (Ref 4), the discovery of ceramic superconductors was soon followed by an intense search for a PVD technique that could be used to cast these materials in thin film form. Ceramic superconductors are generally complex multicomponent oxides containing three or more metals (e.g., $YBa_2Cu_3O_7$, or YBCO) with anisotropic electrical properties. PLD was among the techniques surveyed for possible application in the fabrication of thin-film superconductors at the time that bulk superconductors were being developed. Even though PLD was far from the advanced level of other film growth techniques, it was demonstrated that high-quality superconducting films could be reproducibly deposited by PLD. As a result, the technique became an integral component in the development of thin film applications of HTS materials.

Prior to 1987, there were very few research efforts in the area of PLD. This is despite the fact that literature references as early as 1965 (Ref 5) cite the capability of a short-pulse, high-peak power laser to "flash evaporate" a multicomponent target and transfer the composition of that target to a nearby substrate. PLD did not achieve widespread popularity at the time of its discovery, partly because the lasers required were not commercially available and the duty cycles (≤ 1 Hz) at which research laser systems operated were not suitable thin film production. At the time of its discovery, laser flash evaporation was not perceived to have any clear advantage over conventional evaporation techniques.

Between 1964 and 1987, research on the production of high-powered lasers was accompanied by studies of the interaction of the radiation field with solids, primarily to determine the origin of optical damage (Ref 6). These studies included an analysis of the vapor created by lasers focused to ablation energy densities. Film growth studies included the deposition of complex materials (ReB_{22}) (Ref 7), reactive deposition (Ref 8) (i.e., oxidizing ambients and enhanced gas-phase reaction due to high kinetic energies of evaporated material) (Ref 9), and the growth of high-quality II-VI semiconductor superlattices (Ref 10, 11, 12). However, research in these areas was still not sufficient to distinguish PLD as a new and important coating technology. The rapid development of the technique since 1987 is a combination of a materials need that could not be adequately met by conventional film growth techniques and the commercial availability of high-powered excimer lasers. Had high-temperature superconductivity been discovered in simpler, binary systems, PLD may have remained the interest of a relatively small research community. However, many of these new materials contain four or five elements, and the systems have extremely complex phase diagrams. These systems were the driving force in the development of this new technique.

The general attributes of PLD for thin film growth are summarized in Table 1. In addition to congruent evaporation and stoichiometric vapor transport, the high instantaneous growth rates lead to low impurity incorporation from the background. Although the pulsed lasers used generally have high peak powers, average power is low, and therefore the target remains thermally stable. PLD is a simple technique and therefore leads to reproducible deposition conditions. However, the technique is new, and it is difficult to predict optimum growth conditions. For most materials, it is still a trial-and-error process to determine optimum deposition conditions.

Table 1 Attributes of PLD

Attribute	Effect on film
Positive	
Congruent evaporation	Stoichiometric deposition
Large range of deposition pressures	Control of vapor energy; control of volatile components
High instantaneous deposition rate	Low impurity incorporation
Low average power	Target remains thermally stable
Simple equipment	Reproducible properties
Negative	
Relatively new technique	Difficult to predict film properties
Line of sight	Difficult to coat nonplanar objects

High instantaneous evaporation rate	Particulates

PLD research now covers a wide variety of conducting and insulating metal oxide thin films (e.g., ceramic superconductors, ferroelectrics, and ferrites) as well as nonoxide materials (e.g., semiconductors, metals, nitrides, and diamond-like carbon) (Ref 13). The areas of application range from electronics to biology, tribology, and optics. The list of materials successfully deposited as high-quality thin films is continuously growing. In spite of its success, the technique remains primarily a laboratory research tool, providing high-quality thin films and multilayers of complex materials for materials research and the development of new devices and applications based on these materials. This review describes the PLD technique and the components required for a simple system, examines the properties of the depositing vapor and how it is affected by the deposition parameters, and cites examples of classes of materials for which the technique offers a unique advantage over more conventional processes.

General Description

In PVD of multicomponent thin films, the preparation of a stoichiometric vapor is often difficult to achieve. When single-element sources are used, the arrival rate of each individual component must be calibrated and inter-regulated. In PLD, the composition of the vapor is the same as that of the target. Starting with the correct composition of the vapor greatly facilitates the growth of a desired phase in the depositing film. In addition, the absence of filaments or charged particles allows films to be grown by PLD in the presence of reactive gases. These gases can promote the growth of the desired thin film material through gas-phase reactions with the evaporated target material and gas-surface reactions with the growing film.

The pulsed laser ablation of materials can be viewed as taking place in several stages (Ref 6). The laser deposits energy into the target. Absorption of the radiation by the target material leads to surface heating and defect formation. The energy absorbed per unit volume depends on the optical penetration depth, the thermal diffusivity, and the rate at which the energy is deposited (Ref 14, 15, 16). The rate at which the energy is deposited is determined by the laser pulse width. The rise in surface temperature can be calculated from the ratio of the rate at which energy is deposited into the material to the rate at which the heat is conducted away. Typically, the laser is focused to a small spot (e.g., a few square millimeters) to minimize the volume of material being heated and to achieve surface temperatures that are greater than the melting temperature. If the optical penetration depth is small compared to the thermal diffusion length, surface heating is confined to the thermal diffusion length, and the change in temperature can be calculated from the energy absorbed, the volume of material irradiated, and the heat capacity. If the optical penetration depth is long, the rise in temperature is at a maximum at the target surface but decays exponentially as a function of depth below the surface (Ref 14, 15, 16).

Surface heating is followed by melting and evaporation. For most materials, there is a threshold laser fluence for the macroscopic removal of material from the surface (Ref 17). The high temperatures generated at the surface cause the emission of many species from the target, including ions and electrons generated by thermionic emission as well as atoms and molecules. Continued interaction of the laser pulse with the evaporated material causes the vapor to be ionized via nonresonant multiphoton processes, creating a plasma above the target. As the density of electrons increases, the laser radiation is absorbed preferentially in the plasma by inverse bremsstrahlung scattering (Ref 6). The absorption further heats the plasma and at the same time screens the laser pulse from further interaction with the target.

The high-pressure, high-temperature plasma expands rapidly into the vacuum. The dynamic behavior of the expansion has been compared to a supersonic or free-jet expansion (Ref 18, 19). In a free-jet expansion, the random motion of gas-phase particles in a high-pressure plasma is converted to a directed mass flow by expanding through a pinhole into a low-pressure region. Free-jet expansions are characterized by narrow, energetic velocity distribution about a center of mass velocity (Ref 20). A similar phenomenon is observed in PLD. A small high-pressure region is created at the target surface and then expands into the relatively low pressure of the vacuum system. The laser-generated plasma is a complex mixture of neutral and charged particles, each with different kinetic energies. Average neutral energies of ≈ 10 eV are observed (compared to thermal evaporation particle energies of ≈ 0.1 eV). Charged particle kinetic energies of as much as 10 to 100 times the neutral particle energies are also observed. The fraction of ionized material in the plasma is difficult to measure. Estimates vary between 1 and 10% (Ref 21).

The high energy content of the depositing vapor is believed to be one of the reasons for the success of PLD over other PVD techniques. The added energy can benefit film quality in several ways. First, gas-phase reactivity increases with atom kinetic energy. Enhanced oxidation cross sections are reported for laser-evaporated materials (Ref 22). For some materials, a correlation has been reported between the maximum concentration of metal oxides formed in the gas phase and optimum film properties (Ref 21, 29). Secondly, PLD films can typically be grown at a reduced substrate temperature in comparison to other PVD techniques. Substrates are usually heated to provide the arriving vapor with enough surface mobility for the atoms to build up on the surface in thermodynamically stable sites. Adding the energy to the vapor, as is done in PLD, means the substrate temperature can be lowered. This is desirable in cases in which the vapor can undergo a chemical reaction and the substrate or volatile components can be lost from either the film or the substrate.

Under optimized conditions, oriented thin films can be prepared by PLD in situ, minimizing the production of impurity phases, grain boundaries, and random orientations that might be formed during a postdeposition anneal. Although average film deposition rates for PLD are comparable to those in many other PVD techniques, the pulsed arrival of the vapor at the substrate results in instantaneous deposition rates of ≈ 1000 to 10,000 Å/s. The instantaneous deposition rate minimizes the incorporation of background impurities into the depositing films, further improving the film quality.

Plume Diagnostics. A number of diagnostics have been used to characterize the laser-generated plasma (Ref 23): optical emission (Ref 24, 25, 26), absorption (Ref 27), laser-induced fluorescence (Ref 28, 29), resonance-enhanced multiphoton ionization (Ref 30), mass spectrometry (Ref 31, 32, 33 , 34), and ion probes (Ref 35). These diagnostics are being used to address several mechanistic issues relevant to film growth (Ref 23):

- The role of thermal versus nonthermal evaporation
- The extent to which the laser radiation interacts with the evaporated material
- The effect of the laser-generated plasma on the target
- The expansion mechanism responsible for the high initial particle energy
- The fraction of ionized material from the target surface out to the substrate surface
- The importance of clusters
- The role of the ambient in scattering, diffusion, shock front formation, and gas phase chemistry

The answers to these questions will come not from a single technique, but from a combination of the information provided by each of the diagnostics (Ref 23).

In the laser-generated plasma, the distribution of particles and the particle energy depend on the material, laser wavelength, laser fluence, and ambient composition and pressure. The characteristics are both temporally and spatially dependent. Presumably, this is the reason that optimized deposition conditions vary from system to system. An ideal vapor arrives at the substrate surface compositionally correct and with a kinetic energy that is high enough to allow

adequate surface mobility, but not so high as to introduce defects or sputter the depositing vapor. The goal of these studies is to make a direct correlation between the vapor phase properties and the film properties.

Among the plasma diagnostics mentioned above, optical techniques have dominated the research efforts. These techniques are noninvasive and can be performed at the pressures under which films are deposited. Optical techniques have been used to identify the dominant components of the plume as being atomic and small molecular species. Dispersed emission spectra have been measured as a function of distance above the target from the vacuum ultraviolet through the visible (Ref 23, 24, 25, 26). Close to the target a continuum in the emission spectrum is observed, indicative of bremsstrahlung emission and a high density of free electrons. Several centimeters above the target, emission spectra are more characteristic of the isolated atomic species. The presence of electronically excited atoms and molecules at this distance is due to collisional, not optical, excitation. Secondary electrons generated from background gas ionization recombine with highly charged particles to form electronically excited species.

The dispersed spectra have been used to estimate the plasma temperature, which varies from 5,000 to 15,000 K (Ref 26, 36). Particle velocities (v) have been modeled using Maxwell-Boltzmann distributions $f(v) \sim \exp(-mv^2/2kT)$ and shifted distributions about a common center of mass $f(v) \sim \exp(-m(v-v_{cm})^2/2kT)$ (Ref 30). The shifted Maxwell-Boltzmann arises as a result of a Knudsen layer formed at the target surface (Ref 37, 38). Peak velocities are reported as $\sim 10^5$ to 10^6 cm/s (Ref 21). Optical techniques have also monitored the formation of gas-phase species from the reaction of the ambient with the ablated material. In these studies, maximum gas phase production has been correlated with optimum film growth pressures. For example, in YBCO, the concentrations of YO and CuO are at a maximum at the optimum deposition pressure for high-quality films (Ref 21, 29).

Optical imaging techniques have also been used to detect the presence of a shock front (region where the plume and background gas pressure are the same) (Ref 39, 40, 41). The position of the shock front depends on the plasma temperature and pressure and the total system pressure. In vacuum, the shock front is relatively far from the target surface (several times the target substrate distance in typical deposition systems). As the ambient pressure is increased, the shock front moves in toward the target. The position of the shock front relative to the substrate is important for optimizing the properties of the deposited film.

Equipment

Vacuum System. Figure 1 is a schematic of a PLD system. The laser radiation is focused onto a rotating target at an angle of ~45°. The substrate is mounted at 90° with respect to the target normal. Typically, the target and substrate are separated by ~5 cm, but distances as large as 12 cm have been reported (Ref 42). The vacuum system requirements vary depending on the material. Generally, oxide films are deposited in an oxygen ambient at pressures <1 torr and do not require systems with ultrahigh vacuum base pressures. Gas flow rates of 10 standard cm^3/min at the desired deposition pressure can be achieved by gating the pump with the total system pressure controlled by a solenoid-activated leak valve that is controlled by a pressure transducer. At a minimum the vacuum chamber requires a pumping port, a gas inlet and pressure monitoring, a window transparent at the laser wavelength, and a viewport.

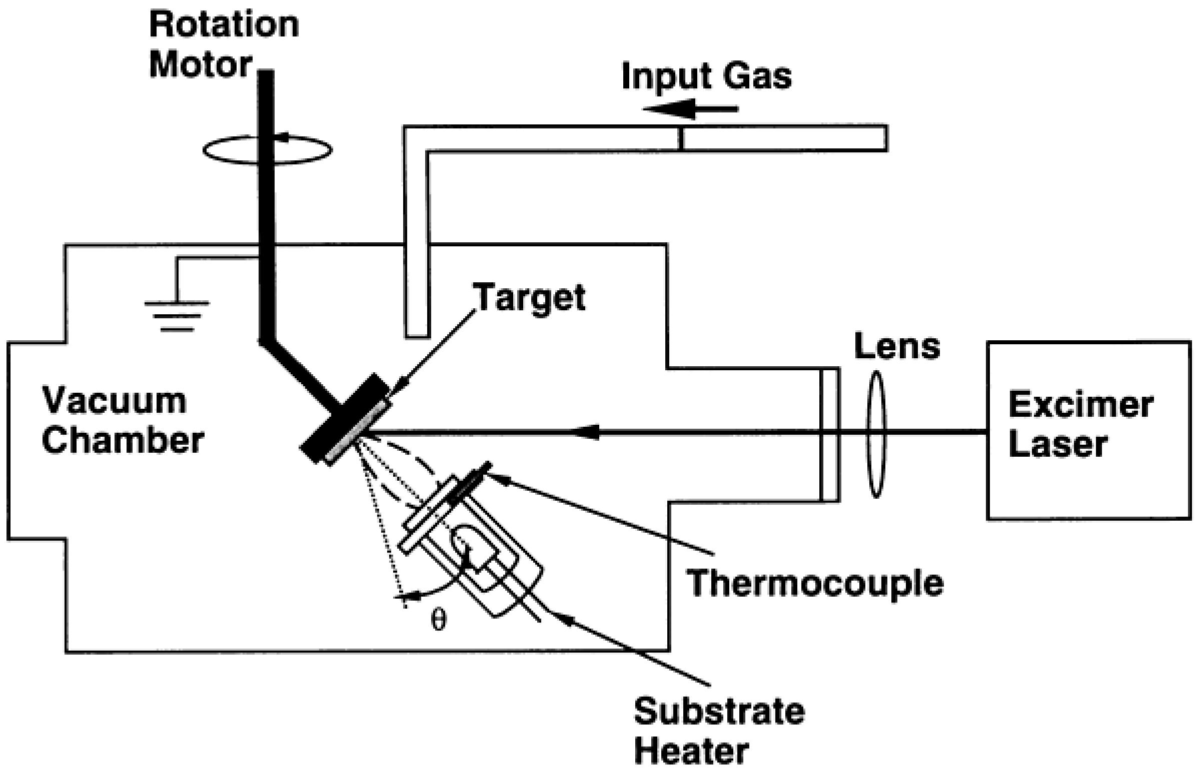

Fig. 1 Schematic diagram of a typical pulsed laser deposition system

Laser. The laser system and focusing optics are located outside the chamber. The focal length needs to be matched to the chamber size so that the required energy densities can be achieved at the target surface. Many different laser wavelengths have been successfully used. The excimer is the most commonly used laser because of its high peak power (> 40 MW) in the ultraviolet and ease of operation. In an excimer laser, the lasing medium is a rare gas/halogen mixture. A summary of rare gas mixtures and the output laser wavelengths is presented in Table 2. KrF (248 nm) is probably the most common excimer used for thin film deposition due to its stability and high peak power. In addition to excimer lasers, other gas laser systems (CO_2) and solid state laser systems (Nd:YAG) have been used to deposit thin films. The output wavelengths of these lasers can vary from 0.2 to 10 μm. Film quality as a function of laser wavelength has been compared (Ref 43), and it is generally accepted that film quality is significantly better for ultraviolet (UV) lasers (200 to 300 nm) than for infrared (IR) lasers (1 to 10 μm). This is due to a decreasing penetration depth of the laser radiation into the bulk material as the wavelength is reduced. The shallower penetration depth results in more energy being deposited per unit volume for comparable UV and IR pulse energies. As a result, UV lasers produce higher surface temperatures and more efficient evaporation of the solid target. IR lasers are often associated with thin films having rough surface morphologies, as a result of the incomplete vaporization of the target and the ejection of micron-size particles. Attenuation of the radiation by oxygen (in addition to the photochemical production of ozone) limits the use of laser wavelengths below 200 nm.

Table 2 Excimer laser wavelengths

Wavelength, nm	Rare gas/halogen mixture
157	F_2
293	Ar-F_2
222	Kr-Cl_2
248	Kr-F_2
308	Xe-Cl_2
351	Xe-F_2

An individual laser pulse transfers a large amount of material from the target to the substrate (~10^{16} atoms per pulse), resulting in average deposition rates of ~1 Å/laser pulse (deposition rates are a strong function of the target composition and phase and the deposition conditions). To achieve a coating thickness on the order of 1.0 μm requires 5000 to 20,000 laser pulses. Commercial excimer systems operate at repetition rates as high as 150 Hz, and high-quality films 0.5 μm thick have been deposited at average growth rates as high as 150 Å/s.

Substrate Heater. For many materials, it is desirable to deposit at elevated substrate temperatures. Two problems are often encountered when trying to achieve uniform substrate temperatures $\leq$900 °C in oxidizing environments. First, the heating element must be inert to the ambient. Second, the typical deposition conditions (10^{-6} to 1 torr) do not allow for efficient gas-phase heat conduction from the radiating element to the substrate. Projection lamps serve as efficient heating elements because the filament is encapsulated in a quartz envelope. The lamps can be used to heat a small steel block to temperatures that approach the softening temperature of the quartz. The substrate is mounted onto the steel heater block. Transfer of the heat from the steel block to the substrate is usually done through a conductive bonding agent such as silver paint. This type of heater can be used for small substrates (up to ~1 in. diameter) and temperatures up to ~950 °C.

Alternatively, substrates can be heated using a pseudo-blackbody heater (Ref 42). Here the substrate is encased in a well-shielded heater with only a small opening for the depositing vapor. The substrate is not required to be in intimate thermal contact with the heater block because the temperature everywhere inside the blackbody is the same. Substrate heaters of this type have been successfully developed for the deposition of large-area films (>1 in. diameter). Rotation of the substrate inside the blackbody heater improves the temperature uniformity.

Target Manipulation. The target must be continuously manipulated to avoid having the laser strike the same spot on the target with successive shots. This is done exclusively by rotating the target during deposition. This minimizes problems associated with erosion at the target surface. Commercial systems are available that hold up to six rotating targets, 1 in. in diameter, that can be selected under computer control to be positioned in front of the laser focus. With this type of system, multilayer structures can easily be formed.

Laser Beam Rastering. Target rotation ensures uniform erosion. The laser beam can also be rastered across the target. In addition to minimizing problems associated with erosion, rastering of the laser beams increases the area of a substrate that can be coated. In PLD, the plume of evaporated material is highly forward-directed. If the position of the laser beam remains fixed in space, the plume of evaporated material is directed at a relatively small area on the substrate. For most deposition systems, a stationary laser beam produces a uniform coating over 1 cm^2. In its simplest form, the laser beam is moved by a motorized mirror mount across the target. The substrate and target are mounted so that their centers are on axis. The plume of evaporated material is swept across the substrate. The main limitation to this geometry is that the coated area is determined by the size of the target. Off-axis geometries have also been demonstrated (Ref 44). Offsetting the target center from the substrate center allows the same aerial coverage with a target that is only half the size of the substrate. Another scale-up technique is to raster the substrate in two dimensions while holding the laser position fixed on the target (Ref 45). This scheme has the advantage of not requiring large-area targets but suffers from the complications of having to move the heating elements.

Research efforts continue on the scale-up of PLD to large areas, although it is not yet clear what technological application will be the first to implement large-scale PLD in an industrial environment. Both ferroelectric and HTS thin films have been deposited over large areas as demonstrations. Uniform coatings have been successfully demonstrated on planar surfaces up to 5 in. in diameter. However, there is still a great deal of work to be done on the device structures based on these materials, and the demands for large-area coatings is relatively small. The versatility of the technique is simply not yet great enough to generate industrial acceptance.

Deposition Parameters. Typical deposition conditions are:

- *Laser wavelength:* 193 nm to 1.06 μm
- *Laser spot size:* 3-5 mm^2
- *Laser pulse energy:* 100-500 mJ
- *Laser pulse width:* 10-30 ns
- *Laser fluence:* 1-5 J/cm^2
- *Laser repetition rate:* 5-100 Hz
- *Substrate temperature:* Room temperature to 950 °C
- *Ambient pressure:* 10^{-6} to 1 torr

Deposition Characteristics

Angular Distribution. In general, the angular distribution of material from the laser-generated plasma is sharply peaked with respect to the target normal, with some tilting of the distribution toward the incident laser beam. Early studies on the PLD of multicomponent films indicated that the spatial distribution of deposited material was also accompanied by a spatial variation in film composition. In thermal evaporation, a small effusive source is described as having a $\cos(\theta)$ distribution (θ is the angle at which the material is ejected from the target relative to the surface normal of the target; see Fig. 1). This results in a $\cos^4(\theta)$ thickness distribution of the film on the substrate. In a purely effusive source, there are no collisions from the evaporation region to the substrate surface. In PLD, a large number of collisions take place in the high-pressure plasma and are responsible for the forward peaking. It is difficult to generalize on the exact functional dependence of the angular distribution of material because it is sensitive to a number of the deposition parameters (e.g., laser wavelength, fluence, spot size and geometry, target-substrate distance, and background gas pressure). As an example, in vacuum the angular distributions, as determined from film thickness, for single and multicomponent materials have yielded values of x ($\cos^x(\theta)$) ranging from 2.3 to 30 (Ref 46).

The angular distribution of ejected material is also sensitive to the shape of the laser spot on the target. The rectangular shape of excimer laser beams typically results in a rectangular focused spot on the target. In some systems, it has been observed experimentally that the deposited film has a rectangular image, with the long and short axis of the film reversed from the image on the target. The rotation of the image is an indication that plume expansion proceeds fastest along the shorter axis (i.e., there are fewer collisions and the particles can achieve greater velocities).

Effects of Added Gas. The addition of a background gas has a strong effect on the angular distribution of the evaporated material. Where direct comparison measurements have been made, the distribution has been less sharply peaked at an elevated pressure. Measurements on multicomponent oxides (e.g., YBCO) are complicated by gas-phase chemistry. For example, a comparison study has shown a reduction from $\cos^{23}(\theta)$ to $\cos^{17}(\theta)$ associated with a change from vacuum to 100 mtorr of oxygen (Ref 46).

The angular distribution changes nonlinearly with the added gas pressure. For elemental systems such as copper (Ref 47) or platinum (Ref 48), the initial addition of either argon (for copper) or oxygen (for platinum) leads to a forward focusing effect; that is, ejection of material occurs at smaller angles. Forward focusing is manifest as a narrowing of the angular distribution function (increasing x) and an increase in the average film deposition rate. This behavior reaches a maximum effect at low pressures (~1 to 50 mtorr). Above this pressure, scattering dominates and the average deposition rate decreases as material is scattered over larger angles.

Particulates

One of the most often cited drawbacks to PLD is the rough surface morphology of the deposited films. The observed surface roughness can originate from a variety of mechanisms. For the same deposition conditions (i.e., laser parameters), the particulate density (number of particles/$cm^2 \cdot Å$ of film) varies significantly from material to material (Ref 49). No one model is able to predict the size and distribution of the particulates. One of the main causes of surface roughness is the ejection of micron-size particles from the target. These particles can be problematic for electronic materials, especially those involving multilayers of conductors and insulators, as well as optical materials in which particles can serve as scattering centers. There are at least three mechanisms associated with formation of surface particulates: subsurface boiling (Ref 50), shock wave recoil (Ref 51), and exfoliation (Ref 52). Subsurface boiling occurs when the required heat transfer time is less than the evaporation time. The subsurface reaches a molten temperature before the surface layer has evaporated. The effect of subsurface boiling can be minimized by reducing the laser power, which also reduces the deposition rate. Above the target surface, a shock wave is formed at the boundary of the high-pressure region and the vacuum. Recoil pressure from the shock wave into the target can also result in the ejection of micron-size particles. These particles can be reduced by reducing laser power. Continuous heating and cooling of the laser target leads not only to erosion but also to modification of the target surface. Micron-size cones that point back at the direction of the incident

laser beam are observed on the surface of ceramic targets and can be broken off by the shock of the laser. The presence of these structures can be minimized by mechanical polishing of the target surface.

Mechanical Filters. Although the presence of particulates seems to be an inherent property of the PLD process, careful control of deposition parameters can minimize their density. Additional particulate reduction can be achieved mechanically through the use of a particle filter (Ref 53). A velocity filter operates on the principle that particle size can be correlated with particle velocity. A shutter can be used to allow fast-moving (10^6 cm/s) atomic vapor to pass while blocking the slower-moving (10^3 cm/s) particulates (Ref 34). In practice, a rotating chopper (3000 to 10,000 rpm) can be synchronized to the firing of the laser. Mechanical filters are effective at reducing the aerial density of particulates regardless of the mechanism of origin.

Off-Axis PLD. The most common PLD geometry has the substrate facing the target, separated by a few centimeters. This is designed to maximize the film deposition rate. Recently, there have been a few reports of off-axis PLD. Non-normal geometries have been successfully used in the PLD of YBCO thin films, and two geometries have been reported. Mounting the substrate surface so that it is parallel to the target normal is essentially equivalent to an off-axis sputtering geometry (Ref 54). The majority of the ejected vapor (in addition to the particulates) travels across the substrate surface, without depositing. Although the deposition rate is decreased, there is substantial discrimination of the larger particulates in the depositing thin film. Additionally, substrates have been mounted facing away from the target surface (Ref 55). Films are deposited in high background pressures of reactive gases. Preferential slowing of the atomic vapor over the particulates allows deposition of smooth films and a substantial reduction in the average deposition rate. The required thermalization of the evaporated material and the absence of energetic ions in the depositing vapor does not seem to affect the properties of YBCO films.

Materials

PLD is currently being used to deposit thin films for a wide range of technological applications. These films vary from epitaxial superlattices of electronic materials to polycrystalline bioceramics. Several recent review articles have attempted to catalog research efforts to date (Ref 15, 56, 57), indexing films by composition, phase, and the laser used to deposit the film. It would appear that the vast majority of research published to date on PLD has been directed at multicomponent oxides. The technique offers a clear advantage when the material contains more than two elements. The ceramic superconductors have provided the complex materials needed to accelerate research in PLD.

High-Temperature Superconductors. More research has been devoted to PLD of superconductors than to PLD of any other class of materials. There are two classes of oxide superconductors:

- *Cuprates:* Y-Ba-Cu-O, Bi-Sr-Ca-Cu-O, La-Sr-Cu-O, Nd-Ce-Cu-O, Tl-Ba-Ca-Cu-O
- *Noncuprates:* Ba-K-Bi-O, Ba-Pb-K-Bi-O

YBCO was the first of these materials to exhibit superconductivity above liquid nitrogen temperatures (Ref 58). Although other materials have since exhibited higher critical temperatures, YBCO still remains one of the more promising materials for applications because it is relatively easy to obtain in single-phase form. Crystallographically, the YBCO unit cell is based on a cubic perovskite structure. The superconductor is a triple layer of the cubic unit cell, with the corners of the perovskite either CuO_4 or CuO_5. The electrical properties of YBCO are highly aniostropic. Phase pure, polycrystalline materials have low critical currents (10^3 to 10^4 A/cm^2) because of the poor electrical conductivity of the randomly oriented grains. Epitaxial or even textured thin films (with the *c*-axis normal to the substrate surface) provide alignment of the conduction planes and high critical currents on the order of 10^6 A/cm^2. Current technological applications of YBCO thin films are divided into two classes: active components (based on Josephson junctions) and passive components (e.g., microwave wave guides) (Ref 59).

Currently, smooth YBCO films can be deposited by a large variety of PVD techniques (Ref 60), including single-source techniques such as sputtering as well as multisource techniques such as molecular beam epitaxy and chemical vapor deposition. In spite of the equivalent film properties of these techniques, PLD remains one of the preferred deposition techniques because of its minimal vacuum system requirements, high average deposition rate, and ease of optimization (see Table 1). However, most applications for superconductors require integration of the superconducting thin film with insulating thin films. The superconductor-insulator interface should be sharp, with the insulating material latticed matched to the superconductor. The deposition technique needs to be versatile to switch between the superconductor and the insulating material.

The first generation of passive microwave electronics based on HTS thin films were fabricated from patterned superconducting thin films deposited onto one side of low-dielectric substrates. MgO and $LaAlO_3$ substrates have been used in the majority of these applications. Advanced microwave devices will be fabricated from trilayer films: superconductor/dielectric/superconductor. In these multilayer structures, the dielectric films (2000 Å to 10 μm thick) must have a low dielectric constant, low loss tangent, and high resistivity, and they must provide a lattice-matched surface for the growth of the top superconducting thin films. Several dielectric films have been successfully deposited in trilayer structures by PLD. Insulating materials include $LaAlO_3$ (Ref 61), $NdGaO_3$ (Ref 62), and $PrGaO_3$ (Ref 63). The deposition of these multilayers can be achieved easily in situ simply by moving the laser beam from the superconducting target to the insulating target.

Barrier layers are also important for the application of HTS materials. Low-dielectric substrates, such as Al_2O_3, and semiconducting substrates, such as silicon or GaAs, react at the elevated deposition temperatures required for HTS thin films, leading to a degradation in the superconducting thin film properties. Barrier layers such as Y-ZrO_2 (Ref 64), $CoSi_2$ (Ref 65), CeO_2 (Ref 66), and $SrTiO_3$ (Ref 67, 68) eliminate substrate film interdiffusion and provide lattice-matched surfaces for superconducting thin film growth. Perhaps the most challenging barrier is that required for a Josephson junction. These barriers (deposited between two superconducting layers) must be on the order of the coherence length for the superconductor (for YBCO, ~10 to 30 Å). The nonsuperconducting praseodymium analog of YBCO is one of the candidate materials for this application (Ref 69, 70). For the application of high-temperature superconductors, PLD has been demonstrated to be capable of integrating many different materials into a multilayer structure.

Ferroelectrics are a class of high-dielectric materials that may also be piezoelectric and pyroelectric. These materials are suitable for a wide variety of thin film electronic applications, including displays, sensors, nonvolatile random access memories, optical switches, modulators, surface acoustic waves, and radio frequency electronics. Although the properties of ferroelectric materials have been known for some time, thin film applications are not very common due to a lack of availability of high-quality thin films. The rate of research into PLD of ferroelectrics is rapidly approaching the rate of research into PLD of HTS materials (Ref 71).

Many ferroelectrics have crystal structures that are based on a modified perovskite, similar to the ceramic superconductors, and as such have benefited from research in the area of PLD. Ferroelectric properties arise as a consequence of a nonsymmetric crystal lattice structure and the ability of that structure to be polarized in an applied electric field. Both the field-induced and spontaneous (or naturally occurring) polarization can be reversed by an applied field of the opposite polarity. A ferroelectric material will retain that polarization, even after the field is removed. Ferroelectric materials are characterized by a phase-transition temperature (Curie temperature). Below the Curie temperature is the ferroelectric phase. Above the Curie temperature is the nonferroelectric (polarizable but with no retained polarization) paraelectric phase.

Many of the electronic applications for ferroelectric thin films require integration with semiconductor electronics. Low processing temperatures are a desirable feature of the film processing technique. Ferroelectric thin films that have been deposited by PLD are:

- *Perovskites:* $PbTiO_3$, $BaTiO_3$, $PbZr_xTi_{(1-x)}O_3$
- *Nonperovskites:* $KTa_{(1-x)}Nb_xO_3$, $Bi_4Ti_3O_{12}$, $LiNbO_3$

Many of these materials contain volatile components such as lead (Ref 72), potassium (Ref 73), or lithium (Ref 74). These elements present unique problems for obtaining crystalline thin films. The crystallization temperatures (500 to 700 °C) can lead to changes in the film composition because of evaporation of the more volatile components. In spite of large differences between component vapor pressures, high-quality ferroelectric films have been successfully deposited by PLD.

In PLD, stoichiometric evaporation and transfer of the target material does not guarantee a stoichiometric thin film. That is to say, the surface temperatures required to ensure adequate surface mobility may give rise to nonstoichiometric films because of evaporation. One simple solution to this problem has been to overcompensate in the target for volatile species that may be lost from the film (i.e., add excess PbO to the target to minimize the loss of lead from the film) (Ref 75). The technique may work in some cases but is undesirable, because the compensating factors may change depending on the conditions.

It has been observed that in several systems the PLD deposition conditions can be adjusted to compensate for the loss of volatile components at elevated substrate temperatures. It appears that in these systems, higher ambient pressures ($\geq$300 mtorr) minimize the loss of these components. This is probably the result of several factors. Higher gas pressures lead to a reduction in the kinetic energy of the arriving vapor (increasing the sticking coefficient). Higher pressures favor increased oxidation, either in the gas phase or as a result of gas-surface collisions. In the case of lead, it is believed that PbO has a lower equilibrium vapor pressure than lead and is therefore retained at elevated oxygen deposition pressures.

As with HTS materials, single-layer ferroelectric films by themselves are not easily incorporated into a device. The ferroelectric properties of interest arise as a result of electric field effects and as such have presented a unique challenge for their implementation. Electrodes are required that are noninteracting under film growth conditions and that do not degrade the ferroelectric film behavior under repeated cycling. Although noble metals such as platinum or gold are commonly used, the interface between the metal and the ferroelectric film causes the ferroelectric to degrade in time. Oxide conductors such as YBCO (Ref 76), $(La,Sr)CoO_3$ (Ref 77), and $(Sr,Ca)RuO_3$ (Ref 78) are ideally suited for ferroelectric integration. These oxide conductors are lattice-matched perovskites. Multilayer structures have been successfully deposited by PLD that have demonstrated superior characteristics over noble metal structures.

Film Thickness Measurements Using Optical Techniques

Harland G. Tompkins, Motorola, Inc.

Introduction

MEASURING THE THICKNESS of thin films can be accomplished in many ways, but this article will focus on the optical method of single-wavelength ellipsometry (SWE) and two multiple-wavelength methods of reflectometry and spectroscopic ellipsometry (SE). Single-wavelength ellipsometry and reflectometry are relatively inexpensive methods that excel when a single film on a substrate is to be measured. Single-wavelength ellipsometry is particularly effective for films a few nanometers thick to a few hundred nanometers thick, and reflectometry is particularly effective for films thicker than a few hundred nanometers. Spectroscopic ellipsometry is a more expensive and more complex method that can be readily used with multiple films.

In this article, the general capabilities and principles of ellipsometry and reflectometry are discussed in terms of nondestructive methods for measuring the thickness of thin films. The film thicknesses to be considered will be from a few. nanometers to a few micrometers. Emphasis is placed on the methods that are available commercially rather than methods that require more specialized development.

In their rudimentary form, the initial expenses for purchasing the equipment for SWE and reflectometry are roughly the same. Although SE has been used in research laboratories for over a decade, it has only been used regularly in industry since the early 1990s. The initial cost of SE in its rudimentary form is three or five times that of the other two techniques. Very few users in industry purchase these techniques in their rudimentary form, however, and the additional options can often double or triple the cost.

This article does not discuss methods such as optical microscopy of cross-sectioned samples or the shift of interference fringes at a purposely fabricated step. The thickness of a thin evaporated metal on a microscope slide can be determined by measuring the fraction of transmitted light, after suitable calibration. This requires a special substrate, however; it is not an in-line technique and will not be considered here.

Acknowledgements

The author would like to acknowledge Mark Keefer, Prometrix Corp.; William Henderson, SOPRA, Inc.; and John Woollam, J.A. Woollam Co. for useful discussions. In addition, Tom Wetteroth, Motorola, Inc., was very helpful in reading the manuscript and making numerous useful suggestions. His careful attention to detail is appreciated.

General Background

A basic requirement for using optical methods for determining the thickness of a film is that the light must be able to reach the bottom of the film and interact with the underlying layer. Transparent materials such as most oxides qualify throughout the above-mentioned thickness range up to a few micrometers. Many semiconductors are nearly transparent and also easily qualify. Metals, however, must be very thin for these optical methods to be applicable.

The intensity change upon reflection for very thin films is quite small. On the other hand, the phase shift differences are significant. For this reason, ellipsometry is one of the most powerful techniques for very thin films. Other traditional thickness measuring techniques such as stylus profilometry and interferometry are ineffective for films thinner than 50 nm. Electrical phenomena. such as eddy currents are sometimes used for thickness measurements of metal films. These techniques require significantly greater calibration efforts, however, and always depend on assumptions wit regard to microstructure.

Ellipsometry and reflectometry basically involve the measurement of changes in phase shift or intensity, respectively, as light reflects from material. Optical properties and film thicknesses of the samples are then calculated based on a chosen model. Regression software is able to determine the thicknesses that give the best fit to within a few angstroms. In many cases, the regression software also gives a "goodness-of-fit" parameter. The "goodness-of-fit" parameter provides a test of the model describing the sample. If the value is outside the acceptable range, then another model may be required. In any event, thickness is not determined directly; the assumption of a model allows calculation of the ellipsometry or reflectometry parameters and subsequent. comparison of calculated values and measured values. Differences between the

results of an analysis and reality are more often due to an oversimplified model than to limitations in the capability of the measuring instrument.

Basic Theory

For general information on electromagnetic waves and optics, the reader should refer to textbooks (Ref 1, 2, 3, 4, 5) and reference books (Ref 6) on the subjects. Some of the salient features that are directly applicable to reflectometry and ellipsometry (Ref 7, 8) are reviewed here.

The electromagnetic wave is a transverse wave consisting of both an electric field vector and a magnetic field vector that are mutually perpendicular and perpendicular to the propagation direction of the wave. The wave can be specified with either the magnetic field vector or the electric field vector. For simplicity, the electric vector only is considered. The light wave can be represented mathematically as a sine wave with amplitude *A*. Waves transport energy, and the amount of energy per second that flows across a unit area perpendicular to the direction of travel is called the *intensity* of the wave and will be denoted as *I*. The intensity, or energy density (Ref 7), is proportional to the square of the amplitude.

Reflection. For a single film on a substrate (Fig. 1), reflections rather than transmission, are the primary concern. As shown in Fig. 1, some of the light is reflected and some passes into the material at the air-to-solid interface. At the second interface, again, some is reflected and some is transmitted. The various rays that leave the material from the top surface combine to make the outgoing wave. For reflectometry, the ratio of the intensity of the outgoing wave to the intensity of the incoming wave is measured. Reflectometry measurements are often made at normal (perpendicular) incidence. The various rays give constructive or destructive interference, depending on the wavelength of the light, the thickness of the film, and the optical properties of the various materials. For the reflectometry technique, one measures the reflected intensity versus the wavelength of light to deduce the film thickness.

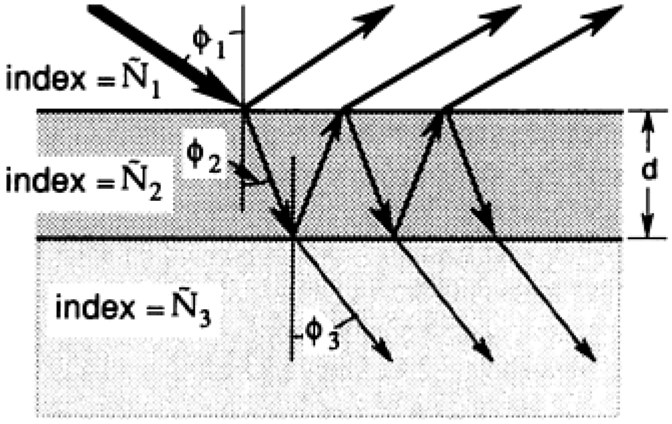

Fig. 1 Schematic of light reflected and transmitted at film interfaces. The outgoing beam is a combination of all of the rays emerging from film from the top interface. Each material is characterized by the index of refraction N_1. The thickness of the film is *d*. Source: Ref 8

For ellipsometry, the measured parameter is the ratio of the wave amplitude parallel to the plane of incidence versus the wave amplitude perpendicular to the plane of incidence. The reflection process also causes a phase shift between these two waves, and this phase shift is measured during ellipsometry. The amplitude ratios and phase shifts are functions of the wavelength, thickness, optical properties of the various materials, and angle of incidence.

Polarized Light. Most light sources emit unpolarized light, or light with electric-field components oriented in all possible directions perpendicular to the direction of travel. If all the photons in a light beam have the electric field oriented in one direction, the light is referred to as *polarized light* or, more completely, *linearly polarized light.* Some light sources emit polarized light. In addition, one can obtain polarized light by passing the light beam through an optical element or by causing the beam to make a reflection under some specific conditions.

Figure 2(a) illustrates two light beams with the same frequency moving along the same path, one polarized in the vertical plane and the other polarized perpendicular to the vertical plane. In this case, the maxima of the two beams coincide (i.e.,

the phase is the same). These two beams can be combined to give a resultant light beam that is also linearly polarized. The key point here is that *when two linearly polarized waves with the same wavelength (or frequency) are combined in phase, the resultant wave is linearly polarized and lies in a plane*.

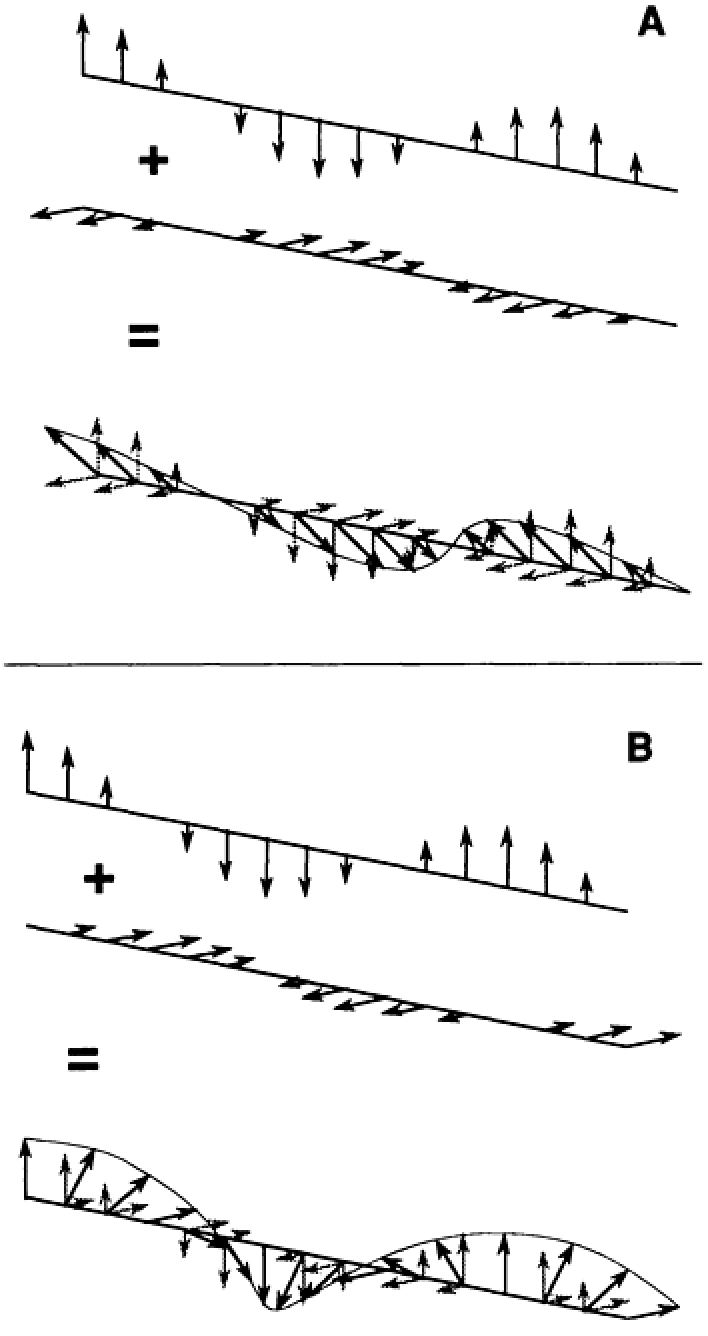

Fig. 2 Linear and elliptical polarization. (a) If two linearly polarized light beams that are in phase are combined, the resultant light beam is linearly polarized. (b) If two linearly polarized light beams that are out of phase are combined, the resultant light beam is elliptically polarized. In this particular example, they are out of phase by 90°. Because the amplitudes are equal, the resultant beam is circularly polarized. Source: Ref 8

Figure 2(b) shows two beams where the maxima do not coincide, but are out of phase. When these two waves are combined, the tips of the arrows do not move back and forth in a plane as in the previous example. This is, in general, elliptically polarized light. The key point is that *when two linearly polarized waves with the same wavelength (or frequency) are combined out of phase, the resultant wave is elliptically polarized or spiraling in three-dimensional space*.

In ellipsometry the important fact is that when linearly polarized light makes a reflection on a metal surface, there is a shift in the phases of both the components (parallel and perpendicular to the plane of incidence). For non-normal incidence, the shift is, in general, not the same for both components, and hence the resultant light will be elliptically polarized. The induced amount of elliptical polarization depends on various factors including the optical properties of the substrate as well as the thickness and optical properties of overlying films. From this concept of elliptical polarization, the term *ellipsometry* takes its name for the measurement of induced ellipticity.

The Complex Index of Refraction. When light passes from one medium (e.g., ordinary room air) into another medium that is not totally transparent (Fig. 1), several phenomena occur at the interface. Some of the light is reflected back and does not enter the second medium, while an unreflected component enters the second medium. The unreflected component will be considered first.

The parameter used to describe the interaction of light with the material is the complex index of refraction, *N*, which is a combination of a real part and an imaginary part and is given as

$$N = n - jk \qquad \textbf{(Eq 1)}$$

where *n* is also called the *index of refraction* (sometimes leading to confusion), *k* is called the *extinction coefficient,* and j is the imaginary number $\sqrt{-1}$.

For a dielectric material such as glass, none of the light is absorbed and $k = 0$. In this case, only *n* is being considered. Both *n* and *k* are functions of the wavelength. It is not uncommon for a material to have $k = 0$ for a range of wavelengths and $k \neq 0$ for another wavelength range.

The index of refraction *n* is defined to be:

$$n = c/v \qquad \textbf{(Eq 2)}$$

where *c* and *v* are the velocities of light in free space and in the material, respectively.

The extinction coefficient *k* is a measure of how rapidly the light is absorbed as a function of depth in the material. A transparent material such as glass has an extinction coefficient of zero. Metals typically have values ranging from $k = 2$ to about $k = 6$.

Dispersion. It should be noted that *n* and *k* are not simple constants for a given medium, but are in fact functions of the wavelength, λ. This is the reason that white light entering a prism emerges with the various colors separated.

The term *dispersion* is used to describe the way in which the optical constants change with wavelength. Figure 3 shows how *n* and *k* vary for a metal such as nickel and for a dielectric such as silicon nitride (Ref 9). The index of refraction *n*, for both materials, is near 2 for the entire range of wavelength. From an optical point of view, the quantity that differentiates these two materials is not *n*, but *k*. In a material with $k \neq 0$, the intensity of light *I* decreases as a function of distance into the material. The functional form is:

$$I/I_0 = \exp(-\alpha z)$$

where *z* is the distance into the material and α is the absorption coefficient (related to the extinction coefficient, *k*). Because the intensity continuously decreases, the concept of how far the light goes into the material has no meaning. Instead, to illustrate penetration, the distance *z* is used where the quantity αz is equal to unity and $I/I_0 = \exp(-1) \approx 0.37$.

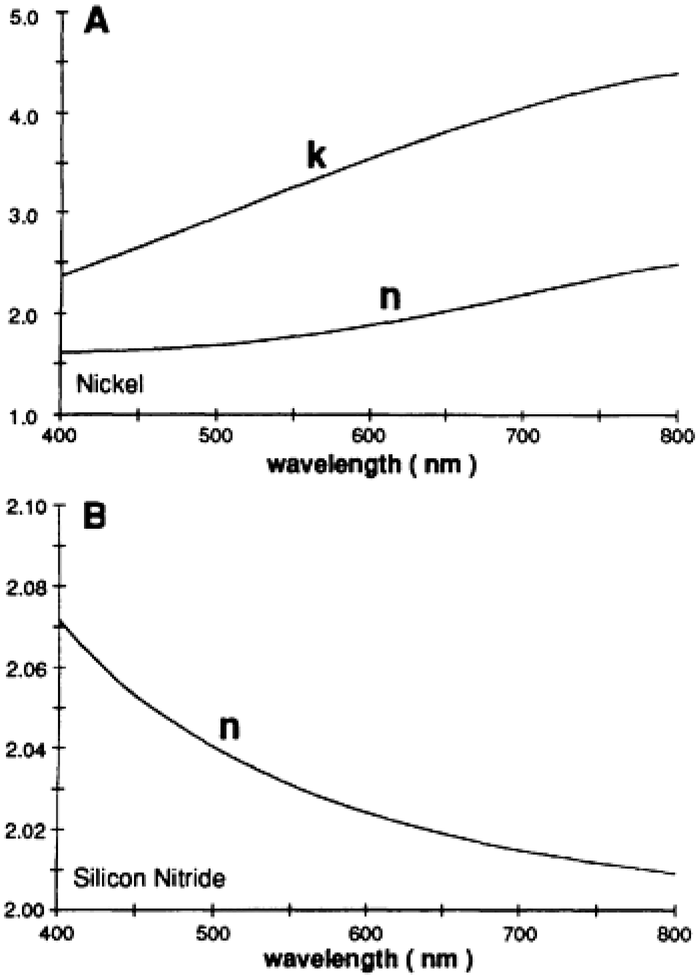

Fig. 3 Optical constants for (a) nickel and (b) silicon nitride. The value of *k* for silicon nitride is zero in the wavelength range shown. Source: Ref 9

Nickel has a value of *k* that is greater than 2 for the entire range. The thickness where the intensity drops to 37% is about 13 nm. For thicknesses three times this value, or about 40 nm, the material is essentially opaque. For silicon nitride, the value of *k* is zero for the entire range. This material is transparent.

Single-Wavelength Ellipsometry (SWE)

Ellipsometry was first practiced by Paul Drude (Ref 10) just prior to 1890. The name *ellipsometry* was introduced by A. Rothen (Ref 11) in 1945. Clearly, this is not a recently developed technique. Ellipsometry uses monochromatic light, optical elements that change the polarization state of the light, some sort of detector, and some calculation facilities. Although rudimentary forms of these requirements have been present throughout this century, the development of the photomultiplier, the laser, and the desktop computer have greatly enhanced the use of this technique to the point that it is now routinely used as a metrology tool in semiconductor wafer manufacturing.

Instrumentation. Figure 4 shows the basic requirements for SWE. The figure shows the arrangement of a manual null ellipsometer. The source generates monochromatic light, and the polarizer passes only light that is polarized in a particular direction. The quarter-wave plate (QWP) then converts the light to elliptically polarized light. If the polarizer and QWP are positioned correctly, the ellipticity is reversed by the reflection, giving linearly polarized light. The analyzer nulls out the light so that the intensity at the detector is zero. The optical elements used for the polarizer and analyzer are both polarizers. The terminology describes function, in that it is the function of the element called *polarizer* to cause the light to be polarized, and it is the function of the *analyzer* to determine the polarization state of the light.

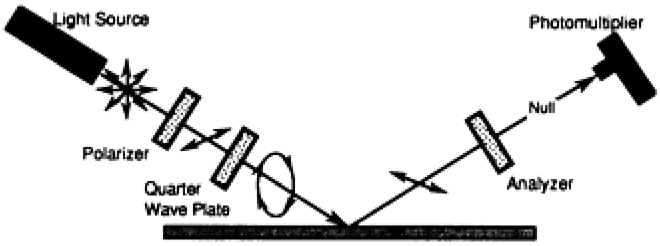

Fig. 4 Schematic of manual null ellipsometer. The quarter-wave plate is fixed at either ± 45° and the polarizer and analyzer are rotated to find the null. The positions of the polarizer and analyzer are then used to calculate the ellipsometric parameters *Del* and *Psi.* Source: Ref 8

Operation of this instrument requires iterative adjustment of the polarizer and the analyzer until the null positions are located. The angular position of the polarizer and analyzer are then used to calculate the ellipsometric parameters, *Del* and *Psi. Del* is the reflection-induced phase shift between the waves that are perpendicular and parallel to the plane of incidence, and *tan* (*Psi*) is the amplitude attenuation ratio of the parallel wave to the perpendicular wave.

Although the manual null instrument illustrates the concepts reasonably well, most commercial instruments are rotating-element instruments. In some cases, the polarizer and analyzer are rotated by the instrument, under microprocessor control, until null is found. In other cases, only the analyzer is rotated, and *Del* and *Psi* are calculated from photometric measurements, rather than null positions.

Analysis of Films. Regardless of whether the measurement is made with a manual null instrument, a rotating-element null instrument, or a rotating-element photometric instrument, the parameters that an ellipsometer measures are *Del* and *Psi.* For a film-free surface (a substrate), *Del* and *Psi* can be converted to the values of the optical constants for the substrate material, $N = n - jk$. The value of *Del* for a substrate will be between zero and 180° and the value of *Psi* will be between zero and 45°. In Fig. 5, the film-free value of *Del*/*Psi* for silicon is about 178°/10.5°. If a dielectric film (i.e., $k = 0$) with index $N = 1.46$ is added, the location of the *Del*/*Psi* joint begins to change on the *Del*/*Psi* domain. When the film thickness is 20 nm, the *Del*/*Psi* location is about 129.9°/13.7°. As the thickness increases, the *Del*/*Psi* trajectory is traced out until the value of thickness reaches the period thickness. At this thickness, the *Del*/*Psi* point has returned to the film-free location. For added thicknesses, the *Del*/*Psi* point simply retraces the trajectory. For the particular example given in the figure, the period thickness is 283.2 nm.

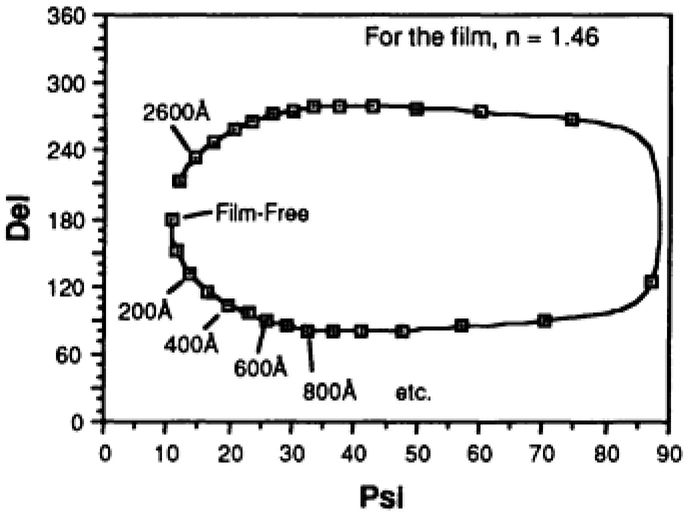

Fig. 5 The *Del/Psi* trajectory for silicon dioxide on silicon with angle of incidence of 70° and wavelength of 632.8 nm. Source: Ref 8

The physics and mathematics for converting ellipsometric measurements to optical constants and film thicknesses are beyond the scope of this article. The reader should refer to books by Azzam and Bashara (Ref 7) and Tompkins (Ref 8) for details. The important point to remember is that the technique relies on differences in phase shift and reflectance for the two directions of polarization, and on changes in these differences as a function of film thickness.

The trajectory that is traced out depends on the index of refraction of the film. Figure 6 shows the first part of trajectories for films on silicon, with *n* values 1.46, 1.6, 1.8, and 2.0. If an unknown film were measured and the resulting values of *Del*/*Psi* were 70.0°/28.9°, it could be determined by inspection from Fig. 6 that the *Del*/*Psi* point falls on the *n* = 1.8 trajectory, and the position on this trajectory indicates that the thickness is 60 nm. Although the calculations to plot these trajectories can be made (Ref 8), normally the microprocessor in the ellipsometer makes the calculations and provides the values of *n* and thickness. This has led to the common misconception that ellipsometers measure the index of refraction and thickness. In fact, ellipsometers measure *Del*and *Psi*, and the values of *n* and thickness are calculated based on a model. The model is implicitly chosen when the program on the microprocessor is chosen (e.g., single film or substrate).

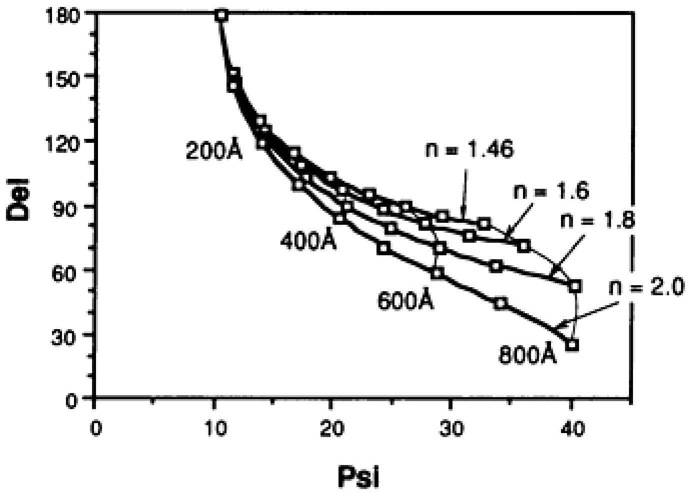

Fig. 6 The *Del/Psi* trajectories for films with several different indices of refraction on single crystal silicon substrates. The first 80 nm is shown. Source: Ref 8

Because of the periodicity, the resulting thickness value is not unique. A *Del*/*Psi* point of 129.9°/13.7° could represent a film 20 nm thick, 283.2 + 20 nm thick, 2 × 283.2 + 20 nm thick, and so on. In many cases, other processing information can be used to deal with this matter. The deposition or film formation rate can often be used to estimate the film thickness to well within one period thickness. For a totally unknown film, however, other methods must be used. The period thickness depends on the index of refraction of the film, the angle of incidence, and the wavelength of light being used. By using another wavelength of light or another angle of incidence, the question of period can often be resolved. If unknown film stacks are routinely encountered, spectroscopic ellipsometry might be a more appropriate technique.

For non-dielectric films, the *Del*/*Psi* trajectory does not close on itself. An example is shown in Fig. 7. Conceptually, with no film present, the *Del*/*Psi* point represents the substrate. When there is a thick film of an opaque material present, the *Del*/*Psi* point will represent a substrate of the film material. The *Del*/*Psi* trajectory during film growth is simply the movement of the *Del*/*Psi* point between the location for the original substrate to the location for a substrate of the film material. In Fig. 7 the growth of a tungsten film on silicon is shown. As long as the film is thin enough that light reaches the silicon substrate, ellipsometry can be used for film thickness measurements. For tungsten, the method could be used for films up to about 20 nm thick. Beyond that, the points are too close together for the method to be useful.

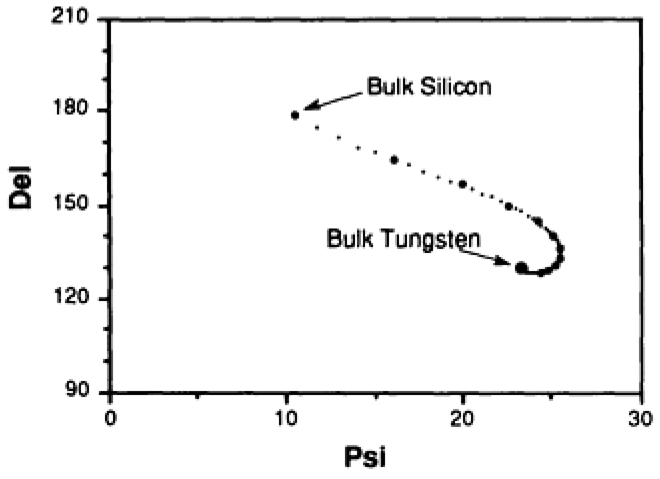

Fig. 7 The *Del*/*Psi* trajectory when a film of tungsten is deposited onto silicon. The small dots are at 1 nm intervals. The large dots are at 5 nm intervals from zero thickness. Source: Ref 8

Areas of Applicability. Ellipsometers can measure *Del*/*Psi* to a few hundredths of a degree. A change in film thickness (with n = 2.0) of 0.1 nm represents about 0.25° in *Del.* This technique therefore can be used to measure monolayer changes. This is a particularly powerful technique in the thickness range from about 1 nm to a few hundred nanometers. When the thickness is greater than several period thicknesses, other techniques such as reflectometry may be more appropriate for thickness measurements. Even in this case, however, ellipsometry may be used to provide index of refraction information for the reflectometry instrument.

When multiple films are present, information about the top film can be determined if information is available for all of the underlying films. In metrology situations, this is often the case, but for totally unknown films, other methods normally must be used.

Reflectometry

Reflectometry is normally done at normal incidence and is simply the measure of the ratio of the intensity of the reflected light to the intensity of the incident light (Ref 12). This is usually done at various wavelengths over the visible, ultraviolet, and/or infrared region. Figure 8 shows the schematic setup of a typical instrument used for this measurement. Measurements are often made on patterned wafers, hence it is necessary to have an image detector for proper positioning of the sample. The diffraction grating separates the light into its various wavelengths. As this is rotated, the photometric detector is used to measure the reflectance spectrum.

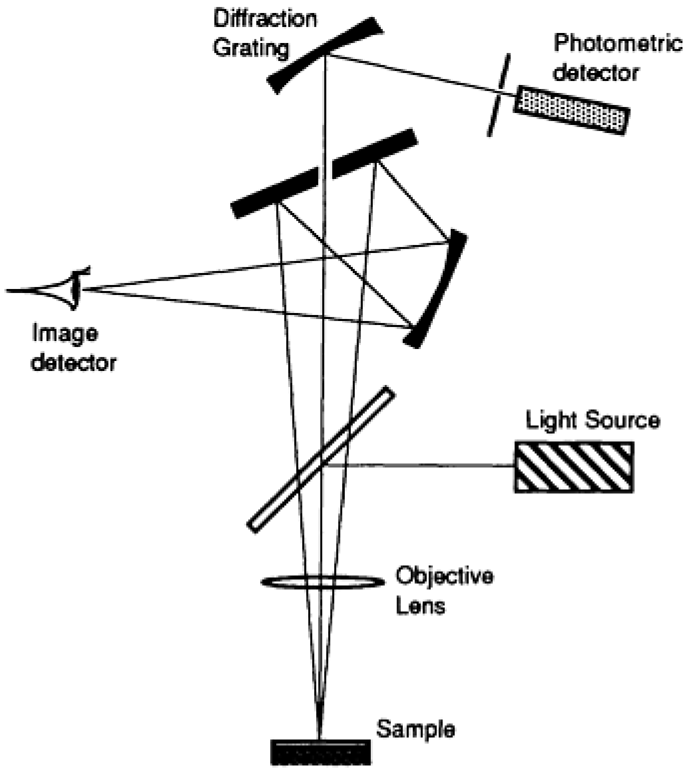

Fig. 8 Schematic of reflectance instrument

Rudimentary instruments scan between about 400 and 800 nm and contain the software to determine film thickness for several specific film/substrate materials (with the optical constants included in the software). More advanced instruments allow the introduction of other values for the indices of refraction and give plots of the calculated spectrum versus the measured spectrum. Other advanced features include regression analysis of thicknesses and optical constants for multiple films and extended wavelength ranges.

Spectral Interpretation. The equipment is basically an interferometer that scans wavelength for a fixed interference path rather than scanning distance at a fixed wavelength. The technique relies on interference between light reflected from the film and light reflected from substrate surfaces. Figure 9 shows a generic reflectance spectrum. When the wavelength/film thickness ratio is large, no interference occurs. As the wavelength/film thickness ratio decreases, the first order minimum is approached. Here, light reflecting from the lower interface destructively interferes with light reflecting from the upper interface and gives a minimum in intensity. As the wavelength/film thickness ratio decreases further, constructive interference causes the first order maximum to be reached. Further decreases in the wavelength/film thickness ratio cause the intensity to pass successively through various minima and maxima. Figure 9 can be described as a generic reflectance spectrum that shows interference phenomena but does not include the influence of dispersion of the index of refraction of either the film or the substrate. What is shown is a rather wide range in wavelength/film thickness. In an actual measurement, only a part of the entire spectrum would be observed because the wavelength range of available instruments is limited.

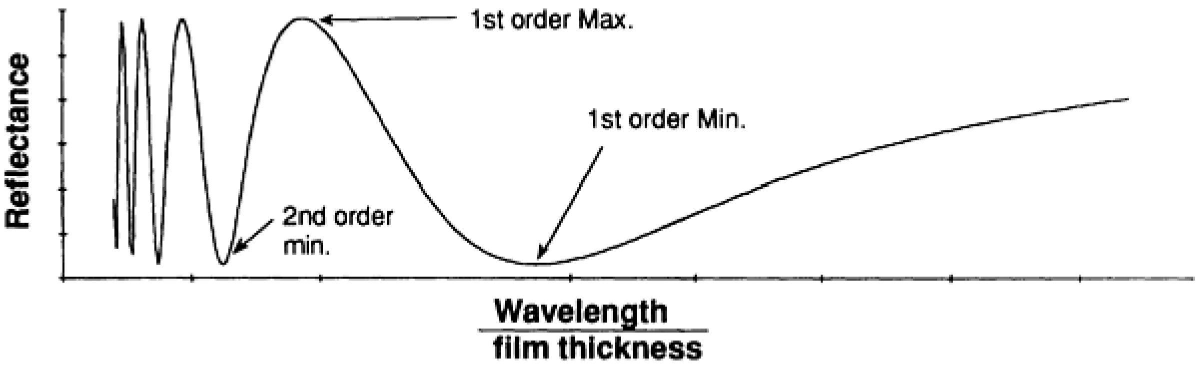

Fig. 9 Generic interferogram plotting reflectance vs. the wavelength/film thickness ratio. Optical constant dispersion is ignored. Note that for a finite wavelength range, a given instrument will not measure the entire interferogram

Moving from the generic to the specific, Fig. 10 shows calculated reflectance spectra for a Si_3N_4 film on a nickel substrate. In Fig. 10(a) the film thickness is 2 μm and in Fig. 10(b) the film thickness is 0.2 μm. Note that there are many maxima and minima in the spectrum from the thicker film. Some instruments simply determine where the maxima and minima occur and use this information for calculating the film thickness. When there are insufficient numbers of maxima and minima for this method (e.g., as in Fig. 10b), curve fitting is used to determine the film thickness. In some instruments, curve fitting is used for all thicknesses. In still other instruments, the reflectances at predetermined wavelengths are used in a lookup table. When the film thickness is below a few tens of nanometers, the curve shapes are insignificantly different from each other, and spectral reflectometry is insufficient for film thickness measurements.

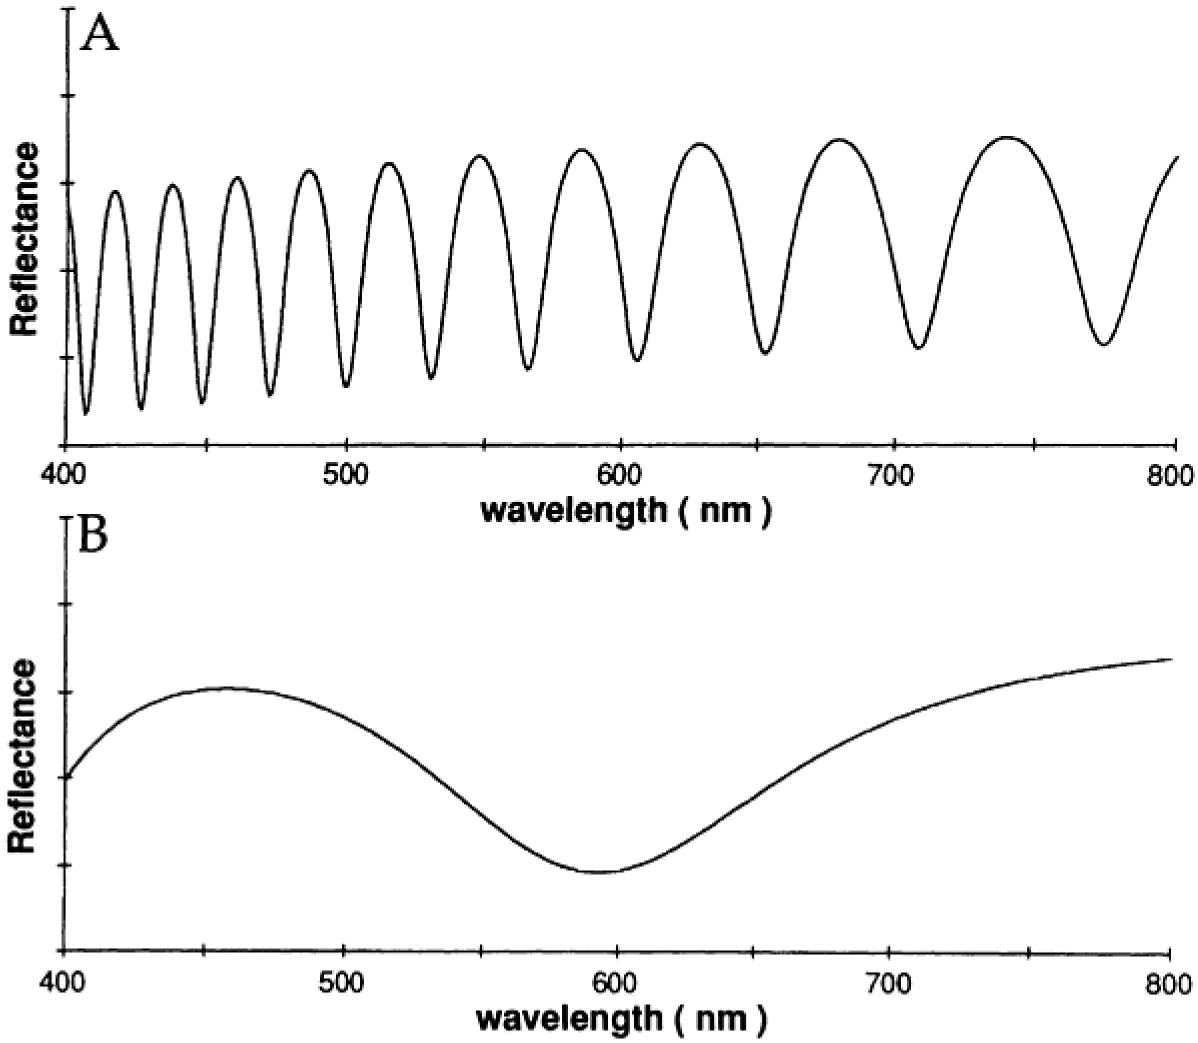

Fig. 10 Interferogram for Si_3N_4 on nickel. (a) The film thickness is 2 μm. Note that there are many maxima and minima in the wavelength range. (b) The film thickness is 0.2 μm. Note that there are only one maximum and one minimum in the wavelength range.

Applicability. The uncertainty due to periodicity found in SWE is not present in reflectometry. The method works best when the optical constants of both the film and the substrate are known and the only quantity to be determined is the film thickness. It is particularly appropriate for films thicker than several hundred nanometers. Some of the latest models make it possible to determine material constants for materials not preprogrammed into the software.

Spectroscopic Ellipsometry

Contrasted to SWE and Reflectometry. Both SWE and reflectometry excel when the sample of interest is a single film on a substrate. For samples with two layers on a substrate, both SWE and reflectometry can be used if many of the optical parameters are known, with only a few to be determined. These are special cases, however. Spectroscopic ellipsometry, on the other hand, is designed specifically to be used with multiple layers (Ref 13).

The function of the SE instrument, like that of the SWE instrument, is to measure the ellipsometric parameters. The primary difference is that for SE, the measurements must be made at many wavelengths. Because a QWP used in SWE is specific to a given wavelength, it cannot conveniently be used for SE. In addition, the light source gives out radiation with

all of the wavelengths of interest, and they are sampled one at a time by using a monochromator. Because many measurements must be made for a single spectrum, the photometric method is used rather than the null method, because it is faster. For rotating-element instruments without QWPs, the quantities measured are *tan*(ψ) and *cos*(Δ) rather than ψ and Δ as in SWE.

Multilayer Example. As an example of the use of SE, Fig. 11 shows the SIMOX structure (Ref 14, 15, 16, 17, 18). This structure is fabricated by implanting oxygen into silicon and then annealing the structure at temperatures above 1200 °C (2200 °F). The anneal helps segregate the implanted oxygen into a well-defined oxide layer and reduces defectivity in the layers. The top silicon retains its crystallinity due to elevated sample temperatures during the implant. One side effect is the formation of the silicon nodules shown near the bottom of the oxide. Any oxide formed on the top silicon layer during the anneal is removed as a final processing step. The usual native oxide then forms upon exposure to the atmosphere.

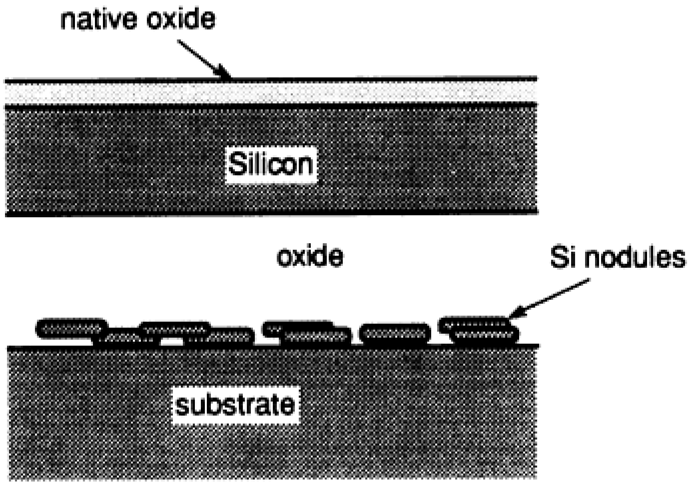

Fig. 11 Film structure formed by implanting silicon with oxygen (SIMOX structure) and then annealing at a temperature greater than 1200 °C (2200 °F)

Analysis with SE consists of measuring the parameters *tan*(ψ) and *cos*(Δ) for the wavelengths of interest and then determining the thicknesses and optical constants of all the layers by regression analysis. In many cases, the optical constants are known and preprogrammed into the analysis software. Figure 12 shows the SE spectra along with the best regression fit when the nodule layer is ignored and the sample is modeled as silicon wafer/oxide/silicon/native oxide.

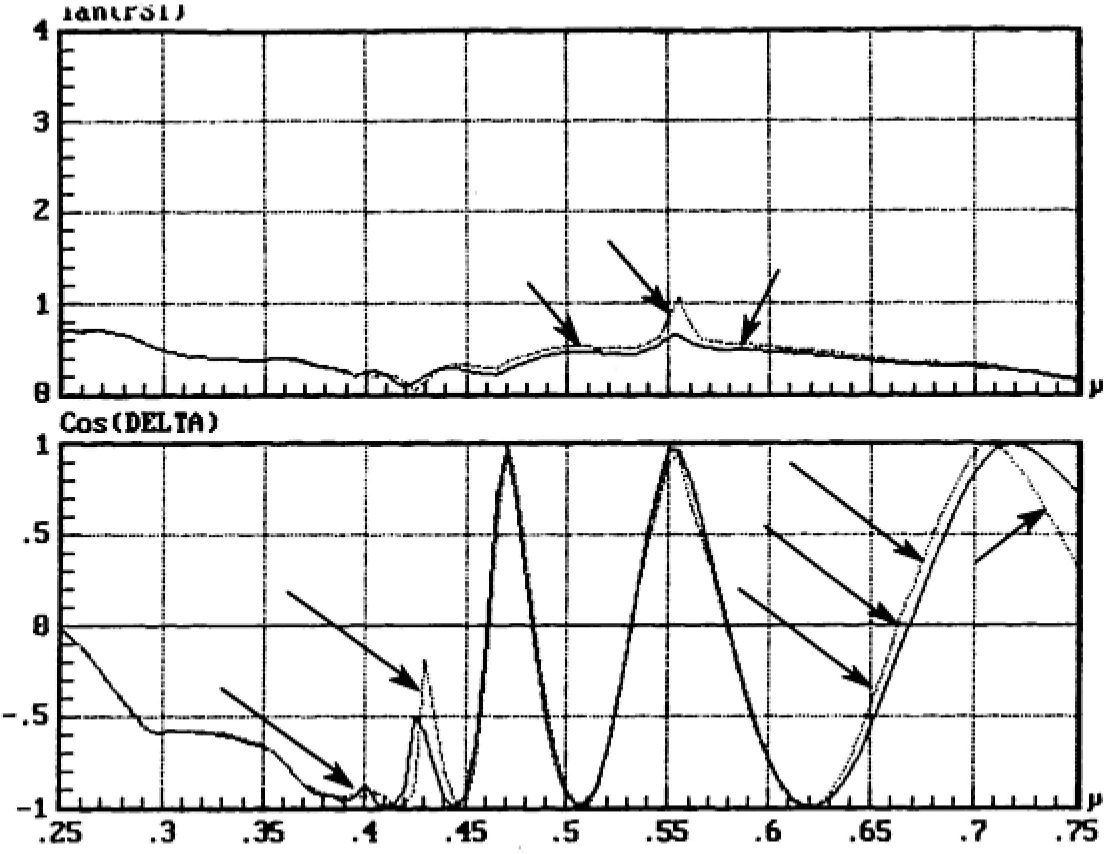

Fig. 12 The measured spectroscopic values for a SIMOX sample along with the calculated values using a model that ignores the silicon nodules. The arrows indicate regions of serious lack of fit.

For this fit, the thicknesses are 360.1, 211.2, and 1.8 nm for the oxide, silicon, and native oxide, respectively. Although the regression analysis curve matches the measured curve in many places, there are several locations where the misfit is noticeable, and these are indicated by arrows.

To improve the fit, the oxide can be modeled as two layers. The top layer is simply the oxide, and the bottom layer (to deal with the nodules) is a mixture of oxide and silicon. The concentration of the silicon in the mixture is one of the quantities to be determined, along with the thicknesses of the various layers. Figure 13 shows the regression fit best for this model, showing that the fit has been improved. Goodness of fit is measured by comparing the calculated curve to the measured curve and is significantly better for the curve shown in Fig. 13 than in Fig. 12. The thicknesses of the layers with this model are 32.9, 325.2, 210.9, and 1.8 nm for the mixture, oxide, silicon, and native oxide, respectively. The concentration of the silicon in the bottom oxide layer is 46%.

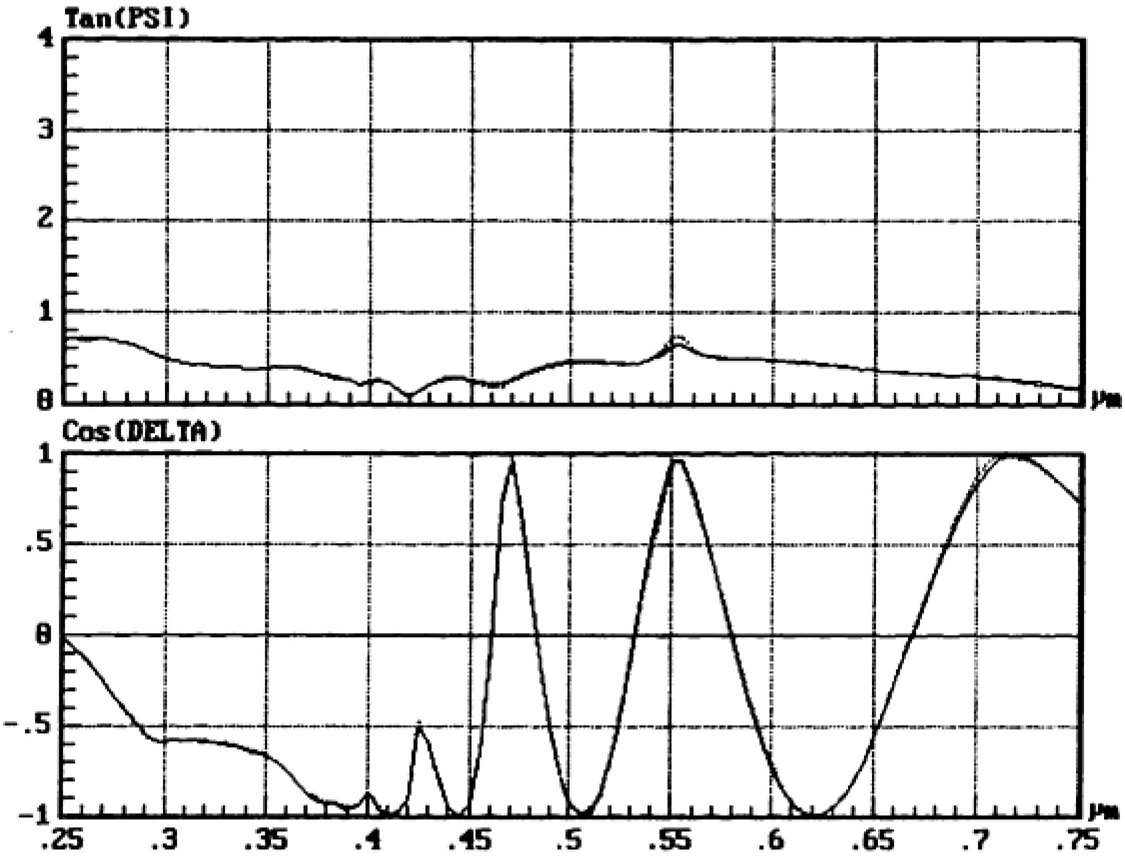

Fig. 13 The measured spectroscopic values for a SIMOX sample along with the calculated values using a model that includes a layer of a "mixture" consisting of oxide and silicon

Applicability. Spectroscopic ellipsometry can be used to measure layers in thicknesses ranging from a few nanometers to a few micrometers. The optical constants of many materials make them opaque in part of the spectral region and transparent in other parts of the spectrum. This feature can be used to advantage to distinguish between top layers and underlying layers. The most important feature of SE is that multilayers can readily be measured.

Corrosion Testing of Coatings

Hermann A. Jehn and Andreas Zielonka, Research Institute for Precious Metals and Metals Chemistry

---

Introduction

CORROSION, according to the *ASM Materials Engineering Dictionary*, is "the chemical or electrochemical reaction between a material, usually a metal, and its environment that produces a deterioration of the material and its properties." Because corrosion is related to the material and its environment, it occurs under an immense variety of conditions. The environment includes not only the gas atmospheres or liquid media in their actual composition surrounding the piece, but also temperature and its changes and specific conditions of flow. This means that corrosion is a materials behavior in a specific environment.

Increasingly, corrosion resistance must be provided even by decorative coatings and those used for wear resistance. Numerous corrosion protection techniques have been developed (e.g., conversion coatings, organic coatings, and metallic thin and thick films). These techniques introduce a new system property, the coating-substrate behavior. The major requirements for good corrosion protection are high corrosion resistance of the coating material, a pore-free structure, and good adhesion. Additionally, production costs play an important role in the selection of a coating-substrate for a given problem.

This article discusses the testing and typical corrosion behavior of coating-substrate systems in aqueous solutions and humid aggressive atmospheres. There is a short review of the fundamentals of corrosion, followed by discussion of specific system behavior, electrochemical and laboratory accelerated tests, and simulated service tests. Finally, the article gives examples of types of corrosion damage and guidelines for improving corrosion resistance by coatings. A more detailed description of general corrosion phenomena, corrosion testing and evaluation, corrosion protection, corrosion of specific alloy systems, and corrosion in specific industries and environments is given in *Corrosion*, Volume 13 of the *ASM Handbook* (Ref 1), as well as in other review books and articles (Ref 2, 3, 4, 5). The behavior of nitride hard coatings deposited by physical vapor deposition or chemical vapor deposition is summarized in Ref 6.

Fundamentals of Corrosion of Coating-Substrate Systems

Corrosion Processes. Corrosion is based on the reaction of a metallic material or layer with its environment. The metal atoms of a component change from the metallic state into an oxidized state. The products may be dissolved species or solid corrosion products. The driving force of this process is the tendency of the system to lower its free energy.

Corrosion in aqueous media is a surface reaction that takes place as an electrochemical process. In terms of electrochemistry, the metal and the corrosive medium are the electrode and the electrolyte, respectively. The electrolyte is conductive due to the presence of dissolved cations and anions. Hence, the corrosion reaction is a closed electrical circuit in which the current is based on the electrical conductivity of the metal on one hand, and on the ionic conductivity of the electrolyte on the other hand. Corrosion results from a direct electrical contact between the metal and the electrolyte. In the case of the formation of a nonconducting, pinhole-free surface layer (e.g., aluminum oxide on aluminum), no corrosion current is possible.

This type of corrosion involves at least two or more separate electrochemical reactions that take place simultaneously. The transfer of a metal atom into a metal forms free electrons, which leads to the reduction of the corresponding oxidant. The deciding factor governing the corrosion reaction is the electrochemical equilibrium between the metallic surface and the aqueous corrosive medium in contact with it. This equilibrium is influenced by which materials are in contact and the activity of the reacting species.

In the case of a very low metal ion concentration in the electrolyte, the corrosion current is anodic to its major part (i.e., the metal is corroded by its dissolution in the electrolyte). Under closed-system conditions, the current exists only as long as the system has not reached its equilibrium state. In the dynamic equilibrium the sum of the anodic and cathodic currents becomes zero (i.e., the rate of metal dissolution equals the rate of metal deposition), and no loss of mass can be observed any longer by microscopy. In practice, the equilibrium state is normally never reached, so corrosion proceeds continuously.

The standard electrochemical potential of metals is defined as the potential in the equilibrium state. The measurement of the electrode potential is only possible relative to that of a second electrode, so all potentials are related to the potential of a standard hydrogen electrode, which is by definition set to zero as reference. Standard potentials can be listed for all metals and for specific electrochemical reactions. Table 1 shows the standard potentials of selected metals. Additionally, potentials are listed for these metals under different conditions. As can be seen, the order of the different metals changes. For corrosion processes, such tables indicate which metal of a pair in contact is more noble or less noble. Factors influencing the actual potential values are temperature, concentration of the electrolyte, and alloy composition of the metal.

(a) pH 7.5, 1 bar (DIN 50907).

(b) pH 6, 1 bar

In practice, where different metals are present as alloy components or in coating-substrate systems, the different electrochemical reactions take place simultaneously, resulting in a mixed or galvanic couple potential. The corrosion behavior of a specific system is determined by the relation of the respective metals in contact. Furthermore,

environmental conditions such as pH value, temperature, concentration of the electrolyte, and the hydrodynamic conditions at the electrode affect the actual behavior (Ref 1, 2, 3, 4).

Corrosion of Coating-Substrate Systems. In principle, the corrosion behavior of a coated part (i.e., a coating-substrate system) is determined by the corrosion resistance of the coating material in the respective medium. However, this holds only for absolutely dense coatings that completely separate the aqueous corrosive medium from the underlying substrate material. In practice, coatings and thin films show pores, pinholes, and other defects after their deposition, or they may be damaged by scratches or other wear mechanisms. Both types of defects allow the corrosive medium to contact the substrate material or the interlayers and underlayers.

Depending on the materials combination, the coating material is either *more* noble or *less* noble than the substrate material. The behavior of the two adjacent layers and the interlayers can be characterized in the same way. The relative corrosion behavior depends on the corrosion medium and the specific conditions. Their order can vary markedly, as shown in Table 1.

The electrochemical reactions are schematically illustrated in Fig. 1. In the case of a more noble coating (Fig. 1a), the corrosion medium reaches the substrate material, and a galvanic cell is formed between the anodic substrate material and the cathodic coating material. This results in strong local corrosion of the substrate. The anodic metal ion current density is rather high because of its very small surface area, whereas the cathodic H^+ discharging or oxygen reduction takes place over the entire coating surface. This explains why defects can be so detrimental. If a system cannot be deposited without defects, a fine and homogeneous distribution of them reduces local corrosion. This explains why the well-known microcrack network is used in electrolytic chromium plating.

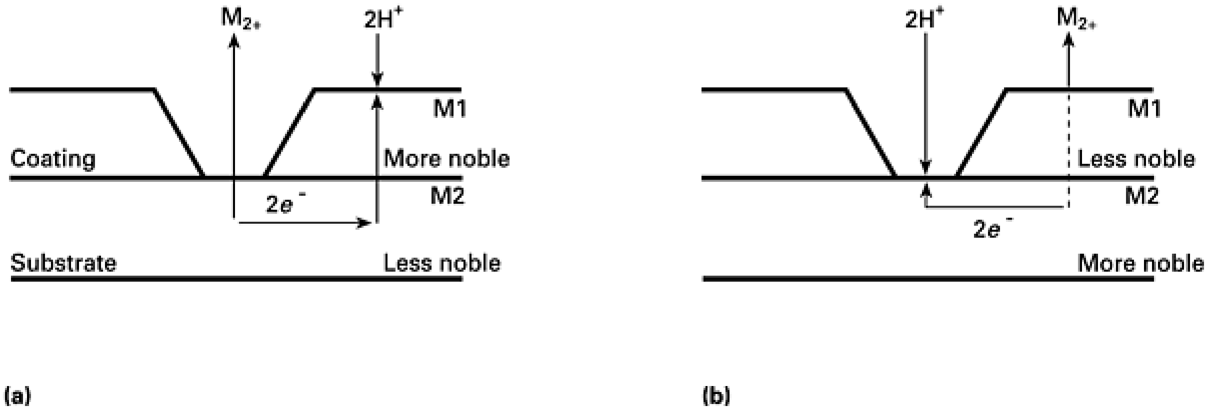

Fig. 1 Schematic illustration of corrosion of coating substrate systems in the presence of pores. M, metal. (a) More noble coating on less noble substrate (galvanic corrosion). Increased corrosion of substrate material, small anodic area, large cathodic area. (b) Less noble coating on more noble substrate (anodic corrosion). Cathodic protection of substrate material, coating material dissolved, large anodic area, small cathodic area

In the case of a less noble coating material (Fig. 1b), anodic protection of the substrate is observed. The anodically polarized coating is uniformly dissolved, and in general the relatively small cathodic area yields a low rate of corrosion.

Figure 2 schematically illustrates some typical examples of corroded coating-substrate systems, demonstrating the system effects in the corrosion performance of a part.

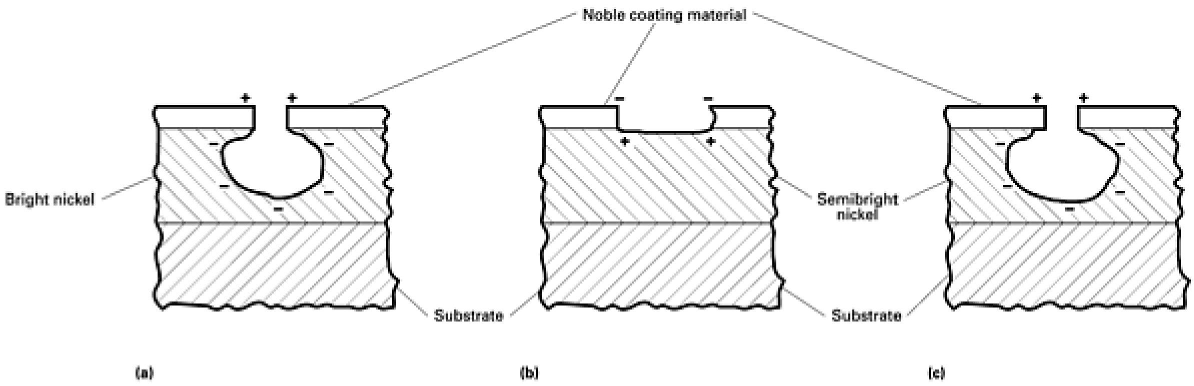

Fig. 2 Corrosion of coating-substrate systems showing the different behaviors with respect to system and electrolyte. Solution 1, Cl^-. Solution 2, SO_4^{2-}. (a) Solutions 1 and 2. (b) Solution 1. (c) Solution 2

As a consequence of these two types of coating-substrate corrosion behavior, two methods for improving corrosion resistance are applied in practice:

- *A more noble coating* protects the less noble substrate. The coating should have high corrosion resistance and be highly defect-free; otherwise, severe local galvanic corrosion can degrade the material. Examples are copper, nickel, and chromium plating.
- *A less noble coating* is deposited as sacrificial protection material. Corrosion protection is virtually guaranteed as long as coating material is present. Examples are zinc and cadmium coatings.

Electrochemical Corrosion Tests

Because corrosion of metals is an electrochemical process, electrochemical measurements are especially suited to it. As described above, the corrosion reaction occurs between the cathodic and anodic parts of a corroding system, resulting in an electric current in the metal and an ionic current in the electrolyte at the metal-electrolyte interface. The amount of current produced is a measure of the oxidation or reduction reaction, so it provides information about the rate of the corrosion process.

In principle, electrochemical methods of corrosion measurements can be divided as follows:

Without external electrical source

- Current measurements
- Potential measurements

With external electrical source

- Polarization measurements

- Tafel extrapolation
- Polarization resistance measurements
- Impedance measurements

In the first type, different electrical parameters can be present. In the latter type, only system-adjusted values are measured (Ref 1, 2, 7, 8, 9). All measurements are performed in different electrochemical cells (Fig. 3). The following paragraphs describe these techniques in more detail.

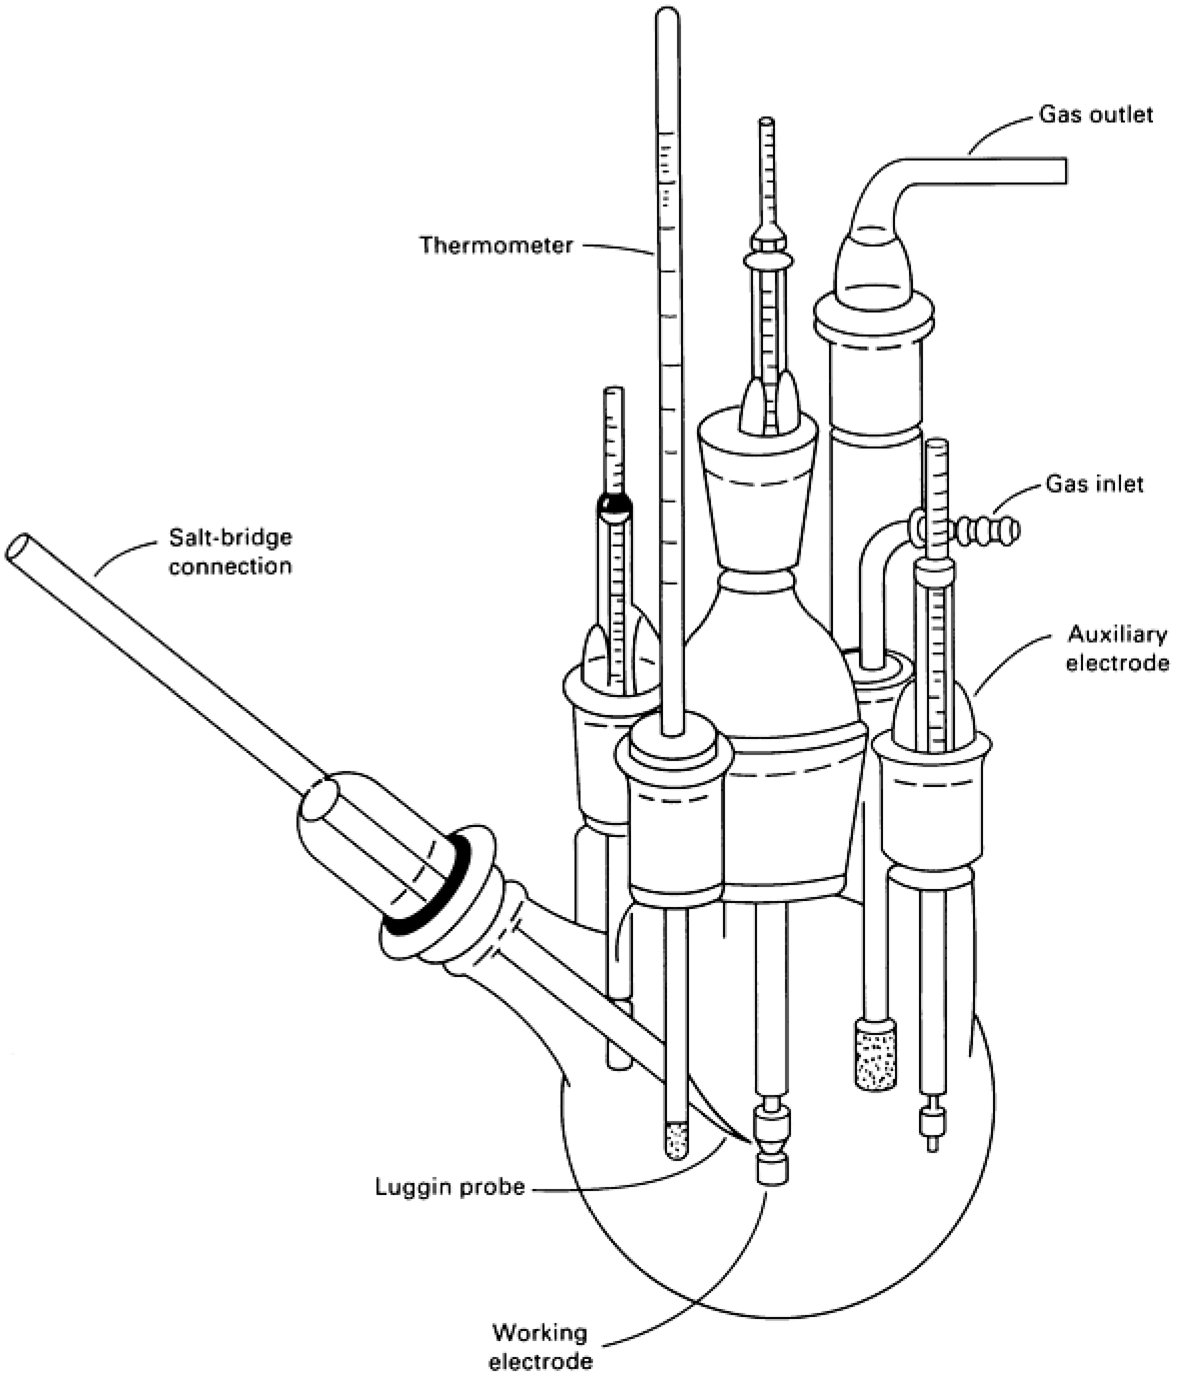

Fig. 3 Electrochemical measurement cell for corrosion investigations. Source: Ref 10

Current Measurements. The calculation of the corrosion rate of metal-electrolyte systems is based on Faraday's law if the reaction follows an electrochemical mechanism:

$$m = \frac{l.t.M}{n.F} \qquad \textbf{(Eq 1)}$$

where *m* is the amount of substance (in mol%) liberated or deposited by the passage of an electric current *I* (in amperes); *t* is time in seconds; *M* is the molecular weight of the electroactive species; *n* is the number of electrons involved in the electrochemical reaction; and F is the Faraday constant. Thus *m* is directly proportional to the quantity of charge passed, *Q*, where $Q = I \cdot t$.

The corrosion current of a homogeneous mixed electrode cannot be measured directly, because the surface is composed of a large number of "short-cut" corrosion elements uniformly distributed over the surface. In contrast, for electrode systems with separate areas of cathodic and anodic processes (e.g., different metals in contact), the corrosion current can be determined directly.

Potential measurements determine the potential established at the (working) electrode versus that established at the electrolyte. A standard reference electrode is used, such as Ag-AgCl-Cl^- (Argental) or Pt-Hg-Hg_2Cl_2-Cl^- (standard calomel electrode). These open-circuit measurements are made under equilibrium conditions (i.e., absence of current flow) to describe the thermodynamic equilibrium of an electrochemical system.

In the case of homogeneous mixed electrodes, the position of the reference electrode is of no importance because of the uniform potential distribution of the working electrode (sample). In contrast, potential measurements on heterogeneous mixed electrodes have to be performed locally. The Haber-Luggin capillary electrode is one of the easiest to use because it is positioned with its capillary tip close to the sample surface.

Potential measurements make it possible to describe the behavior of an electrode-electrolyte system (active or passive state) and the potential distribution of the corroding electrode.

Polarization measurements are based on the application of an external electrical load. The different methods are distinguished by the presetting of a potential or current that is controlled by a potentiostat. Methods using constant or time-dependent potentials are called potentiostatic and potentiodynamic, respectively. Likewise, current-controlled methods are called galvanostatic or galvanodynamic. The variation of the potential or current values can be performed continuously or in stepwise fashion. In the static methods, measurements need to be taken for a long enough period to reach steady-state conditions. In the dynamic measurements, parameters can be changed, such as scan rate or form of scan function. Quasi-steady-state conditions can be reached in the case of stepwise alterations at long holding times.

These polarization measurements involve three electrodes: a measurement electrode, a reference electrode, and a counter electrode. In this system the sample represents the measurement electrode (working electrode). The current flows only between the working electrode and the counter electrode, while the reference electrode is connected to a potentiostat or a high-impedance voltmeter and, hence, is without load. In potential-controlled measurements, the potential of the working electrode is kept constant or is definitely varied; in current-controlled measurements, a defined current flow is applied. In both methods, the potential of the measurement electrode is measured by use of the reference electrode.

Tafel Extrapolation. An application of polarization measurements is the determination of corrosion current density using the Tafel extrapolation. Under the conditions of a pure charge transfer-controlled process, the current density/polarization curves are given by:

$$j = j_{corr}\left[\exp\left(\frac{2.3h}{b_A}\right) - \exp\left(-\frac{2.3h}{b_c}\right)\right] \qquad \textbf{(Eq 2)}$$

where *j* is the applied current density, j_{corr} is the corrosion current density, $\eta$is the polarization, and β_A and β_C are the anodic and cathodic Tafel slopes.

In the case of a highly anodic polarization, the second part of Eq 2 becomes very small, and in the case of a highly cathodic polarization, the first part becomes small. These relationships can be shown as:

$$j_A = j_{corr} \exp\left(\frac{2.3h}{b_A}\right) \quad \textbf{(Eq 3)}$$

$$j_C = j_{corr} \exp\left(-\frac{2.3h}{b_C}\right) \quad \textbf{(Eq 4)}$$

The plotting of polarization versus the logarithm of the current density shows a linear relationship. The extrapolation of these Tafel straight lines to the open-circuit potential can be used to determine the current density of the corrosion process (Fig. 4).

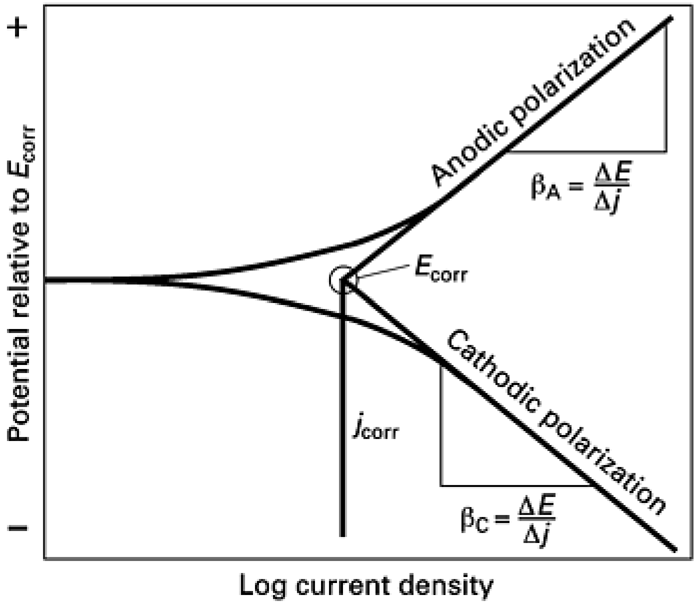

Fig. 4 Tafel plot to determine corrosion current density. β_A and β_C, anodic and cathodic Tafel coefficients; *j*, applied current density; j_{corr}, corrosion current density *E*, potential;E_{corr}, corrosion potential

These equations can be used only in the case of a pure charge transfer-controlled reaction. Therefore, it must be guaranteed that other polarization effects are negligible (e.g., concentration polarization or polarization resulting from the resistivity of the electrolyte depending on the distance of the used reference electrode from the sample surface).

Polarization Resistance. Another polarization technique is the determination of polarization resistance, R_p. This method is based on the fact that the cathodic or anodic current density change is approximately linear with the polarization in the range near the corrosion potential (Ref 11, 12). These relationships can be described by:

$$R_p = \frac{b_A . b_C}{2.3 . j_{corr} (b_A + b_c)} \quad \textbf{(Eq 5)}$$

The advantage of measuring polarization resistance is that only a very small potential range has to be scanned, and thus the measurements take less time. On the other hand, a charge transfer-controlled condition can be reached with very low scan rates without a large increase in total measuring time.

Impedance measurements involve applying a small-amplitude sinusoidal potential to the measurement system and registering the current response to the signal's amplitude and the phase. A corrosion process can be described by an equivalent electrical circuit model. A simple corrosion reaction can be viewed as a circuit, as illustrated in Fig. 5. The impedance of this circuit can be described by:

$$Z = R_\Omega + \frac{R_p}{(1+v^2.R_p{}^2.C^2)} - \frac{j.v\,.C.R_p{}^2}{(1+v^2.R_p{}^2.C^2)} \qquad \textbf{(Eq 6)}$$

where ω is the frequency of the applied signal. To determine *R*Ω and R_p in Fig. 5, it is necessary to make measurements over a wide range of frequencies and to plot the impedance of the system as a function of frequency. A Bode plot for the equivalent electrical circuit in Fig. 5 is shown in Fig. 6. To describe the system it is also necessary to measure the current response that is in phase with the alternating potential wave form, as well as the current response that is out of phase with the applied potential. From these data one can calculate the real and imaginary part of the impedance for each frequency. The plot of imaginary versus real impedance over a range of frequencies, the Nyquist plot, is shown in Fig. 7. When interpreted correctly and applied appropriately, impedance measurements are a powerful tool for describing corrosion processes (Ref 8, 13, 14, 15).

Laboratory Corrosion Tests

To get information on the long-time corrosion behavior of parts, accelerated (short-time) tests have been used for decades. The environment used might simulate a humid tropical area, the salty air of a seaside area, a salted road in winter, a highly industrialized area, or one of many others. Even these few examples show the tremendous variety of aggressive environments that have to be considered.

Laboratory tests can easily compare the performance of materials and systems. They involve continuous exposure or increased corrosion activity so that results will be available within a short period of time. This means, however, that the mechanism of the corrosion reaction may be changed. It is not known for certain that lifelong corrosion can be simulated by a short-time test, considering that real conditions vary greatly and are sometimes much more complex. Nevertheless,

laboratory tests are most widely accepted as a tool for ensuring uniformity and quality of coatings. In general, they have to be verified by field tests.

Laboratory tests are standardized in part, but a huge number of specific test conditions can be applied, depending on the actual conditions of exposure. In principle, three types of tests can be distinguished: wetting of the surface by condensing media in humid atmospheres (simulated atmospheres), spraying of aggressive media, and immersion into corrosive liquid. All tests can be modified by certain intervals or changing conditions. In Table 2 the major laboratory corrosion tests are characterized by their media, procedures, and simulated environments. In general, laboratory corrosion tests are the same as those applied to bulk materials, although the type of deterioration is different.

Table 2 Laboratory corrosion tests

Test	**Conditions**	**Information**
Simulated atmospheres		
Condensed water climate test	Saturated water vapor	Behavior in humid environment
Condensed water alternating climate test	Water vapor + SO_2, temperature change	As in condensed water climate test, with polluted gas
Salt spray tests		
Salt spray test	NaCl solution	Ocean climate
Acetic acid salt spray test	NaCl + CH_3COOH	Salted roads
Copper-accelerated acetic acid salt spray test	As in acetic acid salt spray test	As in acetic acid salt spray test, but more aggressive
Immersion tests		
Artificial sweat test	. . .	Wearing of decorative parts
Immersion tests	Solutions of HCl, HNO_3, etc.	Wearing of decorative parts, corrosion in aqueous media

The samples treated in short-time tests normally are visually or optically inspected. The major information to be obtained is whether the coating or substrate material (at the defects) is corroded, the type of corrosion, if any, and the local distribution of the defect-related corrosion attack. The nature and color of the reaction product may be hints about the type of corrosion. The density and extent of corrosion give information about the coating properties (defect distribution) and coating quality (e.g., homogeneity of thickness).

Simulated atmosphere tests are performed in closed cabinets (humidity-temperature chambers). The samples are hung above the water-covered cabinet floor. The standard test procedure is to dry the samples and visually inspect them after a certain period (cycle), after which the test is repeated several times.

The simple condensed water climate test consists of 24 h cycles performed in saturated water vapor at 40 °C (104 °F) (Ref 16). A more aggressive atmosphere is produced by the addition of SO_2 gas. Alternating conditions may be chosen.

The condensed water alternating climate test consists of 24 h cycles of changing temperature conditions (e.g., water vapor plus 0.07 to 0.7 vol% SO_2 at 18 to 28 °C, or 64 to 82 °F, and 40% humidity, then 75 to 100 °C, or 166 to 212 °F, and 40% humidity) (Ref 17).

Salt spray (fog) tests have long been used to determine the corrodability of metals and the degree of protection provided by inorganic or organic coatings. The reproducibility of these tests and their correlation to actual service performance have been extensively discussed. However, they are easily performed, acceptable standards for comparing the behavior of materials and coatings. In several regulations the test procedures and specific conditions are standardized, but some companies and institutions have established their own standards and procedures.

All variations of the salt spray test are used to evaluate coatings for uniformity of thickness and degree of porosity. They are considered the most useful accelerated laboratory corrosion tests. In particular, they are used to evaluate different lots (for quality control in production) or different samples (for coating development in research). As can be seen from Table 2, the neutral salt spray test has been modified into acidified tests.

The neutral salt spray test is applied for periods ranging from 8 to 3000 h. A 5% NaCl solution of pH 6.5 to 7.2 is used that does not contain more than 200 ppm total solids. The temperature of the salt spray cabinet is kept at 35 °C (95 °F) +1.1 or -1.7 °C (+2.0 or -3.0 °F) (Ref 18).

The acetic acid salt spray test is normally applied for 144 to 240 h or more, but it can be applied for periods as short as 16 h. As in the neutral salt spray test, a 5% NaCl solution is used, but pH is adjusted to a value from 3.1 to 3.3 by adding acetic acid. The temperature is the same. This test is especially useful for decorative chromium platings (Ref 19).

The copper-accelerated acetic acid salt spray (CASS) test is applied for 6 to 720 h. Once again, a 5% NaCl solution is used, but with 1 g $CuCl \cdot H_2O$ (Cu-II chloride) per 3.8 L salt solution. The pH value is adjusted to a value from 3.1 to 3.3 by adding acetic acid. The temperature is somewhat increased, 49 °C (120 °F) +1.1 or -1.7 °C (+2.0 or -3.0 °F) (Ref 20).

Immersion Tests. In certain cases, complete immersion of the test sample in a corrosive solution is the best simulation. However, the test conditions need to be controlled to ensure reproducible results. The solutions are usually selected according to the actual problem (e.g., seawater or wastewater, liquids used in technical processes, or biological agents such as sweat or saliva). They are often of increased concentration in order to accelerate the corrosion process. For the most part, standardized test conditions are applied (Ref 21, 22). The parameters are solution composition, temperature, aeration, velocity, duration, and cleaning at the conclusion of the exposure.

Immersion of the test samples can be complete or partial (the latter simulates local corrosion, especially at the liquid line). It can also be continuous or intermittent (the latter simulates the moving of liquids in chemical plants, for example). The evaluation of immersion tests is by visual inspection.

An example of a specific test is alternate immersion in 3.5% NaCl. The samples are tested in 1 h cycles that include 10 min of immersion in 3.5% NaCl, followed by 50 min of immersion (Ref 23). The total test period can reach 90 days or longer.

Field Corrosion Tests

Field tests show the real performance of a coated part that is exposed to all the variations in environmental conditions that cannot be simulated by laboratory tests. As with laboratory tests, the same field test procedures are applied for coating-substrate systems as for bulk materials. Evaluation is by visual inspection or surface analytical techniques. For reliable predictions of corrosion behavior, a thorough comparison of field test results with accelerated laboratory tests and electrochemical tests is indispensable.

Corrosion Performance of Coated Parts

Deposition of a more noble material provides good corrosion protection in the case of a pore-free or defect-free coating. Defects, however, may allow severe local corrosion to occur. As shown schematically in Fig. 2, corrosion of the substrate or interlayers may result in caves underneath the coatings. This effect is further illustrated in Fig. 8 for TiN deposited by physical vapor deposition onto NiP deposited on brass by electrochemical deposition. Already dezincification can be detected. Similar results are found in coatings and thin films deposited by other techniques, such as electroplating or electroless plating, plasma spraying, or chemical vapor deposition.

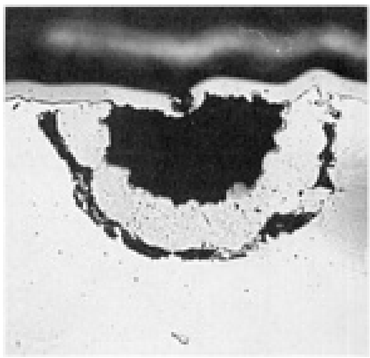

Fig. 8 Pitting corrosion after salt spray testing of the coating-substrate system TiN deposited by physical vapor deposition NiP electrochemically deposited on brass. Source: Ref 24

Polarization (electrode potential versus current density) curves provide useful information about the corrosion behavior of coating-substrate systems. The more noble and defect-free the coating, the greater the reduction in the measured current density. In general, thicker films exhibit fewer defects penetrating from the surface to the base material. Figure 9(a) shows polarization curves for TiN films deposited by plasma-assisted chemical vapor deposition onto 304 stainless steel. Even at a coating thickness of 10 μm, the behavior of the coated steel does not correspond to that of pure TiN deposited on glass (Ref 25). The deposition parameters also influence the coating morphology; this holds true for all deposition techniques. For PVD coatings, the substrate temperature, among other factors, determines the morphology (porosity) of the coatings (Fig. 9b).

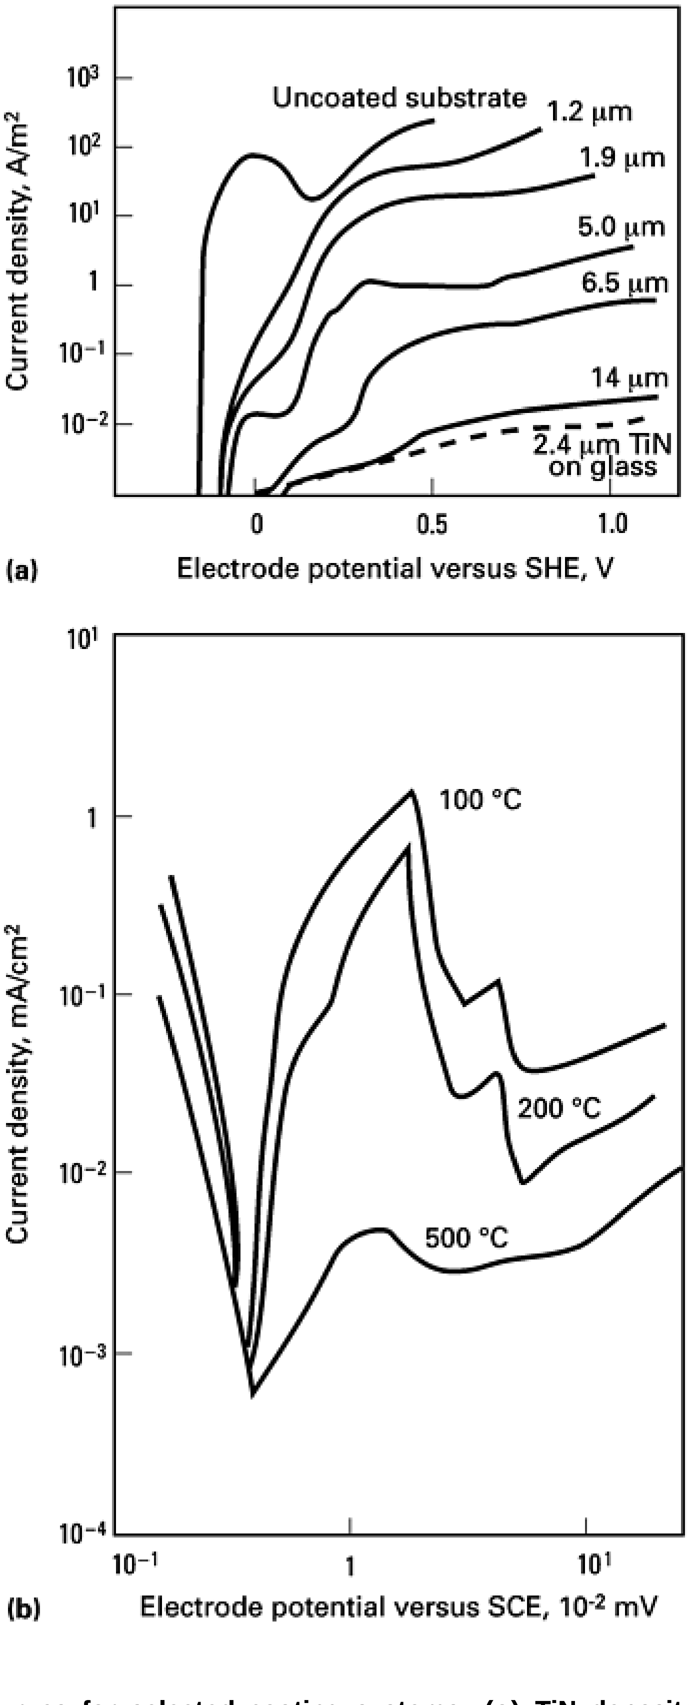

Fig. 9 Anodic polarization curves for selected coating systems. (a) TiN deposited on 304 stainless steel by plasma-assisted chemical vapor deposition. Curves for TiN deposited on glass and for the uncoated base metal are provided for comparison. Environment: 1 *M*/L HCl. Source: Ref 25. (b) TiN ion-plated onto ball bearing steel. Environment: 1 *N* H_2SO_4. Source: Ref 26

Polarization curves also show that corrosion resistance can be improved by the deposition of dense electrochemical or physical vapor deposition interlayers, alone or in combination. The polarization curves for reactively magnetron-sputtered

TiN on brass in Fig. 10 demonstrate the marked influence of interlayers. The coating with a 5 μm thick electrochemically deposited 80Pd-20Ni interlayer performs almost as well as pure TiN deposited on glass. The coating with a 2 μm PVD titanium interlayer does not perform quite as well, but much better than the TiN coated on brass without an interlayer. The titanium film was sputter-etched before the TiN was deposited.

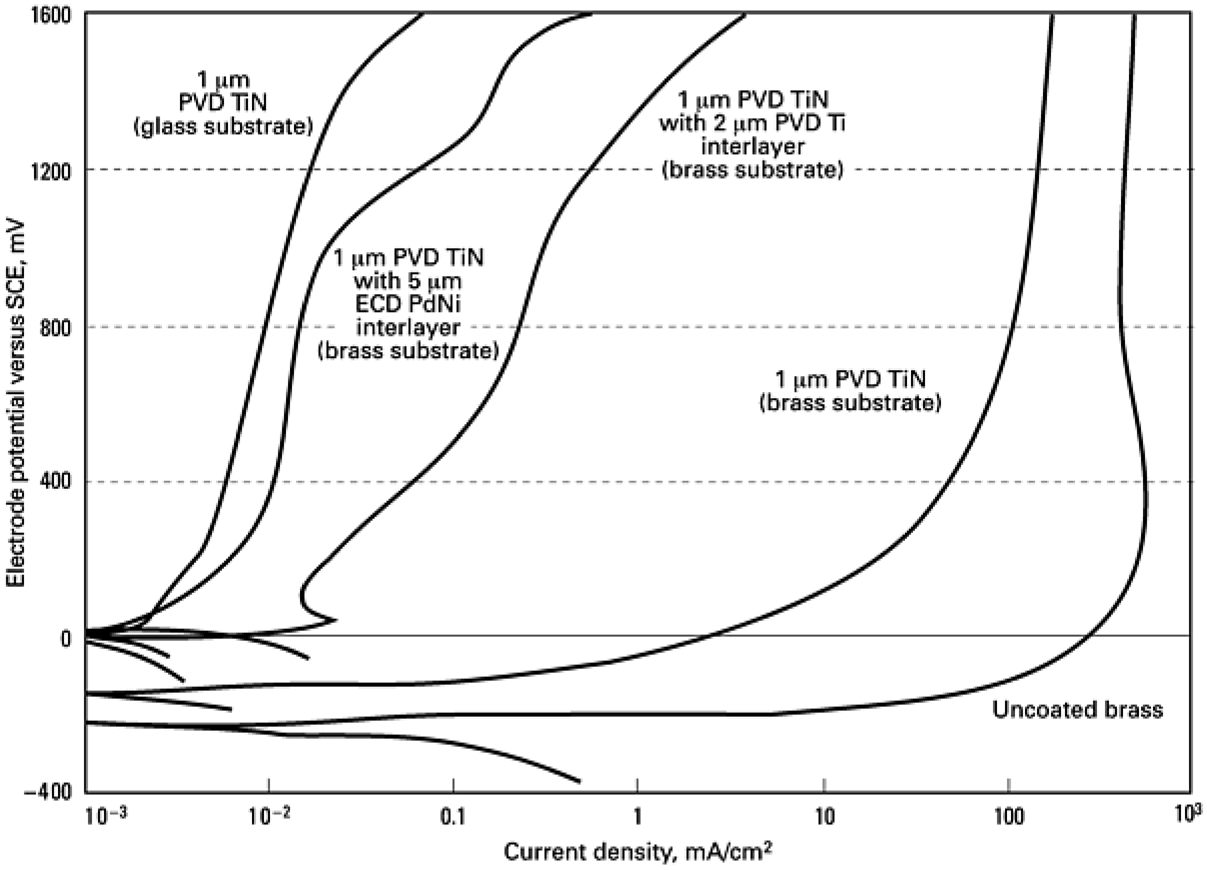

Fig. 10 Polarization curves for selected coating systems with and without interlayers. Environment: 0.8 *M* NaCl. Source: Ref 6

Conclusion

Electrochemical measurements provide useful information about the fundamental corrosion behavior of coating-substrate systems in particular environments. However, it is not valid to draw conclusions about one aspect of a system from the results of one test. For example, a relatively low current density measurement for one coating system in a specific environment does not necessarily mean that the coating material is better than the others being tested. For a fairly complete analysis of corrosion mechanisms and behavior of a particular system, a combination of tests and measurements is needed.

Accelerated tests can only partially simulate the actual corrosion behavior of a given system. However, they are able to provide qualitative and reproducible results for the development and quality assurance of coating systems. Often, a combination of tests is used in practice.

In general, the corrosion resistance of a system can be improved by producing dense coating structures through the optimization of deposition techniques and process parameters, by selecting noble coating materials, and by using dense and noble interlayers.

Evaluation of Mechanical Properties of Thin Films

Franz R. Brotzen, Rice University

Introduction

THE TERM "THIN FILMS" is usually applied to metallic and nonmetallic layers of thickness of the order of microns or fractions of microns that are deposited on a variety of substrates. Their mechanical resistance is of particular interest, because high stresses often develop in the films during deposition or in service as a result of differences between the thermal expansion coefficients of the films and their substrates. This is a matter of special concern in the manufacture of microelectronic devices, where metallic films having high thermal expansion are often deposited on low-expansivity semiconductor substrates and where service temperatures vary by several hundred degrees Celsius. Similar conditions may prevail when thin films are deposited on bulk materials for the purpose of providing protective coatings.

The mechanical behavior of a given material in the form of thin films may differ substantially from that of the same material in bulk. Consequently, specialized thin-film testing methods have been developed. In these methods, one must differentiate between testing of freestanding films, that is, films removed from their substrates, and in situ films, that is, films still adherent to their substrates. Substantial differences may be observed between test results obtained from the two types of samples, mainly because of epitaxial and interfacial effects on adherent films.

Evaluation of Freestanding Films

Testing of freestanding films requires that the films be removed from their substrates without impairing their integrity. A relatively simple procedure can be applied in which the films are deposited on substrates or intermediate layers that will readily dissolve in water or some other medium. Alkali halides, such as sodium chloride or cesium iodide, have been used to this end. Organic substances (e.g., collodion or certain polymers) have also been used as substrates. However, inherent properties of films deposited on different substrates may vary, so it is often desirable to use films deposited on a specific substrate. This is particularly true of microelectronic circuits in which metallizations, such as aluminum, are deposited on silicon or silicon oxide. In these cases, the metal films are separated from the substrate by exposure to a stream of fluorine in an inert carrier gas. The silicon is removed in the form of gaseous silicon tetrafluoride, while the metal is covered by a very thin protective metal fluoride film. As the substrate is consumed, a freestanding film is produced.

Uniaxial Tensile Testing of Films. The most direct way to obtain the stress-strain relations of thin films in tension is by uniaxial testing. In principle, this procedure is analogous to conventional tensile testing of bulk materials, yet the fragility of the films and their extreme sensitivity to even the smallest flaws make uniaxial tensile testing a difficult and often frustrating task. In view of the high surface-to-volume ratio in thin films, specimens must be virtually free of surface flaws, because even the smallest defects will lead to premature failure. Tensile specimens usually have the form of a "dog bone." This shape, which has proved to be most advantageous, is obtained either by covering the substrate with a mask during deposition or by standard photolithographic techniques.

Problems are caused also by internal stresses that are created in the films during the deposition process. When the films are separated from the substrates, the stresses often cause films to wrinkle or to curl severely, rendering them useless for testing. To alleviate this condition, special devices have been developed that keep the films stretched during ablation (Ref 1).

Equipment used for uniaxial tensile testing of thin films is generally based on the simple principle of deforming a freestanding film by a known amount through the application of a known force to the ends of the specimen. The testing devices can be divided into two categories:

- *"Soft" machines*, in which the loading rate is constant and the ensuing elongation is measured
- *"Hard" machines*, in which the elongation rate is constant and the applied loads are measured

An example of tensile curves obtained by uniaxial testing of plasma-deposited aluminum films of 1μm thickness is given in Fig. 1. The initial portion of the curves often contains a clearly noticeable "unwrinkling" stage that can be ignored or discarded.

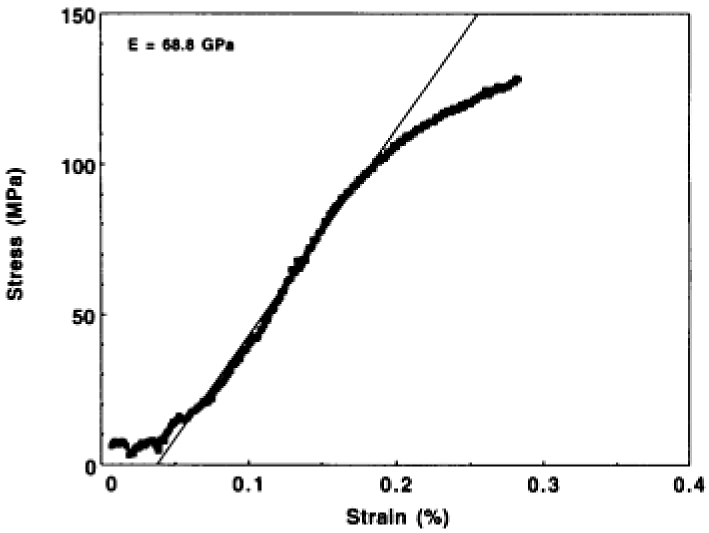

Fig. 1 Stress-strain curve obtained by uniaxial testing of a freestanding 1 μm thick annealed aluminum film

The absence of a well-defined yield point is characteristic for aluminum in bulk and, as evidenced by Fig. 2, for thin films.

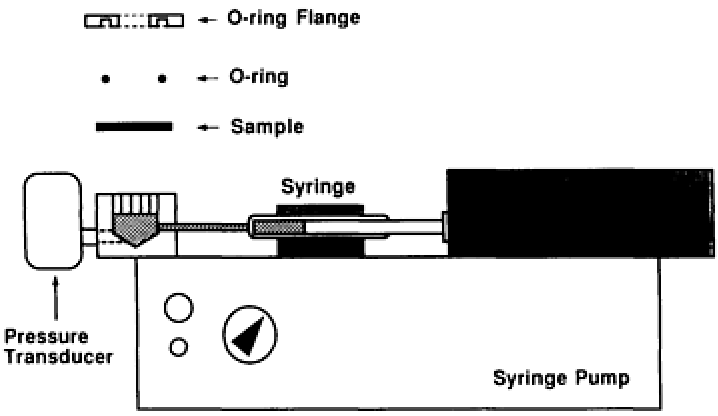

Fig. 2 Schematic drawing of a bulge-testing device. Source: Ref 3

The effect of film thickness on film strength has been the subject of intense study. Tests indicate that the strength of metallic films rises dramatically when the thickness falls below about 0.3 μm. There is evidence that the strength of films obeys the Hall-Petch relation:

$$Strenght = K + \frac{b}{\sqrt{t}}$$

where K and b are constants and t is the film thickness. However, the details concerning the thickness effect in films are still open to question and appear to be greatly influenced by the deposition conditions.

Whereas the elastic properties of metal films closely approach those of metals in bulk form, some investigations reveal a substantially higher fracture-strength level for thin films than for the corresponding bulk materials. The fracture stress of metallic polycrystalline and single-crystal films tends to rise sharply as the film thicknesses drop below 0.2 μm.

Uniaxial Creep Testing of Films. Uniaxial testing equipment can be readily employed in creep tests of freestanding thin films by keeping the load constant. In such tests, characteristic creep curves consisting of a primary and a secondary stage are obtained. The stress and temperature dependence of the secondary creep rates is very similar to that of bulk materials. For high strain rates, secondary creep rates are modeled as:

$$\varepsilon = B \exp - [(Q_0 - \beta\sigma) / kT] \quad \textbf{(Eq 1)}$$

For low strain rates, the relation is:

$$e = \frac{ADGb}{KT}\left(\frac{s}{G}\right)n \quad \textbf{(Eq 2)}$$

where B, A, $\beta$and n are constants, Q_0 is the activation energy at zero stress, $\sigma$is the applied tensile stress, k is Boltzmann's constant, T is the absolute temperature, D is the diffusion coefficient (i.e., D_0 exp [Q_D/kT]), G is the shear modulus, b is the interatomic distance, D_0 is a constant, and Q_D is the activation energy for self-diffusion. The values of the stress exponent n are usually in the range between 4 and 10 and are highly sensitive to the grain structure of the material. The material constant βin Eq 1 for thin aluminum films, for example, is close to 10^{-27} m^3/atom and about half of that in aluminum-silicon alloy films of 1 μm thickness. The activation energy at zero stress, Q_0, for steady-state creep in unannealed, vapor-deposited copper films is about 1.3 eV. In sputtered 1 μm thick aluminum and aluminum-1% silicon-alloy films, Q_0 is 0.56 and 1.10 eV, respectively (Ref 2). The low activation-energy value for aluminum approaches that of grain-boundary diffusion of vacancies in that metal.

In summary, the uniaxial testing method provides an excellent means for obtaining readily interpretable results in terms of tensile stress and strain. These results can be applied to well-known descriptions of the fundamental processes of plastic deformation. On the other hand, the uniaxial testing technique requires extreme care in specimen preparation and handling, and the elongations that can be obtained are often limited.

Biaxial Testing of Films. The bulge-testing technique is a biaxial testing method that can be applied to freestanding thin films. A film whose edges are fixed may be viewed as an impermeable membrane. Applying a known fluid pressure, liquid or gas, to one side of this membrane will cause it to bulge, so that the film material is strained biaxially. By monitoring the bulge expansion as a function of the fluid pressure, a stress-strain relationship is obtained. In principle, bulge testing is a straightforward technique by which problems associated with defects on the sample edges are eliminated. However, the interpretation of bulge-testing results is far more complex than that of uniaxial-test results.

Bulge testing can be performed by applying fluid pressure through a hole drilled on the back of the substrate without damaging the deposited film. An alternative procedure (Fig. 2) employs films that are removed from their substrates (Ref 3). The films are fastened by an O-ring on top of a small cylindrical chamber. A syringe pump then injects glycerol into the chamber at a constant rate. The glycerol pressure is monitored by a pressure transducer, and the injected volume is determined by the elapsed time. The bulge extension can be determined either by the displaced fluid volume or by the height of the bulge. In general, when designing bulge-testing equipment, the ratio of the bulge orifice to the film thickness should be at least between 200 and 300, so that the effect of flexural rigidity is minimized.

Films used in the bulge-testing technique must be separated from their substrates. The film-ablation techniques are identical to those described in the preceding section. It should be noted that metal films, such as aluminum or aluminum alloys, deposited on a silicon substrate tend to dissolve silicon, which often precipitates in the form of silicon-rich nodules. These nodules are removed during the ablation process together with the silicon substrate, producing very fine pinholes in the film that vitiate the bulge-testing procedure.

The analysis of the pressure-bulge deformation is generally based on a model proposed by Hill (Ref 4), which gives the meridional stress as:

$$s_m = \frac{\Pr_0}{2t} = \frac{Pa^2}{4th} \qquad \textbf{(Eq 3)}$$

where P is the fluid pressure, r_0 is the radius of curvature at the top of the bulge, t is the thickness of the film, a is the radius of the orifice, and h is the height of the bulge. This is an approximate expression that is predicated on the bulge height's being much less than the radius of the orifice. The calculation of the meridional strain, also based on Hill's work, is:

$$e_m = a\,\frac{h^2}{a^2} \qquad \textbf{(Eq 4)}$$

where α is a constant that is generally taken to be $\frac{2}{3}$. This, too, is an approximation based on the premises that the bulged film assumes a spherical shape and that the film is a plane at zero tension. The realization of true sphericity is questionable, but experimental results have shown that the meridional strain may be accurate within about 8% for strains up to 1% (Ref 5).

A serious criticism of bulge testing centers about the initial state of the film, that is, its flatness at zero pressure. Whenever bulge testing is carried out on films adherent to the substrate by removing the substrate over a given area, there may be residual compressive or tensile stresses in the film. In the former case, this results in buckling or wrinkling of the film, and in the latter case, in a film stressed in tension (Ref 6). These conditions must be taken into account when calculating the stress-strain relations obtained from the tests.

The bulge test presents an attractive method for determining mechanical properties of thin films, mainly because--in contrast to the uniaxial test--flaws at the edges of the film specimens do not affect bulge-test results. It is seen from the above comments, however, that the value of this method for the accurate determination of mechanical behavior of freestanding thin films is diminished because of the many imponderables with which the interpretation of bulge-testing data is fraught.

Beam-Bending Methods Applied to Free-standing Films. When a specimen in the shape of a beam is bent, the portion on one side of a longitudinal "neutral" plane is strained in tension, while the portion of the other side of the plane is strained in compression. If the specimen has a uniform composition, such as a freestanding film, the stress-strain relation of the material can be readily calculated from the load-deflection data determined during bending. In this technique, very small cantilever-beam specimens are used, which are produced by microelectronic fabrication methods. In such test, a Nanoindenter device can be employed that applies the load to the free end of the cantilever beam and simultaneously measures the deflection (Fig. 3). The elastic modulus and the yield strength of the material are determined from the load-deflection curve. The specimens for the microbeam method are prepared by creating the required pattern of the film and the subsequent removal of the substrate. Microbeam fabrication and testing are briefly reviewed in Ref 8. A detailed review of micromachining of beam specimens is given in Ref 9.

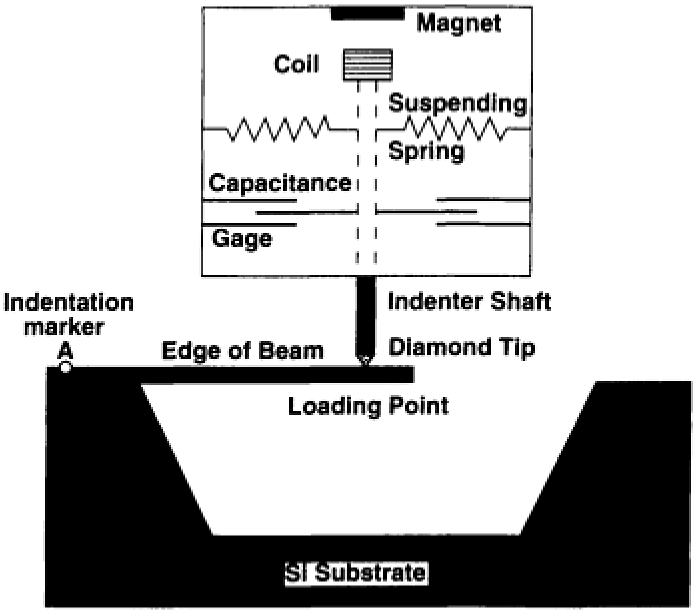

Fig. 3 Schematic drawing of a Nanoindenter used as a loading device on a microcantilever beam. Source: Ref 7

When the deflections are small and the material is considered to be uniform and isotropic and to deform elastically, the well-known equation for the cantilever-beam deflection δ under a load *P* applied to the free end of a beam is given by:

$$d = \frac{PL^3}{3EI} = \frac{4PL^3}{bEh^3} \qquad \textbf{(Eq 5)}$$

where *L* is the length of the beam, *E* is Young's modulus, *I* is the moment of inertia, *b* is the width of the beam, and *h* is the thickness of the beam. This equation is modified, for the case of thin and broad plate-like specimens (*b* ? *h*), where plane stress is applied in the direction of the beam thickness and plane strain is applied in the direction of its width, to read:

$$d = \frac{4(1-v^2)PL^3}{bEh^3} \qquad \textbf{(Eq 6)}$$

where ν is Poisson's ratio. Young's modulus is derived from the slope of δ(*P*).

The simple beam theory described above can also be employed in the determination of the yield strength of the beam material. When the beam is bent under a downward load applied to its free end, the maximum tensile stress occurs at the fixed end. When this stress reaches the yield strength, the load-deflection curve ceases to be linear. The load that marks this deviation from linearity is denoted by P_v, so that the yield stress is (Ref 7):

$$s_y = \frac{6LP_v}{bh^2} \qquad \textbf{(Eq 7)}$$

An interesting modification of the simple curved-beam method has led to a resonance technique for the determination of the elastic modulus. Specimens similar to the ones used in the technique described above were vibrated electrostatically, and Young's modulus was obtained from the observed natural frequency (Ref 10).

The beam-bending method is well suited for the determination of elastic and some plastic properties of freestanding films. The principal drawback to this technique is the inherent difficulty of specimen preparation.

Evaluation of Films Adherent to Their Substrates

Indentation testing of thin films resembles in many aspects the well-known hardness measuring techniques, such as the Vickers and Brinell hardness tests. However, in the "nanoindentation" technique, the indentations extend only to extremely shallow depths, often as low as nanometers. A hard indenter, usually an accurately ground diamond, is gradually pressed into the film, which is deformed first elastically and then plastically. Upon gradual removal of the load, the elastic deformation is recovered (Fig. 4). Analysis of the load-displacement curves provides information not only on the hardness, but also on the elastic and creep properties of the films. In contrast to traditional hardness measurements, the nanoindentation technique furnishes a continuous record of both load and indentation depth during loading and unloading, so that imaging of the indentation is no longer required.

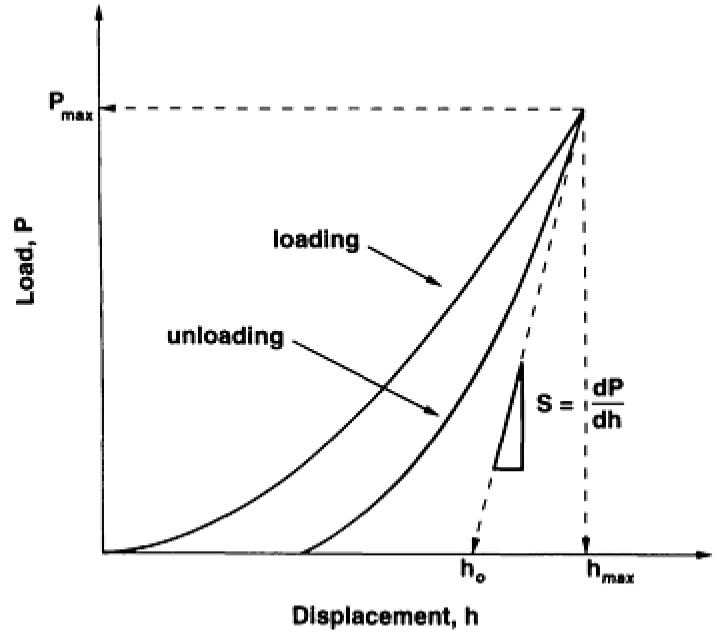

Fig. 4 Typical curve of load as a function of indenter-penetration depth. Source: Ref 11

The determination of mechanical properties of thin films by nanoindentation has gained widespread use in recent years. Its popularity stems not only from the high spatial resolution of the indentations--less than 1 μm^2--but also from the simplicity with which mechanical properties of surface layers on bulk materials and of films adherent to their substrates can be determined under essentially compressive conditions. Details of nanoindentation testing techniques and equipment can be found in the literature (see the "Selected References" in this article. The most common means of applying the load

in nanoindentation equipment is through electromagnetic or piezoelectric devices, in which the resolution obtained is often better than 0.01 μN. The displacements are typically measured by a capacitive device giving resolutions as small as 0.1 nm. The most commonly used indenter is a diamond of the Berkovich type, a triangular pyramid with the same depth-to-area relation as the standard Vickers indenter (square pyramid)--that is, the cross-sectional area varies as the square of the depth of the indentation.

Determination of Elastic Properties by Indentation. The indentation technique provides a simple means for determining the elastic modulus of the film. During penetration of the film by the indenter, both elastic and plastic deformations occur. Upon withdrawal of the indenter, the depth of the permanent indentation changes as a result of the elastic recovery of the film. Repeated applications of the load generate a truly elastic recovery for which mathematical solutions are known, so that the unloading curves can be related effectively to the elastic properties of the material, that is, the elastic modulus, E, and Poisson's ratio, ν. The effective modulus is obtained from the slope of the unloading curve:

$$S = \frac{dP}{dh} = \frac{2}{\sqrt{p}} b \sqrt{AE_r} \qquad \textbf{(Eq 8)}$$

where S, P, and h are given in Fig. 4, A denotes the contact area of the indenter, E_r is the effective elastic modulus, which takes into account the small deformation of the indenter, and βis a dimensionless parameter that depends on the geometry of the indenter. For any indenter that can be described as a solid of revolution of a smooth function, β= 1. Although neither the Vickers nor the Berkovich indenters falls into this category, βdeviates only very slightly from unity for these indenters. To compute the modulus E_r, according to Eq 7, the slope of the unloading curve dP/dh must be known and the projected contact area, A, at the maximum load would have to be known as well. The area is obtained from an area function F(h), which relates the cross section of the indenter to the appropriate depth, h, of the indentation measured from the tip of the indenter. As an example, for an ideally sharp Berkovich indenter the area function is $F(h) = 24.5\ h^2$. In reality, this function is much more complex because of the impossibility of achieving ideal tip sharpness. To determine the appropriate depth of indentation, various models for elastic unloading were proposed (Ref 11). An improved method for determining the contact area at peak load uses the contact depth h_c found by the equation

$$h_c = h_{max} - e \frac{P_{max}}{dP/dh} \qquad \textbf{(Eq 9)}$$

whose terms are defined in Fig. 4. The value of ε depends on the geometry of the indenter and can be taken to be 0.75 for the Berkovich indenter. Once h_c is determined from the above equation, the appropriate contact area can be calculated from the area function $A = F(h_c)$. The effective elastic modulus, E_r, can now be determined from the unloading curve in accordance with Eq 7.

Indentation Hardness Testing of Films. The indentation technique is very well suited for determining the hardness of films adherent to their substrates. Hardness is a measure of resistance to local deformation and is defined by the ratio $H = P(\max)/A$, where P(max) is the peak load applied to a given type of indenter and A is the projected area of the hardness impression. In general, the determination of the contact area A follows the procedure outlined in the preceding section.

The effect of indentation depths on hardness measurements has been a matter of concern. It has been shown, however, that a variation in the applied load has little effect on the hardness of several different materials, provided that the projected area has been properly determined. When the hardness of films deposited on a substrate is measured, the region deformed by the indentation may extend to the film/substrate interface, which affects the hardness measurements. As the plastic zone under the indentation in the film reaches the substrate, the measured hardness becomes a function of the ratio of maximum penetration depth to film thickness and ceases to be the true hardness of the film. A rule of thumb suggests that the indentation depth should not exceed 10% of the film thickness.

It should be noted that silicon, as well as ceramic materials, may develop cracks when indentation strains are not accommodated by plastic deformation. These cracks affect the measured load-displacement relations. To overcome the troublesome substrate effects in very thin films, extremely shallow indentation techniques have been applied successfully.

Strength Measurements by Indentation Testing. It would be, of course, very desirable to derive plastic properties, such as the ultimate tensile strength or the yield strength, from indentation measurements. Because of the complexity of the mechanics of the indentation process, such a task is very difficult. In 1951, Tabor (Ref 12) formulated

an equation that related the ultimate tensile strength, σ_{UT} (in kg/mm^2), to the Vickers hardness number, H_v, for a material whose work-hardening exponent (n) is as follows:

$$\frac{s_{UT}}{H_v} = \frac{1-n}{2.9}\left(\frac{12.5n}{1-n}\right)n \quad \textbf{(Eq 10)}$$

This equation yielded reasonable agreement with experimental data.

Actual stress-strain curves were obtained by indentation of 1 μm thick gold and aluminum-copper metallizations deposited on silicon (Fig. 5). Here, spherical diamond indenters of radii of 5, 10, and 22 μm were used. The analysis of the load displacement data was based on Tabor's work and presupposed a strain-hardening equation in which the flow stress, σ, was exponentially related to strain, ε, such that $\sigma \approx \varepsilon^n$. While the application of Tabor's analysis has been helpful, correlations fo pressure-indentation results with stress-strain curves of ductile materials have not been promising.

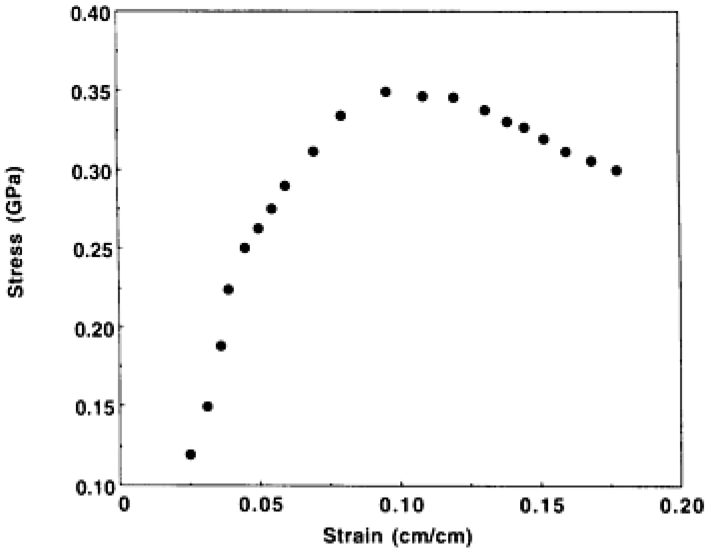

Fig. 5 Stress-strain curve for an annealed gold film, obtained by the indentation technique using a spherical-tipped diamond indenter of 20 μm radius. Source: Ref 13

Creep and Stress-Relaxation Testing by Indentation. Modern indentation equipment is designed to monitor the movement of the indenter under a given load as a function of time as well as the changes in load at a fixed depth of penetration. The equipment is therefore capable of measuring the equivalents of creep and stress relaxation.

When recording the penetration rate under a constant indenter load, curves are obtained that bear a strong resemblance to typical creep curves of bulk materials (Fig. 6). The classical stress dependence for secondary creep rate (ε) = constant σ^n can be applied, where ε is the stain rate, σis the stress, and n is the stress exponent. The latter is close to the one found by uniaxial creep testing of films (see the section "Uniaxial Creep Testing of Films" in this article).

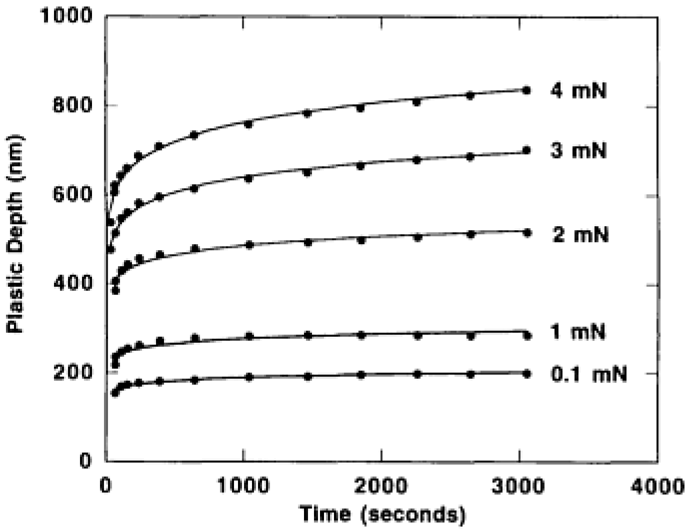

Fig. 6 Penetration depth (plastic deformation only) in a 1.6 μm thick sputtered aluminum film at constant indenter loads. Source: Ref 14

Valuable information can also be obtained from stress-relaxation experiments. In a typical experiment of this kind, the indenter is pressed into the specimen at a constant rate, usually of the order of 10 nm · s^{-1}, to a predetermined depth while monitoring the change in load. After the displacement is halted, a record is made of the relaxation effected by the specimen and the elastic reactions of the testing equipment. The modulus describing these elastic reactions is obtained from the initial slope of the unloading curve at a constant displacement rate. The relaxation curve yields data on the plastic strain rate, ε, as a function of stress, σ, the strain-rate sensitivity being defined by:

$$m = \frac{\partial \ln e}{\partial \ln s} \quad \textbf{(Eq 11)}$$

One concludes from the above that the indentation method provides a consistent picture of elastic modulus, hardness, and strain-rate sensitivity measurements of surface layers of bulk materials, including thin films deposited on substrates. It is particularly well suited for use with hard surface films, in which plastic deformation plays only a minor role. Indentation testing is attractive in view of its simplicity and the absence of complex sample preparation. The principal drawbacks of the indentation method lie in uncertainties of interpretation, particularly in ductile materials.

Beam-Bending Methods Applied to Adherent Films. This technique is based on the same principles as the beam-bending technique applied to freestanding films, described earlier. In the case of testing of adherent films by the beam-bending technique, the specimen is a composite of two materials, the film and the substrate. If the mechanical characteristics of the substrate are known, the stress-strain relation for the deposited material can be inferred from the load-deflection curve.

The elastic deflection at the free end of a bilayer cantilever beam under an external load is related to the elastic constant by an equation similar to Eq 6:

$$d(L) = \frac{PL^3}{3(EI)_{eff}} \quad \textbf{(Eq 12)}$$

where Young's modulus *E*, and the moment of inertia, *I*, are replaced by the product of the effective modulus and the effective moment of inertia:

$$(EI)_{eff} = b\left[\frac{1}{3}(E_{ps}h_s^3 - E_{pf}h_f^3) - C_i^2(E_{ps}h_s - E_{pf}h_f\right] \quad \textbf{(Eq 13)}$$

Here, the subscripts "p," "s," and "f" refer to "plate," "substrate," and "film,"respectively, and $E_p = E/(1 - u^2)$. The distance between the film/substrate interface and the neutral plane of the beam is given by:

$$C_i = \frac{(E_{ps}h_s^2 - E_{pf}h_f^2)}{2(E_{ps}h_s - E_{pf}h_f)} \qquad \textbf{(Eq 14)}$$

A comparative beam-bending technique can also be employed, in which the load-deflection curve of a cantilever-beam sample consisting only of the substrate is registered. This operation is repeated after a film is deposited on the substrate. The difference between the two tests is used to find the elastic modulus of the film. The modulus can be evaluated by this method without prior knowledge of the properties of the substrate material, as shown in Ref 9.

Elastic properties of thin films adherent to the substrates are sometimes investigated by subjecting the specimen to temperature changes. In this case, calculable thermal stresses are introduced that produce an observable curvature in the specimen. It is possible to derive elastic and certain plastic properties of thin films from the curvature-vs.-temperature records by techniques shown in Ref 15.

The cantilever-beam technique in its different forms is a useful tool for determining elastic and yield properties in films. However, although it provides a means to determine these properties in situ, that is, properties of films adherent to their substrates, it suffers from the difficulty of specimen preparation.

Stress Determination for Coatings

J. Albert Sue, Praxair Surface Technologies, Inc.; Gary S. Schajer, University of British Columbia

---

Introduction

COATINGS AND THIN FILMS can be produced by a large variety of deposition techniques. Typical processes are physical vapor deposition (PVD), chemical vapor deposition (CVD), electroplating, electroless deposition, anodizing, thermal growth, and thermal spraying. Since the early 1980s, considerable progress has been made in improving deposition processes for a wide range of high-technology applications. Consequently, many new ceramic coatings and films have been introduced in various industries. Typical examples are metal-oxide semiconductors for microelectronics; titanium nitride, titanium carbide, aluminum oxide, and silicon nitride for machining tools; and thermal-sprayed tungsten carbide/cobalt, M-chromium-aluminum-yttrium (where M stands for iron, cobalt, or nickel), and yttrium oxide/partially stabilized zirconia coatings for aerospace applications.

Residual stresses, which are internal and therefore locked in, are contained in materials that are produced by nearly every mechanical, chemical, and thermal process, either alone or in combination. As a result, most coatings are in a state of internal stress, including metallics and ceramics. The stress can be either compressive or tensile. It is generally recognized that compressive stresses in coatings are more favorable than tensile stresses, because they increase resistance to fatigue failure. However, extremely high compressive stresses may cause either coating separation from the base metal or intra-coating spallation. Generally, if a tensile stress causes strain that exceeds the elastic limit of the coating, then it will cause cracking in the coating perpendicular to the direction of the stress. Therefore, understanding the formation of residual

stress in the coating is important to prevent the coating from peeling or cracking during service. Furthermore, residual stresses have significant influences on the mechanical and physical properties of the coatings, particularly electrical resistivity, optical reflectance, fatigue, and corrosion.

There are three types of residual stresses:

- Macrostresses, which are nearly homogeneous over macroscopic areas of the material
- Microstresses, which are nearly homogeneous over microscopic areas, such as one grain or subgrain
- Inhomogeneous microstresses, which are inhomogeneous even on a microscopic level

Residual macrostresses are the ones of most interest in engineering practice, because they can substantially affect component service performance. Both residual and inhomogeneous microstresses are of more interest in material science.

This article intends to provide a useful guide for measuring residual macrostress on a coating. The most commonly used measurement methods are mechanical deflection, x-ray diffraction, and hole-drilling strain-gage. After a discussion on the origins of residual stress, the fundamental principles, as well as examples of practical measurements, are described for each method.

Origins of Residual Stress

Residual macrostress in a coating combines the intrinsic stress and the thermal stress acting in the coating plane parallel to the coating/substrate interface:

$$\sigma_t = \sigma_i + \sigma_{th} \qquad \textbf{(Eq 1)}$$

where σ_t is the total macrostress, and σ_i and σ_{th} are intrinsic stress and thermal stress, respectively. Intrinsic stress results from the growth processes, depending primarily on deposition parameters, whereas thermal stress arises from a mismatch in coefficients of thermal expansion between the coating and the substrate.

Many phenomenological models have been proposed to explain the occurrence of intrinsic stresses by correlating them with a variety of coating microstructure and process features. To varying degrees, the intrinsic stress of a coating is associated with these deposition conditions and coating features:

- Incorporation of residual gas atoms in the coating
- Grain size, microvoid, and dislocation density in the coating
- Energetic particle bombardment during coating growth
- Lattice misfit between the substrate and the growing coating
- Combined effect of surface tension and growth process at grain boundaries
- Deposition temperature relative to the melting temperature of the coating material
- Annealing and shrinkage of disordered material buried behind the advancing surface of a growing coating

Although many studies have described the intrinsic stresses, information on the corresponding structural details is limited. It seems unlikely that one can formulate a generalized model of intrinsic stress for various coating materials and deposition processes.

Any coating that is prepared at elevated temperatures (T_2) and then cooled to room temperature (stress measurement temperature, T_1) will be thermally stressed because of the difference in the coefficients of thermal expansion between the coating and the substrate. Assuming no deformation of the substrate, the magnitude of the thermal stress in the coating is:

$$\sigma_{th} = (\alpha_c - \alpha_s)\,(T_2 - T_1)\,E_c/(1 - u_c) \qquad \textbf{(Eq 2)}$$

where α_c and α_s are the coefficients of thermal expansion for the coating and the substrate, respectively, and E_c and ν_c are the Young's modulus and Poisson's ratio of the coating, respectively. A coating deposited at an elevated temperature exhibits compressive stress if $\alpha_s > \alpha_c$, but tensile stress if $\alpha_s < \alpha_c$. In the case of $\alpha_s > \alpha_c$, the substrate shrinks more than the coating does during cooling from the deposition temperature and compresses the coating to maintain dimensional compatibility.

In some cases, thermal stress is the primary residual stress of the coating. For example, a titanium nitride coating can be deposited on a cemented carbide substrate (tungsten carbide-1 wt.% tantalum-10 wt.% cobalt) via a CVD process at 1000 °C (1830 °F). With the values of $\alpha_s = 5 \times 10^{-6}$/K, $\alpha_c = 9.54 \times 10^{-6}$/K, E_{TiN} = 411 GPa (60 × 10^6 psi) and $\nu_{TiN} = 0.24$, the stress in the coating, as calculated from Eq 2, is 2.39 GPa (0.35 × 10^6 psi) in tension at 25 °C (77 °F).

Deflection Method

The deflection method is the most widely used technique for determining the residual stress in a coating. In terms of basic principles, it involves measuring the amount of bending in a strip that is due to the deposition of the coating. A formula for calculating the residual stress in an electrodeposited coating was first derived by Stoney (Ref 1) in 1909. Subsequent researchers have derived more complex formulas to improve the accuracy of the stress evaluation. Comparative studies on those stress-evaluation formulas are reviewed and discussed elsewhere (Ref 2, 3, 4). Nearly all formulas are variants of Stoney's formula.

Consider a coating deposited on one side of a strip substrate. Both coating and substrate are assumed to be homogeneous. A mismatched force at the coating/substrate interface results in residual stress in the coating, which bends the strip either upward (concave) or downward (convex), depending on whether the stress is tensile or compressive. For overall force and moment equilibrium of the coating/substrate composite, it can be shown that the residual stress in the coating is (Ref 5):

$$\sigma_c = (E_s d_s^2) / [6(1 - \nu_s) R d_c] (d_s \ ? \ d_c) \qquad \textbf{(Eq 3)}$$

or, in general,

$$\sigma_c = \{E_s d_s^2 / [6(1 - \nu_s) R d_c]\} \{(1 + \Gamma \Theta^3) / (1 + \Theta)\} \qquad \textbf{(Eq 4)}$$

where

$$\Gamma = [E_c(1 - \nu_s)] / [E_s(1 - \nu_c)], \ \Theta = d_s / d_c, \text{ and } R \approx L^2 / 8f \approx L^2 / 2\delta \qquad \textbf{(Eq 5)}$$

where E is Young's modulus; ν is Poisson's ratio; d is thickness, with the subscript c denoting coating and s denoting substrate; R is the radius of curvature of the bent strip, L is the length of the strip, f is the deflection from the free end of the strip, and δ is the deflection at the center of the strip (Fig. 1).

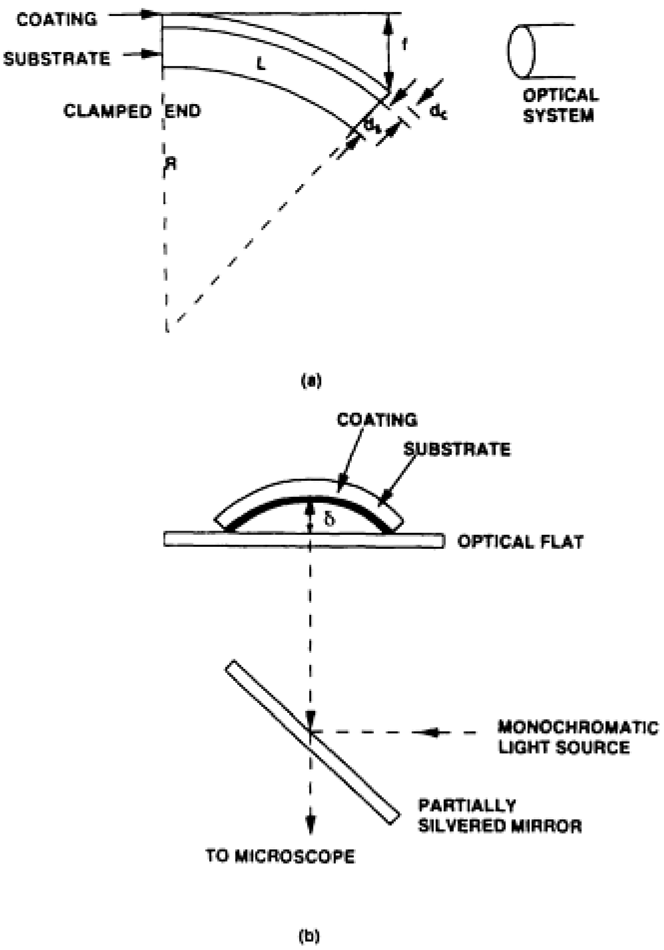

Fig. 1 Stress measurement techniques. (a) Bending of cantilever beam. (b) Disk deflection. Source: Ref 7

Although Eq 3 is most often used in practice and represents a generalized Stoney's formula for a planar state of stress, it tends to overestimate the value of measured stress. However, it does not require knowledge of the elastic properties of the coating. Equation 4 provides a much better approximation than Eq 3, but it does require knowledge of elastic properties. Equation 4 differs from Eq 3 in terms of a correction factor $[(1 + \Gamma \Theta^3)/(1 + \Theta)]$. Table 1 compares stresses as a function of d_s/d_c, calculated from both Eq 3 and 4. In the calculation, it was assumed that E_c = 400 GPa (60 × 10^6 psi), E_s = 200 GPa (30 × 10^6 psi), and $\nu_c = \nu_s$. It is clear that both equations are in good agreement when $d_s/d_c > 50$. By choosing a large value of d_s/d_c, the error can be minimized if Eq 3 is used.

Table 1 Comparison of average residual stress calculated using Eq 3 and 4

d_s/d_c	Calculated stress			
	Eq 3		Eq 4	
	MPa	ksi	MPa	ksi
200	-1143	-165.7	-1137	-164.9
100	-571	-82.8	-565	-81.9

50	-286	-41.5	-280	-40.6
20	-114	-16.5	-109	-15.8
10	-57	-8.3	-52	-7.5

Cantilever Beams. To measure the deflection of cantilever beams, various techniques have been developed (Ref 6), including optical, capacitance, mechanical, electromechanical, interferometric, and electromechanical or magnetic restoration. Figure 1(a) shows the setup for the deflection measurement when an optical system is used. In this example, a titanium nitride coating was deposited on a quartz beam via a PVD process, and the average residual stress in the coating was determined by measuring the amount of deflection at the free end, *f*, of the bent beam, according to the relation:

$$\sigma_c = [4E_s d_s^2 f] / [3(1 - \nu_s)L^2 d_c] \qquad \textbf{(Eq 6)}$$

With the values of E_s = 71.7 GPa (10.4×10^6 psi), ν_s = 0.16, d_s = 3 mm (0.12 in.), $d_c = 3 \times 10^{-6}$ m (1.2×10^{-4} in.), L = 50 mm (2 in.), and $f = 2 \times 10^{-6}$ m (8.0×10^{-5} in.), the stress in the coating is determined to be 273 MPa (40 ksi) in compression.

Disks. The average stress in the coating on a disk substrate can be determined from the amount of deflection, δ, at the center of the disk caused by the deposition of a coating on one side. This value can be measured optically by interferometry or microstylus profilometry. Figure 1(b) shows a typical interferometry apparatus setup. Either technique measures deflection at the same position, across a diameter of the disk, both before and after coating deposition. The stress in the coating is then calculated:

$$\sigma_c = \{E_s d_s^2 [(\Delta\delta_x + \Delta\delta_y) / 2]\} / [3(1 - u_s)r^2 d_c] \qquad \textbf{(Eq 7)}$$

where $\Delta\delta_x$ and $\Delta\delta_y$ are deflection changes measured before and after coating deposition, and *r* is the radius of the disk. Whether the stress is tensile or compressive, it is determined by the curvature of the disk before and after coating deposition, as determined by a depth microscope. When the change in curvature is upward (concave), viewed from the coating side, the stress in the coating is tensile. The opposite change in curvature indicates a compressive stress in the coating.

Typical interference fringe patterns are shown in Fig. 2. Figures 2(a) and 2(b) correspond to equal and unequal principal stresses of the same sign, whereas Fig. 2(c) corresponds to a biaxial stress state with principal stresses of opposite signs. Using Fig. 2(a) as an example, the measured defection, δ, is equal to the wavelength of monochromatic light multiplied by the number of light fringes (δ = 632.8 nm × 17).

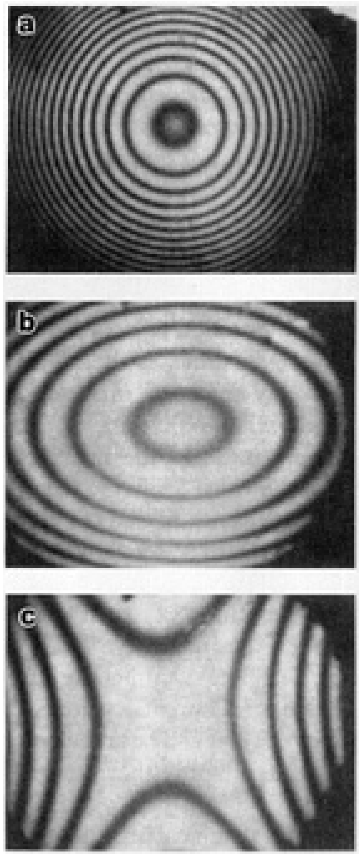

Fig. 2 Typical patterns of interference fringes. (a) $\sigma_x = \sigma_y$. (b) $\sigma_x \neq \sigma_y$, where both components are in compression or tension. (c) $\sigma_x \neq \sigma_y$, where one component is in compression and the other is in tension. Source: Ref 8

Figure 3 shows typical microstylus traces on the titanium nitride coated surface of an AISI 304 stainless steel disk, both before and after coating deposition. The curvature of the coated surface was downward (convex), viewed from the coated side. With the values of E_s = 193 GPa (28 × 10^6 psi), ν_s = 0.28, d_s = 4.74 mm (0.186 in.), r = 11.94 mm (0.4700 in.), d_c = 20 μm (800 μin.), and the deflection $\Delta\delta$= 6.3 × 10^{-6} m (2.5 × 10^{-4} in.), the stress in the titanium nitride coating is 4.44 GPa (0.644 × 10^6 psi) in compression. The measurement errors from both the optical and the microstylus trace setups are within one-half light band and ±0.1 μm (4 μin.), respectively.

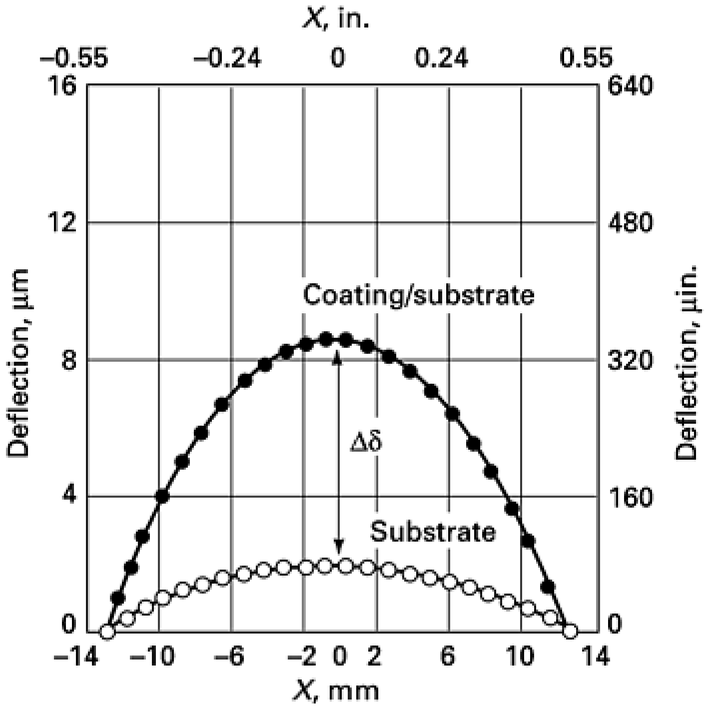

Fig. 3 Typical microstylus trace on titanium nitride-coated AISI 304 stainless steel disk before and after coating deposition

Practical Considerations. First, either strip or disk-shape substrate specimens should be parallel within 0.02 mm (0.001 in.) over their length or diameter. Specimen edges should be free from visible flaws and chips. In addition, the surfaces on which the deflection measurements (interferometer or profilometer) will be performed should be ground and lapped to a finish better than 0.08 μm R_a (3 μin. R_a).

Second, the dimensions of a strip of length L, width w, and substrate thickness d_s should obey $L > 10\ w > 10\ d_s$. The substrate thickness of a strip or disk depends on the coating thickness to be deposited. The thickness ratio of the substrate to the coating, d_s/d_c, should be greater than 50 to ensure the accuracy of the stress calculation from Eq 3.

Third, substrate specimens should be stress relieved before coating deposition. They should be placed between two stainless steel surface plates under at least an 8.8 kPa (1.3 psi) normal load, at an annealing temperature, in a vacuum furnace for at least 1 h. The annealing temperature is dependent on the substrate material.

Fourth, for coatings with an inherently smooth surface, such as those produced by PVD and CVD, the deflection can be determined either by interference fringe or microstylus profilometer measurements on the coated surface. For a coating with a relatively rough surface, such as those produced by thermal spraying and electroplating, the measurements can be made on the surface that is opposite the coated surface.

Significance and Use. The deflection measurement method is recommended for determining the average stress in the cross section of a coating with a thickness ranging from several hundred angstroms to several hundred micrometers. Typically, the elastic constants of a thin coating are much different from those of a bulk material. Equation 3 provides a means for stress measurement on a thin coating without any knowledge of its elastic constants. The measurement normally applies only to a test sample. The disk deflection method is particularly useful for the direct inspection of silicon wafers used in solar cells or integrated circuits.

X-ray Diffraction Method

Basic Principles. Stress measurement, using the x-ray diffraction method, is based on the change in the interplanar spacing (strain) close to the surface of the specimen material. The details of the theory and interpretation of residual stress measurements are well described in the article "X-Ray Diffraction Residual Stress Techniques" in Volume 10 of the *ASM Handbook*, as well as in Ref 9, 10, and 11. Consider an isotropic material with a lattice parameter d_0^{hkl} for unstressed material in the sample plane normal. The strain in a direction inclined by an angle y to the surface normal of the coating and the stress acting in the surface plane of the coating at an angle φwith the principal axis of the specimen are related by:

$$e_{jy}^{hkl} = (d_{jy}^{hkl} - d_0^{hkl}) / d_0^{hkl} = [(1 + \nu^{hkl}) / E^{hkl}] \\ (\sigma_x\cos^{2\varphi} + t_{xy}\sin^{2\varphi} + \sigma_y\sin^{2\varphi} - \sigma_z)\sin^2\psi \\ + [(1 + \nu^{hkl}) / E^{hkl}]\,\sigma_z - (\nu^{hkl} / E^{hkl})(\sigma_x + \sigma_y + \sigma_z) \\ + [(1 + \nu^{hkl}) / E^{hkl}]\,(t_{xz}\cos\varphi + t_{yz}\sin\varphi)\sin^2\psi \qquad \textbf{(Eq 8)}$$

where *h*,*k*, and *l* are the indices of the Bragg reflection; e_{jy}^{hkl} and d_{jy}^{hkl} $d\varphi\psi$ are the strain and interplanar spacing of (*hkl*) in the direction of (φ, ψ) respectively; ν^{hkl} and E^{hkl} are Poisson's ratio and Young's modulus in (*hkl*) in the coating; σ_x, σ_y and σ_z are normal stresses; t_{xy}, t_{yz}, and t_{xz} are shear stresses; σ_x is the normal stress acting in the *x* direction on a plane perpendicular to the *x* axis; and t_{yz} is the shear stress on a plane normal to the *y* axis (the first subscript) in the *z* direction (the second subscript). Residual stresses of the coating in various stress states can be determined using Eq 8.

Biaxial Stress. At a free plane, the out-of-plane stress components σ_z, τ_{xz}, and τ_{yz} are all zero, at a free surface. Because the penetration depth of x-rays is very small, the resulting measurements refer specifically to near-surface material. Plane stress conditions therefore often apply to x-ray measurements, and Eq 8 is simplified to:

$$e_{jy}^{hkl} = (d_{jy}^{hkl} - d_0^{hkl} / d_0^{hkl} = [(1 + \nu^{hkl}) / E^{hkl}] \\ \sigma\varphi\sin^2\psi + (\nu^{hkl} / E^{hkl})(\sigma_x + \sigma_y) \qquad \textbf{(Eq 9)}$$

where $\sigma\varphi = \sigma_x\cos^2\varphi + \sigma_y\sin^2\varphi$ is the macrostress in the coating parallel to its surface at an angle φwith the principal axis of the sample.

For a biaxial stress state, $\sigma_x = \sigma_y = \sigma\varphi$, and at $\psi = 0$,

$$(d_{j,y}^{hkl} = 0 - d_0^{hkl})/d_0^{hkl} = 2\nu^{hkl}\sigma\varphi / E^{hkl} \qquad \textbf{(Eq 10)}$$

From Eq 9 and 10,

$$d_{jy}^{hkl} = d_{j,y}^{hkl} = 0 + \sigma\varphi\, d_0^{hkl}\ [(1 + \nu^{hkl}) / E^{hkl}]\sin^2\psi \qquad \textbf{(Eq 11)}$$

In practice, high-angle diffraction peaks of an (*hkl*) reflection are obtained from -ψ to +ψ at a given angle φ. Lorentz polarization, absorption, and background corrections are applied to the diffraction peak profile. The peak positions are

determined by profile fitting or other methods and are subsequently converted to interplanar spacing $d_{\varphi\psi}^{hkl}$ for stress analysis.

In the linear plot of $d_{\varphi\psi}^{hkl}$ vs. $\sin^2\psi$, the intercept is $I = d_{\varphi\psi}^{hkl} = 0$ and the slope is $M = \sigma\varphi\, d_0^{hkl}\ [(1 + \nu^{hkl})/E^{hkl}]$ .The stress of the coating can then be determined by:

$$\sigma\varphi = M / \{ d_0^{hkl}\ [(1 + \nu^{hkl}) / E^{hkl}]\} \qquad \textbf{(Eq 12)}$$

Triaxial Stress State Without Shear Stress. For a material in a three-dimensional (triaxial) stress state without shear stress, but with the stress component σ_z having a finite value within the x-ray penetration volume, Eq 8 becomes (Ref 9, 11, 12):

$$\begin{aligned} e_{\varphi\psi}^{hkl} &= (d_{\varphi\psi}^{hkl} - d_0^{hkl}) / d_0^{hkl} \\ &= [(1 + \nu^{hkl}) / E^{hkl}](\sigma_x\cos^2\varphi + \sigma_y\sin^2\varphi - \sigma_z)\sin^2\psi \\ &\quad + [(1 + \nu^{hkl}) / E^{hkl}]\, \sigma_z \\ &\quad -(\nu^{hkl} / E^{hkl})\, (\sigma_x + \sigma_y + \sigma_z) \end{aligned} \qquad \textbf{(Eq 13)}$$

Two data sets, φ= 0° and φ= 90°, are needed to obtain σ_x, σ_y, and σ_z. The slopes and intercepts of a linear function of $d_{\varphi\psi}^{hkl}$ vs. $\sin^2\psi$ at φ= 0° and φ= 90° are given by:

$$\begin{aligned} M\varphi=0° &= d_0^{hkl}\ [(1 + \nu^{hkl}) / E^{hkl}]\, (\sigma_x - \sigma_z); \\ M\varphi=90° &= d_0^{hkl}\ [(1 + \nu^{hkl}) / E^{hkl}]\, (\sigma_y - \sigma_z); \\ I &= d_0^{hkl}\, \{[(1 + \nu^{khl}) / E^{hkl}]\, \sigma_z \\ &\quad -(\nu^{hkl} / E^{hkl})\, (\sigma_x + \sigma_y + \sigma_z)\} \end{aligned} \qquad \textbf{(Eq 14)}$$

Stresses σ_x, σ_y, and σ_z can be determined from the sum of the slopes and the intercept in Eq 14.

Triaxial Stress State With Shear Stress. A coating with a three-dimensional (triaxial) stress state, including shear stresses, is fully described by Eq 8. The shear stresses, t_{xz} and t_{yz}, have a $\sin^2\psi$ dependence. The $d_{\varphi\psi}^{hkl}$ vs. $\sin^2\psi$ distribution is no longer linear and has two branches of an ellipse for ψ> 0 and ψ< 0. This effect is termed "ψ splitting," which is an indication of the presence of shear stress.

To obtain these stress-tensor components, three data sets (φ = 0°, φ= 45°, and φ= 90°) are obtained for both -ψ and +ψ. The average strain a_1 and the deviation a_2 from the strains of "ψ splitting" are determined to be (Ref 9, 11, 12):

$$\begin{aligned} a_1 &= (e_{\varphi\psi}^{hkl} + e_{\varphi\psi}^{hkl} -) / 2 = [(d_{\varphi\psi}^{hkl} + d_{\varphi\psi}^{hkl}) / 2\, d_0^{hkl}] -1 \\ &= [(1 + \nu^{hkl}) / E^{hkl}]\, (\sigma_x\cos^2\varphi + t_{xy}\sin^2\varphi \\ &\quad + \sigma_y\sin^2\varphi - \sigma_z)\, \sin^2\psi + [(1 + \nu^{hkl}) / E^{hkl}]\, \sigma_z \\ &\quad - (\nu^{hkl} / E^{hkl})\, (\sigma_x + \sigma_y + \sigma_z), \end{aligned} \qquad \textbf{(Eq 15)}$$

$$\begin{aligned} a_2 &= (e_{\varphi\psi}^{hkl} + - e_{\varphi\psi}^{hkl} -) / 2 = (d_{\varphi\psi}^{hkl} - d_{\varphi\psi}^{hkl}) / 2\, d_0^{hkl} \\ &= [(1 + \nu^{hkl}) / E^{hkl}]\, (t_{xz}\cos\varphi + t_{yz}\sin\varphi)\, \sin^2\psi \end{aligned} \qquad \textbf{(Eq 16)}$$

The stress-tensor components can be calculated from the slopes of linear plots of a_1 vs. $\sin^2\psi$ and a_2 vs. $\sin^2\psi$. For a_1 vs. $\sin^2\psi$, (σ_x - σ_z) is obtained at φ= 0°, (σ_y - σ_z) at φ= 90°, and t_{xy} at φ= 45°, whereas σ_z is evaluated from the intercept if d_0^{hkl} is known. Similarly, t_{xz} and t_{yz} are obtained when φ= 0° and φ= 90 °, respectively, from the slope of a_2 vs. $\sin^2\psi$.

Stress Measurement. Modern diffractometers are fully automated and equipped with computer software for performing numerically intensive analyses. Diffractometers are capable of measuring residual stresses efficiently and economically. Typically, the measurement can be completed in several hours. The following examples illustrate some

stress measurements using Cu Kα radiation on cathodic arc PVD titanium nitride coatings on a substrate with various stress states.

Biaxial. An approximately 10 μm (400 μin.) thick coating of highly (111) oriented titanium nitride was deposited on AISI 304 stainless steel at 500 °C (930 °F). The x-ray diffraction $\sin^2\psi$ technique was applied to determine the residual stress in the (333)/(511) reflection of the coating. Figure 4 shows the linear distribution of d_{jy}^{hkl} vs. $\sin^2\psi$, indicating typical biaxial stress in the coating. As shown, the slope M = -1.1933 × 10^{-3} nm (4.698 × 10^{-11} in.) and the intercept I = $d_{jy}^{hkl} = 0$ = 0.082123 nm (0.003233 μin.). Young's modulus and Poisson's ratio for titanium nitride in (333)/(511) are 364 GPa (52.8 × 10^6 psi) and 0.245, respectively (Ref 13). The calculated residual stress for titanium coating is -4248 MPa (-615 ksi) in compression. For highly (111) oriented titanium nitride film, (511) contribution is negligible. This is addressed in Ref 13. The (422) reflection has 2θ < 130°, which is not desirable.

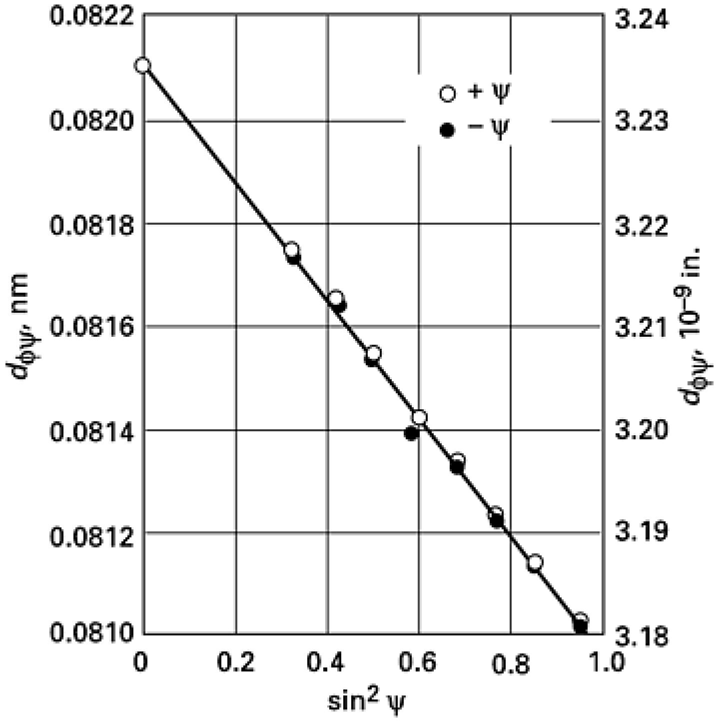

Fig. 4 Linear distribution of d_{jy}^{hkl} as a function of $\sin^2\psi$ of titanium nitride coating from (333)/(511) reflection

Triaxial Without Shear Stress. To exemplify a triaxial stress distribution, without shear stresses, triaxial stress analysis was applied to a titanium nitride coating deposited on Inconel 718 substrate at 550 °C (1020 °F). The d_{jy}^{hkl} vs. $\sin^2\psi$ distributions were obtained from (333)/(511) for φ= 0° and φ= 90° (Fig. 5). The slopes *Mφ=0* and *Mφ=90°* are -0.96782 and -1.01415 × 10^{-3} nm (-3.8103 and -3.9927 × 10^{-11} in.), respectively, and the intercept I is 0.082083 nm (0.003231 μin.). The strain-free interplanar spacing for (333)/(511) is 0.08160 nm (0.003213 μin.). Based on Eq 14, the stress tensor (σ_{ij}) from this analysis, in units of MPa, is:

$$s_{ij} = \begin{pmatrix} s_x & t_{xy} & t_{xz} \\ t_{yx} & s_y & t_{yz} \\ t_{zx} & t_{zy} & s_z \end{pmatrix} = \begin{pmatrix} -2653 \pm 151 & 0 & 0 \\ 0 & -2819 \pm 150 & 0 \\ 0 & 0 & 815 \pm 140 \end{pmatrix}$$

The result shows that the planar stresses are equal biaxial within experimental error and that the stress perpendicular to the coating surface is in tension.

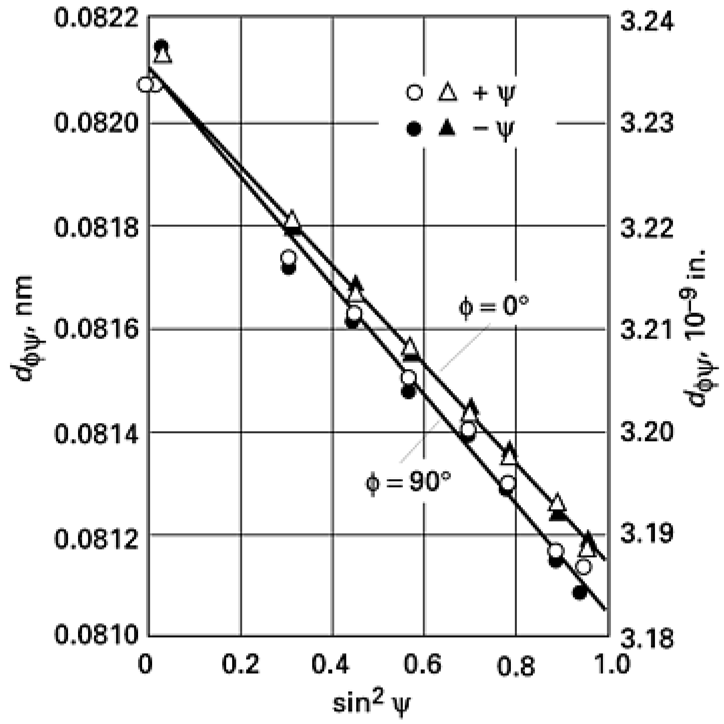

Fig. 5 Linear distribution of d_{jy}^{hkl} as a function of sin^{2}ψ of titanium nitride coating from (333)/(511) reflection at φ= 0° and φ= 90°

Triaxial With Shear Stress. A triaxial stress distribution, including shear stresses t_{xy}, t_{yz}, and t_{xz}, was studied in a cathodic arc PVD titanium nitride coating on AM-355 stainless steel. The d_{fy}^{hkl} vs. sin^{2}ψ distributions were obtained from (333)/(511) at φ= 0°, φ= 45°, and φ= 90° using Cu Kα radiation. Figure 6 shows the typical ellipse distribution of d_{jy}^{hkl} vs. sin^{2}ψ at φ= 0°. Based on analysis discussed at the beginning of this section, the stress tensor in the titanium nitride coating, in units of MPa, is:

$$s_{ij} = \begin{pmatrix} -2899 \pm 148 & 1 \pm 181 & 110 \pm 32 \\ 1 \pm 181 & -2776 \pm 148 & -34 \pm 34 \\ 110 \pm 32 & -34 \pm 34 & 833 \pm 148 \end{pmatrix}$$

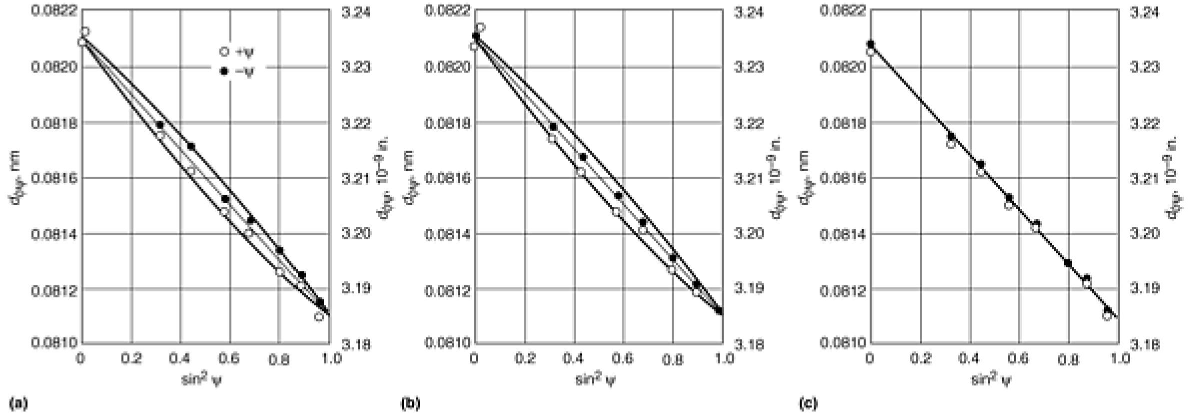

Fig. 6 Typical ellipse distribution of d_{jy}^{hkl} as a function of sin^{2}ψ of titanium nitride coating from (333)/(511) reflection at varying angles. (a) φ= 0°. (b) φ= 45°. (c) φ= 90°

Practical Considerations. First, a ψ-diffractometer is preferable for conducting stress measurements. The Ω-and ψ-diffractometers are defined on the basis of the sample axis for ψ tilt perpendicular or parallel to the plane of the incident and detected x-ray beam, respectively. A ψ-diffractometer gives symmetric irradiated areas in -ψ and +ψ tilted angles at a given (*hkl*) reflection line and a greater range of $\sin^2\psi$ (from 0 to 0.95 for a ψ-diffractometer and 0 to 0.5 for an Ω-diffractometer).

Second, the diffractometer should be mechanically aligned and calibrated using a stress-free standard sample (NIST SRM 660 lanthanum hexaboride powder or SRM 640 silicon powder) to obtain the peak position of the (*hkl*) reflection line within ±0.01° at Bragg angles 2θ in the range of ψ> 0 and ψ< 0.

Third, an appropriate x-ray wavelength should be selected to achieve the desired sampling volume (penetration depth) for a particular set of (*hkl*)planes. The penetration depth, which is defined as the distance from the surface to the depth with 63% or 1/*e* of the intensity of the reflection line, is calculated for Ω- and ψ-diffractometers, respectively:

$$t\ \Omega = (\sin^2\theta - \sin^2\psi) / [2\mu(\sin\theta \cos\psi)]$$
$$t\ \psi = (\sin\theta \cos\psi) / 2\mu$$

where μ is the linear absorption coefficient, which can be obtained from Ref 14 for various materials and radiations.

Fourth, to achieve high accuracy in residual stress, the measurement should only be carried out on an (*hkl*) reflection line with Bragg angles 2θ > 130° and with sufficient intensity for peak position determination.

Fifth, an appropriately sized collimator should be selected. It should have an irradiated area large enough to ensure that a statistically relevant number of grains or subgrains in the coating are included in the measurement. The angular resolution is essential in stress measurement. If the spot mode of x-ray beam cannot sample a sufficient number of grains, one should use another method.

Sixth, appropriate methods (Ref 9, 10, 15, 16, 17), such as modified Lorentzian, Gaussian, Cauchy, Pearson VII, parabola, center of gravity, gravity line, and cross correlation should be applied to determine the peak positions of the reflection line (*hkl*).

Seventh, a sufficient number of measurements in the -ψ and +ψ directions should be conducted to obtain an accurately linear distribution or ψ-splitting of d_{jy}^{hkl} vs. $\sin^2\psi$. The significance of this distribution should be verified by repeating measurements at different φangles. If a nonlinear relation other than ψ-splitting is obtained in the d_{jy}^{hkl} vs. $\sin^2\psi$ distribution, then the coating being measured is inhomogeneous and, therefore, the x-ray diffraction $\sin^2\psi$ method is no longer applicable.

Eighth, the x-ray elastic constants of the coating for an (*hkl*) plane, $S_1^{hkl} = -\nu^{hkl}/E^{hkl}$ and $S_2^{hkl}/2 = (1 + \nu^{hkl})/E^{hkl}$, can be calculated from single-crystal compliance, according to an appropriate model (Ref 11, 12), or measured experimentally in uniaxial tension or bending tests with a series of loads (Ref 13, 18, 19). X-ray elastic constants and applied loads (σ_a) obey these equations:

$$S_2^{hkl} / 2 = (1 + \nu^{hkl}) / E^{hkl}$$
$$= (1 / d_0^{hkl})[\partial / \partial \sigma_a(\partial d_{jy}^{hkl} / \partial \sin^2\psi)]$$
$$S_1^{hkl} = -\nu^{hkl} / E^{hkl} = [1 / (2 d_0^{hkl})](\partial d_{jy}^{hkl} = 0 / \partial\sigma_a)$$

Ninth, a stress-free interplanar spacing, d_0^{hkl}, for a coating may not be readily available in practice. For biaxial stress analysis, the lattice spacing measured at ψ= 0, $d_{jy}^{hkl} = 0$, can be substituted for d_0^{hkl}. In this case, the contribution to the total error is less than 0.1%. For a triaxial stress analysis, the difference between $d_{jy}^{hkl} = 0$ and d_0^{hkl} is included in the calculation. Consequently, a small error in d_0^{hkl} can lead to a relative large error in the measured stress. To obtain acceptable stress results, d_0^{hkl} must be within 0.01% of its true value. The stress-free interplanar spacing d_0^{hkl} in the strain-free direction ψ* is given by (Ref 20):

$$\sin^2\psi^* = [-S_1^{hkl} / (S_2^{hkl} / 2)] \{1 + [(\sigma_y - \sigma_z) / (\sigma_x - \sigma_z)] + [3 + (S_2^{hkl} / 2 S_1^{hkl}) \sigma_z] / (\sigma_x - \sigma_z)\}; \varphi=0$$

$$\sin^2\psi^* = [-S_1^{hkl} / (S_2^{hkl} / 2)] \{1 + [(\sigma_y - \sigma_z) / (\sigma_x - \sigma_z)]\}$$
$$\text{when } | \sigma_x + \sigma_y - 2\sigma_z | \ ? \ 2 | \sigma_z |$$

$$d_0^{hkl} = d_{jy}^{hkl} = 0 / [1 + S_1^{hkl} (\sigma_x + \sigma_y + \sigma_z) + (S_2^{hkl} / 2)\sigma_z]$$

Significance and Use. The advantage of the x-ray diffraction method is its capability for measuring residual stress directly and nondestructively on a product component. Portable diffractometers are commercially available and can be used for on-site measurement. The method can apply to a coating with a thickness ranging from 0.5 to 350 μm (2×10^{-5} to 1.4×10^{-2} in.). However, it is difficult to measure residual stresses in extremely thin coatings and, in some cases, highly textured coatings. Furthermore, x-ray diffraction is inapplicable to amorphous coatings, and a large scatter in stress measurement is often encountered in coatings with large grain size.

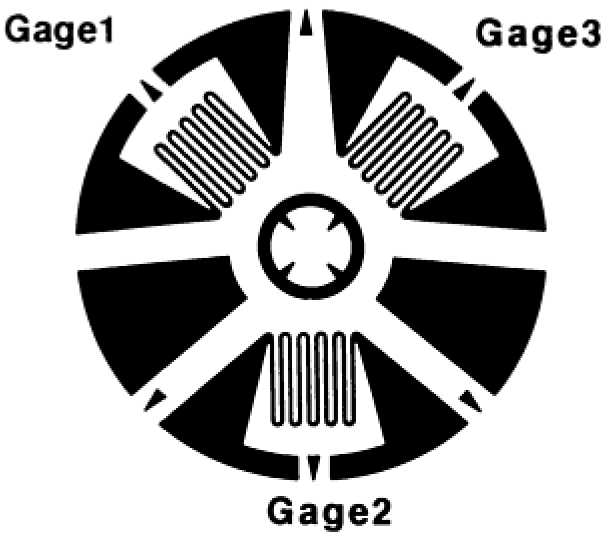
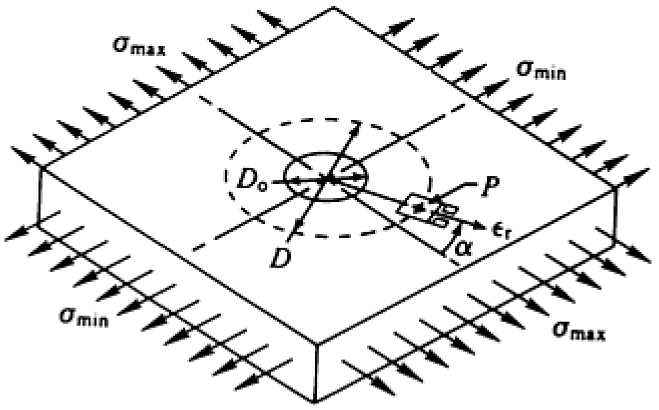
Hole-Drilling Method

Basic Principles. The hole-drilling method for measuring residual stresses involves drilling a shallow hole in the test specimen to a depth approximately equal to the hole diameter. Typical hole diameters range from 0.8 to 5.0 mm (0.030 to 0.200 in.). The creation of the hole redistributes the stresses in the material surrounding the hole. A specially designed three-element strain-gage rosette, such as that shown in Fig. 7(a), measures the associated partial strain relief. The in-plane residual stresses that originally existed at the hole location can then be calculated from the measured strain reliefs using the method described in ASTM E 837-92 (Ref 21). The ASTM standard also gives details of practical drilling procedures.



(a)



(b)

Fig. 7 (a) Typical three-element strain-gage rosette. (b) In-plane strain components caused by release of residual stress through introduction of a hole. Source: Ref 21

The partial strain relief measured by one of the three strain gages in the rosette in Fig. 7(b) is related to the principal in-plane residual stresses by:

$$\varepsilon_r = (\sigma_{max} + \sigma_{min})A + (\sigma_{max} - \sigma_{min})B \cos 2\alpha \quad \textbf{(Eq 17)}$$

where σ_{max} and σ_{min} are maximum and minimum principal residual stresses, and α is the angle from the gage axis to the maximum principal stress direction. *A* and *B* are calibration constants, the values of which depend on the specimen material properties, the rosette geometry, the hole diameter, and the hole depth. ASTM E 837-92 tabulates the calibration constants for the standard rosette pattern shown in Fig. 7.

Equation 17 can be inverted to determine the principal residual stresses from the measured strain reliefs. The result is:

$$s_{max}, s_{min} = [(e_3 - e_1)/4A] \pm \{[(e_3 - e_1)^2 + (e_3 + e_1 - 2e_2)^2]^{1/2}/4B\}$$
$$b = \tfrac{1}{2}\arctan[(e_3 + e_1 - 2e_2)/(e_3 + e_1)]$$
(Eq 18)

where β is the angle measured clockwise from the location of gage 1 to the direction of σ_{max}. The above equations are valid for a homogeneous isotropic material that is wide, when compared with the hole diameter, and thick, when compared with the hole depth. The equations also apply to a through-the-thickness hole in a material in the form of a thin sheet, provided that the sheet thickness is uniform near the hole. The associated calibration constants have slightly different values than those of the thick-material case. Table 2, reproduced from ASTM E 837-92, lists the dimensionless calibration coefficients for both the thin-sheet and thick-material cases. *A* and *B* can be determined from the dimensionless coefficients using:

$$A = -(1 + \nu)\,\bar{a}/2E$$
$$B = -\bar{b}/2E$$
(Eq 19)

(a) In a thin sheet.

(b) In a thick material.

Residual stress measurements in coated materials create an additional complication because the combination of coating and substrate is no longer a homogeneous material. The calibration coefficients provided in ASTM E 837-92 no longer accurately apply. However, the above two equations are still valid for coated materials, if the coating has a uniform thickness. If the substrate is less than several times greater than the hole depth, then it is also necessary for the substrate thickness to be uniform.

The calibration coefficients A and B for hole drilling in a coated material differ from the standard values given in ASTM E 837-92. The actual values depend on the elastic properties of the coating and the substrate, the coating thickness, and the hole diameter and depth. These coefficients can be determined by either experimental calibrations (Ref 22) using known externally applied stresses or finite-element calculations (Ref 23).

Approximate values of A and B for thick coatings can be estimated from the values given in ASTM E 837-92. For this purpose, a "thick" coating is one that is at least 0.25 times the mean radius of the strain-gage rosette. For the smallest commercially available hole-drilling rosette, the mean radius is about 1.25 mm (0.050 in.). Therefore, the minimum acceptable coating thickness is about 0.3 mm (0.012 in.).

An approximate estimation of A and B for a coated material is based on the observation that the hole-drilling method is most sensitive to the stresses closest to the specimen surface. Almost all of the measured strain relief is due to the stresses in the material within a depth of about 0.25 times the mean radius of the hole-drilling rosette. Thus, a specimen coated to at least this depth is likely to behave similarly to a homogeneous thick specimen consisting only of coating material. Thus, the A and B calibration coefficients for a "thick" coating are approximately equal to the ASTM tabulated values for a homogeneous material with the elastic properties of the coating.

The *A* and *B* coefficients for coatings that are thinner than 0.25 times the mean radius of the hole-drilling rosette will deviate significantly from the ASTM tabulated values. The coefficients must be determined on an individual basis, either by experimental or computational means. The use of the hole-drilling method with such "thin" coatings is not generally recommended because the sensitivity of the resulting strain measurements is rather low. As a result, small absolute errors in the strain measurements can cause large relative errors in the computed residual stresses.

Stress Measurement. The following example illustrates a hole-drilling measurement on a detonation gun type of tungsten carbide-cobalt (WC-Co) coating deposited on an AISI 1018 steel substrate. The coating was approximately 0.75 mm (0.03 in.) thick and had a macroscopically homogeneous structure. The elastic properties of the coating were E_c = 172 GPa (25 × 10^6 psi) and u_c = 0.3.

A 062-RE hole-drilling strain-gage rosette (5.13 mm, or 0.202 in., strain-gage mean diameter) was attached to the coated specimen. A 2.44 mm (0.096 in.) diameter hole was cut in the WC-Co coating by abrasive-jet drilling using 27 μm (1080 μin.) alumina particles. Drilling proceeded in four approximately equal depth increments, up to a final depth of 0.356 mm (0.014 in.). The strain measurements listed in Table 3 were made after each hole-depth increment. Using the *A* and *B* calibration coefficients from ASTM E 837-92, adjusted for the elastic properties of the coating material, the principal residual stresses in the coating were found to be -260 MPa (-38 ksi) and -286 MPa (-41 ksi), respectively. As might be anticipated, the residual stresses in the coating are approximately isotropic.

Table 3 Hole-drilling residual stress measurements on a detonation gun WC-Co coating

Depth		Strains, με			Average stress												α
					σ_x		σ_y		t_{xy}		σ_{max}		σ_{min}		t_{max}		
mm	in.	ε_1	ε_2	ε_3	MPa	ksi	MPa	ksi	MPa	ksi	MPa	ksi	MPa	ksi	MPa	ksi

0.28	0.011	163	155	168	...	...	...	...	...	...	...	...	...	...	...	...	...
0.36	0.014	210	200	218	...	...	...	...	...	...	...	...	...	...	...	...	...

Note: Rosette type, EA-XX-062RE; Young's modulus, 172.0 GPa (25 × 10^6 psi); Poisson's ratio, 0.3; hole diameter, 2.440 mm

Practical considerations for the use of the hole-drilling method are:

- A high-speed drilling technique using carbide drills is recommended for producing a hole in a ductile coating. Abrasive-jet drilling is recommended for a brittle, hard coating (Ref 24).
- The use of specially made hole-drilling strain-gage rosettes is essential. The application of the strain-gage should follow the procedure recommended by the manufacturer.
- A smooth coating surface less than 0.41 μm R_a (16 μin. R_a) is desirable for secure strain-gage adhesion. An abrading or grinding process that does not induce significant residual surface stress should be used for surface preparation.
- The selection of an appropriately sized strain gage should be based on coating thickness, as well as on

the depth and diameter of the hole to be drilled. The diameter of the drilled hole, D_0, should be related to the diameter of the gage circle, D, where $0.3 < (D/D_0) < 0.5$.

- A depth microscope with a resolution better than 12.7 μm (0.0005 in.) should be used to measure the depth of the drilled hole at each depth increment.
- The center of the drilled hole should coincide with the center of the strain-gage circle within $\pm 0.015\ D_0$. A measurement microscope should be used to align the drill holder or abrasive-jet nozzle with the center of the rosette.
- Precautions should be taken to ensure that the walls of the drilled hole are square to the coating surface on which the rosette is cemented. It is important to protect the strain gage from abrasive-particle erosion or mechanical damage during the drilling operation.
- Values for the Young's modulus and Poisson's ratio of the coating should be independently measured in order to determine the residual stress from strain relaxations.

Significance and Use. The hole-drilling strain-gage method is a semidestructive technique for measuring residual stress on a coating with a thickness of at least 0.1 mm (0.004 in.). The method, which is quite versatile, can apply to test samples as well as to actual components with complex geometries. Furthermore, it can be used for on-site measurements.

Method Comparison

The mechanical-deflection method is capable of measuring the average stress throughout the coating thickness, but requires the stress to be uniform over large distances in the in-plane directions. In contrast, the x-ray diffraction and hole-drilling methods can make a much more localized measurement in-plane, but they have a significantly more limited depth capability. A good agreement in stress measurements between the deflection and x-ray diffraction methods has been demonstrated (Ref 13). With the extrapolation of blind-hole measurements to the near surface, the stress measurement is in good agreement with that measured by x-ray diffraction (Ref 25). A user can select the most suitable method based on economics, environment, coating microstructures, and the geometry of the component to be measured.

Testing of Stability and Thermal Properties of Thermal Barrier Coatings

Thomas A. Taylor, Praxair Surface Technologies, Inc.; Ray E. Taylor, Purdue University

---

Introduction

THERMAL BARRIER COATINGS (TBCs) are applied to metallic components of advanced heat engines to reduce the metal temperature, increase the environmental resistance and life of the component, and in some cases reduce noxious exhaust emissions. This thin coating usually consists of a metallic bond coat applied to the metal component, followed by a layer of magnesia- or yttria-stabilized zirconia (YSZ). If the TBC is on nickel- or cobalt-base superalloy components

intended for high-temperature operation, it is advisable to heat treat the TBC to achieve bond coat densification and diffusion bonding to the substrate. The selection of the TBC system involves many considerations, principally knowledge of the intended service conditions, temperature reduction expectations, component life estimates, cost, and in some cases the external surface finish requirements. It is implicit that a successful TBC will also survive the rigors of service without spalling or eroding. This article discusses the various tests applied to the TBC system, and to the zirconia layer separately, to establish thermal design properties and thermomechanical and environmental stability.

Acknowledgements

The authors wish to thank Danny L. Appleby and Dr. Glenn C. Whichard of Praxair Surface Technologies, Inc. for providing the data for Fig. 5 and providing the samples and doing the x-ray analysis for Fig. 7, respectively. We also appreciate the suggestions of the reviewers of this article: Catherine Cotell (Naval Research Laboratory), Robert Miller (National Aeronautics and Space Administration, Lewis Research Center), Albert Sue (Praxair Surface Technologies), Gary McGuire (MCNC), and Michael Barber (Allison Engine Co.).

Thermomechanical Stability

The TBC system is expected to survive the thermal shock of rapid cycle heating and cooling, as experienced in gas turbine or diesel engines, without spallation. Spallation is the result of the thermal stress pattern created when the thermal cycle repeatedly exceeds the stress for crack growth within the zirconia layer. This results in a time-dependent extension of pre-existing cracks within the plane of the coating until critical link-up and spallation. In many tests, the location of the spall line is in the zirconia layer, but near the bond coat interface. In the finite element modeling studies of Chang et al. (Ref 1), the near-interface area in the zirconia layer was shown to be the high-stress zone in simulated thermal cycling. In the thermal spray process, the crack nuclei are probably the interfaces between splats in the coating.

Two strategies to improve the resistance to in-plane crack growth in thermally sprayed zirconias are to use a low-density coating, with the pores acting to blunt growing cracks, or to increase the cohesive strength between splats, which requires high-density coating conditions. In the first case, 12 to 15% porosity is useful, and in the latter case, it is critical to generate macrocracks vertical to the plane of the coating, spaced about 0.2 to 1 mm apart, to relieve short-range stress (Ref 2). In physical vapor deposition coating, the zirconia deposition conditions are adjusted to grow columnar grains, which similarly reduce the in-plane modulus and limit the accumulation of coating stress during a thermal cycle.

Thermal Fatigue Testing. Laboratory testing has been used, particularly in the coating development stage, to cycle thermally a TBC specimen followed by post-test microscopic examination for spallation-type cracks. The thermal cycle for evaluation of thermal shock resistance employs rapid heating and cooling rates, using direct impingement flames or heating jets on the oxide face of the specimen, with little hold time at the maximum temperature. This test principally challenges the oxide layer, because the bond coat remains at relatively low temperatures due to the insulating nature of the zirconia layer and the short time at high temperatures.

Figure 1 illustrates a cycle that simulates the thermal shock of first-stage gas turbine outer airseals with a zirconia layer 1.27 mm (0.050 in.) thick. Detail of the flame impingement on the button sample is shown in Fig. 2. The test sample is a 25 mm (1 in.) diameter button, 3.2 mm (0.125 in.) thick, made from the substrate alloy of interest. After the button is coated with the TBC system, the edges are ground and polished to produce a square edge to allow examination of the coating layers.

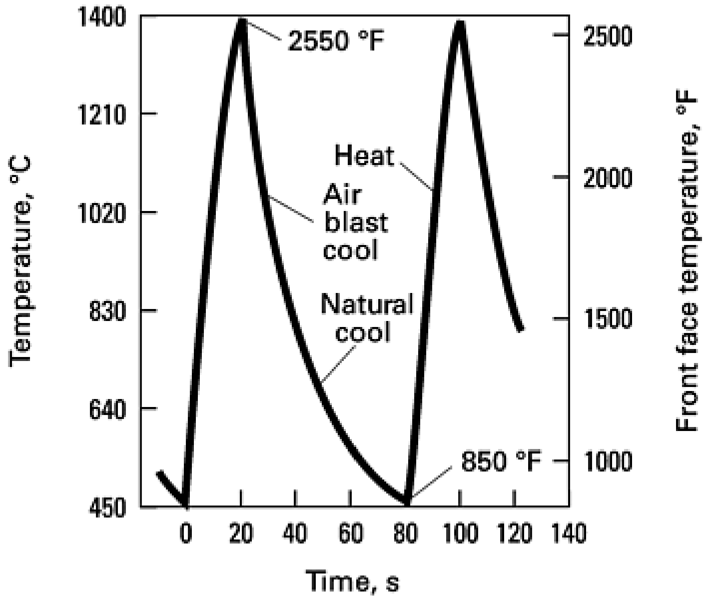

Fig. 1 Schematic illustration of oxide surface temperature cycle used for thermal fatigue testing of ZrO_2-coated test buttons 1.27 mm (0.050 in.) thick, simulating a first-stage gas turbine outer airseal application

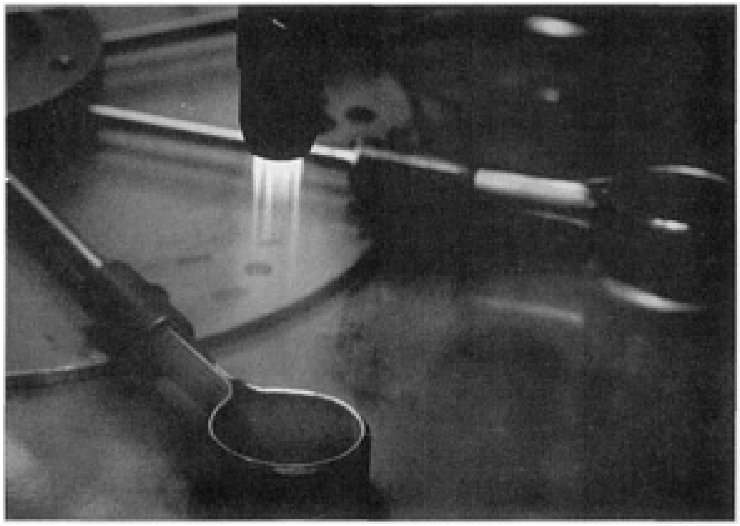

Fig. 2 Flame impingement on the button sample in a thermal fatigue test rig

The test rig consists of an oxygen-propane or propylene burner, a fixture arm to hold the button sample, a stepping motor system to advance quickly between stations and to hold for prescribed times in the heating and cooling positions, and a means to record at least the front oxide face temperature during the heating cycle. Two-color infrared optical pyrometers are widely used for the latter task, with the output connected to a chart recorder or computer. One word of caution concerning the temperature measured. If the zirconia coating is not an ideal gray body, that is, the emissivity is not the same at the two wavelengths used by the pyrometer, the reading may be in error. This issue is under study at several test facilities, and it could affect burner rig tests as well. If the samples being tested are all the same material, such as plasma-sprayed 8% YSZ coatings of common thickness, the measured temperatures should be relatively correct.

In one test configuration, the heating cycle is 20 s, followed by a 20 s air blast and two 20 s periods of natural convection cooling. The burner-to-specimen standoff, burner size, and gas flows are set to heat the oxide face of a standard specimen rapidly to 1400 °C (2550 °F) in the first 20 s. The air blast then drops the front face temperature to about 815 °C (1500 °F), and it finally reaches about 454 °C (850 °F) after 40 s of natural cooling. After the cycle is repeated 2000 times, the

edge of the coated button is examined at 10× to 30× for evidence of separation-type cracking in the zirconia layer. The specimen edge should also be inspected before the test, with few to no starting cracks expected.

The post-test cracking of good TBC systems having zirconia thicknesses of about 1.27 mm (0.050 in.) should be less than 15% of the circumference, and typically much less. If a tested specimen is mounted in cross section and serially polished, it will be seen that the crack is indeed at the edge of the coating and extends inward toward the center of the button. The cracks will continue to extend around the circumference and grow inward until eventual spallation, for the case of a TBC with poor thermal fatigue resistance. In good TBC systems, additional sets of 2000 cycles will show little crack growth, if any, and typically at a lower rate than in the first test period.

It has been found that the edge-cracking rate is a function of the zirconia coating density (Ref 2), as shown in Fig. 3. In addition, use of the conventional tensile bond-cap test (ASTM C 633-79) has shown that the higher-density coatings have increasing cohesive strength within the zirconia (Ref 2). The result of Fig. 3 must be further qualified. The coatings of density above about 90% of theoretical density (below 10% porosity) also had intentional long macrocracks throughout the coating running perpendicular to the coating plane. Without these macrocracks, the higher-density zirconia coatings will spall quickly, perhaps even on the first thermal cycle.

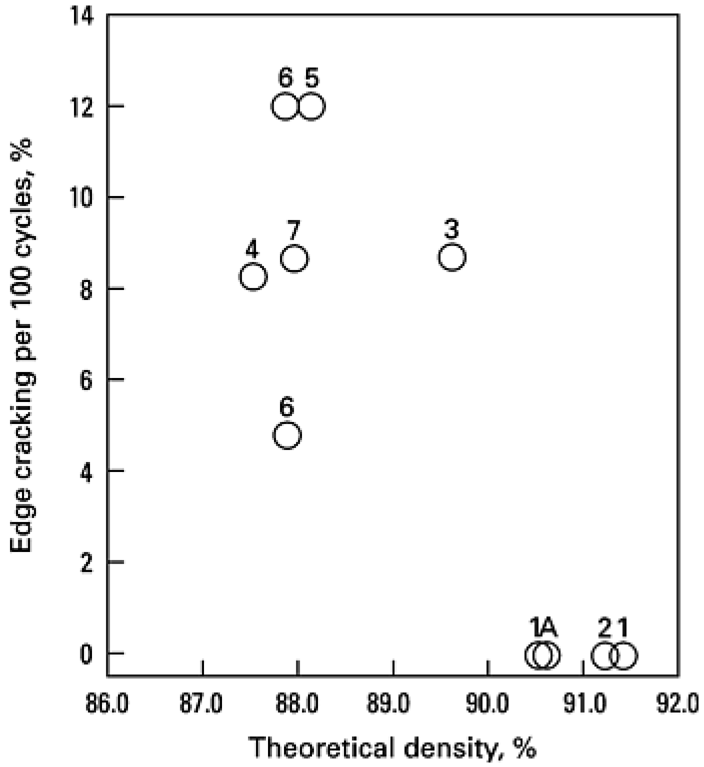

Fig. 3 Thermal fatigue edge-cracking rate for thick ZrO_2 coatings as a function of coating density. Thermal fatigue test with peak temperature of 1400 °C (2550 °F) and 1.1 to 1.3 mm (0.4 to 0.5 in.) thick oxide. Specimen numbers allow correlation to Fig. 4. Source: Ref 2

If the back metal side of the button specimen also has temperature instrumentation, the differential front-to-back temperature drop, ΔT, can be measured at the peak of the heating cycle. Figure 4 shows that ΔT is also related to coating density, with lower-density coatings having greater thermal insulation.

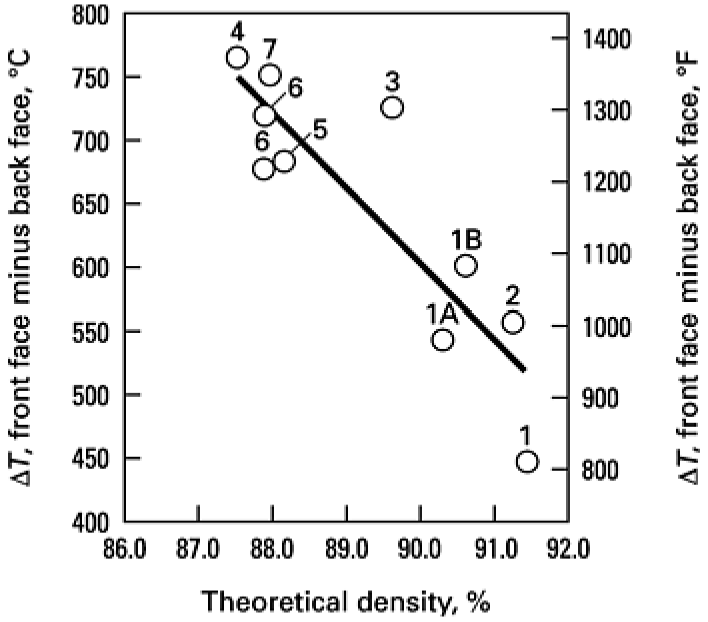

Fig. 4 Temperature drop across thick ZrO_2 coatings on an IN 718 substrate (thickness, 3.2 mm) as a function of ZrO_2 coating density. Thermal fatigue test with peak temperature of 1400 °C (2550 °F) and 1.1 to 1.3 mm (0.4 to 0.5 in.) thick oxide. Specimen numbers allow correlation to Fig. 3. Source: Ref 2

The same rapid heating test rig can be used to evaluate thin TBCs. On aircraft turbine components such as first-stage blades or vanes, the zirconia thickness required may be from 0.13 to 0.30 mm (0.005 to 0.012 in.), and on combustion chambers, 0.30 to 0.38 mm (0.012 to 0.015 in.). If the front face oxide peak temperature is set at 1400 °C (2550 °F) on a standard YSZ sample of 90 to 91% theoretical density and 1.27 mm (0.050 in.) thickness, specimens with thinner zirconia layers will reach lower temperatures in the same test cycle, while those with thicker layers will reach higher temperatures. Figure 5 shows this dependence on oxide layer thickness when other conditions are constant. For this reason, the burner parameters should be set using a standard sample to ensure a constant heat flux for all tests. One way to do this is to have a rotary carousel of samples, including one standard sample, that provides a check on the test conditions every time it cycles through the heating station. The parameter ΔT will also increase with zirconia thickness, as one would expect. Furthermore, the edge-cracking rate will depend on coating thickness for constant coating density and structure. For example, a dense macrocracked TBC specimen 0.30 to 0.38 mm (0.012 to 0.015 in.) thick can easily sustain 20,000 or more of the above cycles without edge cracking.

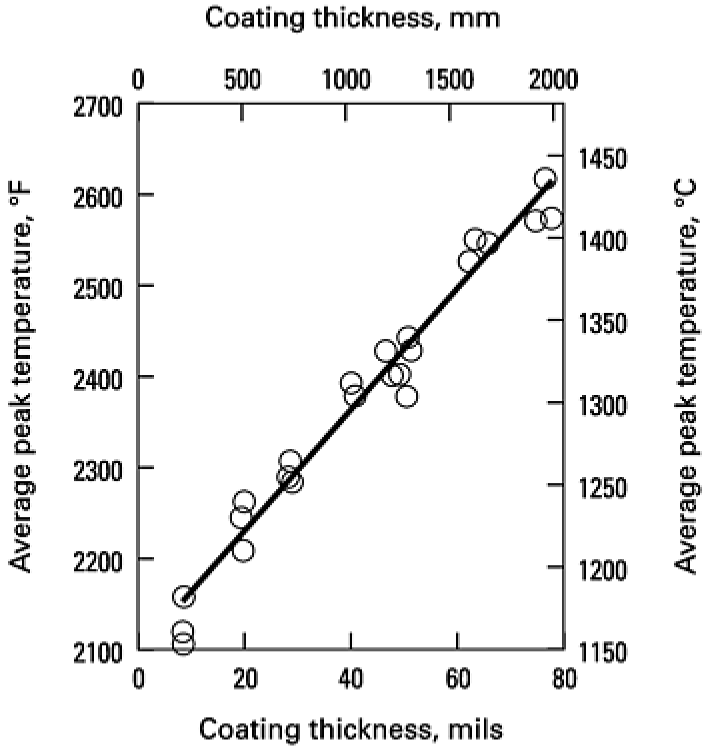

Fig. 5 Peak temperature of zirconia surface for ZrO_2 coatings as a function of coating thickness, in standard thermal cycle test of Fig. 1 (20 s cycle to 1400 °C, or 2550 °F). All samples were run at the same relative heat flux (1330 °C, or 2423 °F, on a nominal coating 1270 μm, or 50 mils, thick).

A similar thermal fatigue test cycle can be established for testing TBCs for the diesel environment. In this case, the heat flux across the TBC is expected to be greater than in gas turbines, but the peak temperature is expected to be lower. In one test configuration, the burners were moved closer to the oxide face of the coated button, the heating cycle was reduced to 8 s, and the peak oxide temperature was held to 982 °C (1800 °F).

Another testing approach, used by aircraft gas turbine manufacturers and the National Aeronautics and Space Administration, is to coat solid 1.2 cm (0.5 in.) diameter burner bars and expose a rapidly rotating carousel of bars to a high-velocity fuel-oxygen burner. This test has the advantage of allowing use of commercial engine fuel, with controlled doping of known impurities such as sulfur or vanadium if desired. Substrate-side air cooling is sometimes introduced by using hollow bars, to make the test a better simulation of actual coated hardware conditions where back-side cooling is typical.

Although the button tests establish the capability of the basic coating candidate, the button and burner bar coating conditions are usually ideal. Only on real components will practical issues such as the effect of component geometry on the coating structure be faced. One further stage of testing might be considered: putting actual coated components in large thermal cycling chambers. Even so, the laboratory screening tests described above should be followed by actual engine tests of components with TBCs.

Environmental Stability

A TBC must also resist environmental degradation. This may occur as oxidation of the bond coat, phase transformation stress deterioration of the zirconia layer, or chemical destabilization of the oxide layer. The severity of these effects depends on the oxidation resistance of the bond coat, the initial crystalline phase mixture of the zirconia coating, the service temperature, and the environmental impurities present.

Bond Coat Oxidation. To test the oxidation resistance of the bond coat and its effect on the spallation of the TBC, a thermal cycle needs to combine extended soak time at high temperatures with periodic heating and cooling cycling to induce thermal stress. One such cycle used to test TBCs for aircraft gas turbine applications is a simple tube furnace that operates at a constant temperature of 1121 °C (2050 °F), with the sample set pneumatically moved in and out of the hot zone. The TBC samples rest on an alumina firebrick boat, with dense alumina pushrods made from thermocouple insulator ceramics, for an all-oxide hot-zone support system. The samples heat to furnace temperature in about 5 min, soak for 50 min, and then are quickly pulled out for a 5 min cooling period. At the end of every 25 cycles, the samples are held out and visually examined at room temperature. After 200 cycles, the samples are inspected for spallation or edge cracking, then are mounted in plastic for evaluation in polished cross section. There the extent of bond coat oxidation and interface cracking can be measured. The test temperature is as much as 110 °C (200 °F) higher than expected for the component in service and is thus an accelerated test for oxidation of the bond coat. To make this comparison test valid, care should be taken that the furnace temperature profile is uniform and covers the full zone occupied by the TBC samples.

A cycle for testing coatings for diesel applications can be similarly designed by setting the soak temperature about 110 °C (200 °F) higher than the measured steady-state temperature of the substrate metal of the component in question. In the case of coatings for steel or cast iron substrates, the bond coat is typically not heat treated, which may allow internal oxidation of the Ni-Cr or Fe-Cr-Al-Y alloys used for thermally sprayed layers. Thus, a cycle soak temperature of 650 to 982 °C (1200 to 1800 °F) may still challenge inadequate coating systems.

Zirconium Oxide Phase Stability. Pure zirconium oxide is an allotropic material and has a cubic structure from its freezing point at 2680 °C (4856 °F) down to 2370 °C (4298 °F), where it transforms to a tetragonal structure of similar cell size. Because of this small difference in crystalline cell volume, thermal cycling across the cubic-tetragonal transition temperature does not impose severe internal stresses. Following further cooling to below 1170 °C (2138 °F), zirconia transforms to the monoclinic structure, which has about a 4% larger crystalline cell volume than the tetragonal structure (Ref 3). Large internal stresses are generated as the transformation front sweeps through the material, which can lead to crack initiation. Commercially useful zirconia is alloyed with yttria, which has a cubic-plus-tetragonal two-phase field in its phase diagram (Fig. 6) and inhibits the low-temperature tetragonal-to-monoclinic transformation (Ref 3, 5, 6).

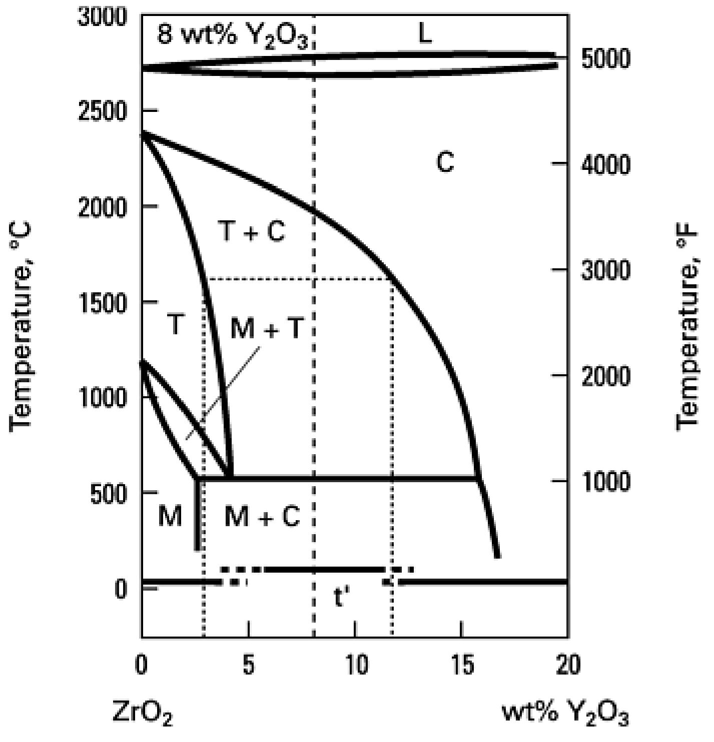

Fig. 6 Phase diagram of the ZrO_2-rich region of the ZrO_2-Y_2O_3 system. M, monoclinic phase; C, cubic phase; T, tetragonal phase; L, liquid; t, nontransformable tetragonal. Source: Ref 4

In thermally sprayed yttria-stabilized coatings, the feedstock is powder, which may be fabricated by a variety of methods (Ref 7). Partially stabilized zirconia, with about 6.5 to 9 wt% Y, mostly avoids the monoclinic phase and the fully stabilized cubic-only phase, which is known to have less thermal shock resistance than the dual-phase cubic-plus-tetragonal structure (Ref 8). A powder feedstock may have the correct average yttria content, but it may not be homogeneous at the crystalline grain level. An inhomogeneous powder may have some local volumes that have no yttria and others with yttria concentrations far higher than the bulk analysis. The x-ray diffraction pattern of such a powder thus shows the monoclinic phase characteristic of the nearly pure zirconia grains, along with tetragonal and cubic phases from the volume of the material that was sufficiently combined with yttria. When an inhomogeneous powder is plasma sprayed to form a coating, the particle melting in the arc improves the degree of homogeneity. However, this may not be sufficient to fully homogenize the material, depending on the state of the starting powder and the chosen spray parameters.

Figure 7 shows the x-ray diffraction patterns of an inhomogeneous powder and a sprayed coating. In this example, the spray conditions did eliminate nearly all of the starting monoclinic phase. The following table gives the phase distribution for the two materials in Fig. 7, based on the areas under the diffraction peaks:

Material	**Phase, mol%**		
	Monoclinic	**Tetragonal**	**Cubic**
Starting powder	6	76	18

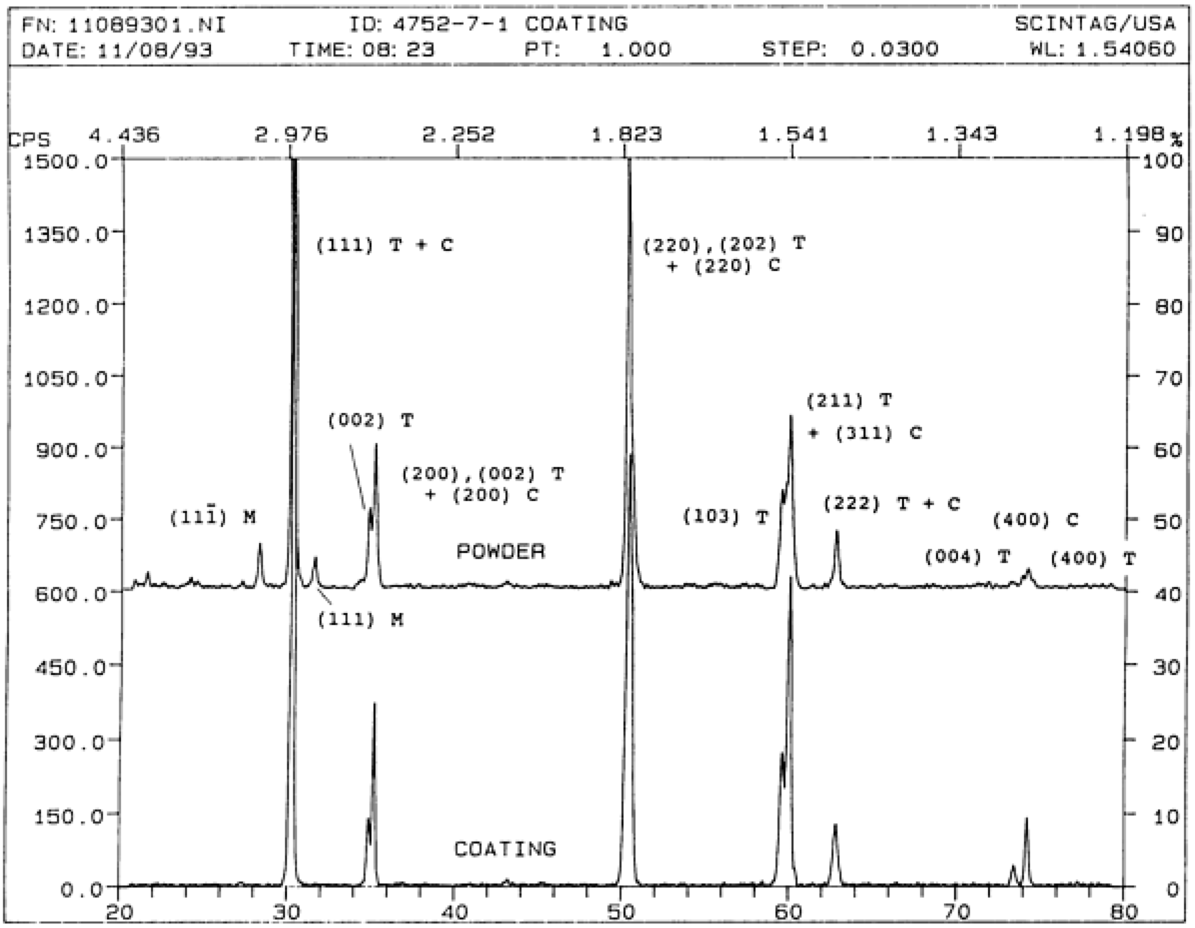

Fig. 7 X-ray diffraction patterns of yttria-stabilized zirconia powder showing some monoclinic phase, and of a coating made from that powder. M, monoclinic phase; C, cubic phase; T, tetragonal phase; T + C, overlapping tetragonal and cubic reflection

The values in the table were obtained with the Miller algorithm (Ref 6):

$$\frac{M}{T+C} = 0.82\frac{I_{(11\bar{1})M} + I_{(111)M}}{I_{(111)T+C}} \qquad \textbf{(Eq 1)}$$

$$\frac{C}{T} = 0.82\frac{I_{(400)C}}{I_{(400)T} + I_{(004)T}} \qquad \textbf{(Eq 2)}$$

$$M+T+C = 1.00 \qquad \textbf{(Eq 3)}$$

where M, T, and C denote the mole percentages of the monoclinic, tetragonal, and cubic phases, respectively, and $I_{(hkl)}$ is the integrated intensity for the (hkl) diffraction peak. For the high-angle (400) peaks, a deconvolution routine was used first to separate the three overlapping peaks.

Not all TBCs need to be made from homogeneous 6 to 9 wt% YSZ. The importance of the degree of homogeneity and the allowable amount of monoclinic phase in the starting powder depend on the maximum temperature to be experienced by the TBC. Consider the zirconia-yttria phase diagram in Fig. 6 in the following argument. Assume that a coating made from inhomogeneous 8% YSZ powder has some fraction of grains of very low yttria content. These grains will behave as if they were a separate entity and experience the phase transitions characteristic of nearly pure zirconia. At room temperature these grains should exist in the monoclinic structure. The other grains may be partially stabilized with yttria and exist mainly as the nontransformable tetragonal phase, and possibly some cubic-phase material. These higher-yttria-content nontransformable tetragonal grains exist as a nonequilibrium phase because of the rapid quench from the liquid

state upon deposition at the substrate. They have high thermal fatigue resistance because they will not transform to the monoclinic phase and experience the large volume change. On the other hand, the nearly pure zirconia grains having the monoclinic structure may be safe from transformation stresses as long as they remain below the temperature of the M + T two-phase field, which can be as high as about 1100 °C (2000 °F).

Therefore, coated components that have a maximum exposure of only 760 °C (1400 °F) should be stable against deleterious phase transformation, even though they may have a zirconia coating composed of both stabilized and unstabilized grains. As the operating temperature of the component increases, the need for a homogeneous coating increases. Applications at temperatures above about 1100 °C (2000 °F) should require fully homogeneous coatings. For applications at 760 to 1100 °C, thermal cycle testing is needed to determine whether the powder and coating process selected are adequate. If monoclinic-phase material exists in the coating and is tested with flame impingement on the oxide face to temperatures that cycle through the transformation temperature, the surface layer will begin to flake away small particles. Because of the insulating effect of zirconia, the lower layers of the coating would be at a lower temperature and thus remain intact. If the same nonhomogeneously stabilized coating is exposed to a uniform temperature test, the whole zirconia layer could develop cracks, leading to early spallation if the whole layer is cycled through the phase-transformation temperature.

Although the use of fully homogeneously stabilized coatings may seem warranted for all applications, regardless of operating temperature, economic considerations argue against this. Fully homogeneous powders, which are more costly, must either be fused and crushed or sintered from pure zirconia and yttria components at high temperatures. If the exposure temperature of the TBC does not demand monoclinic-phase-free material, a less costly powder will still meet the thermal barrier performance required. The key is to know the relation between operating temperature limits and the phase content of the coating.

Chemical Effects on Phase Stability. As discussed above, powders that are inhomogeneous in regard to yttria concentration could lead to coatings with phase-transformation-induced cracking if used at high temperatures. It has also been found that fully homogeneous yttria-stabilized coatings used in high-temperature environments containing vanadium and/or sulfur can experience surface degradation. In this case, the impurities can form yttrium vanadate and yttrium sulfide by leaching yttrium from the coating (Ref 5, 9). This leads to a surface layer that is progressively depleted in yttria content, and eventually to a material that is in the fully monoclinic structure when cooled and has a large volume change and disruptive stresses when thermally cycled. This surface transformation can also be detected by x-ray diffraction, which will give the evidence needed to understand the failure mechanism.

Thermal Property Measurements

Coefficient of Thermal Expansion. The coefficient of thermal expansion (CTE) of the TBC in the in-plane direction should match as closely as possible the CTE of the bond coat. The expansion in the through-thickness direction is not of

great interest, which is fortunate because this measurement is relatively difficult to perform. The in-plane expansion on a freestanding sample can be determined using a conventional pushrod dilatometer (ASTM C 228). In the case of a differential pushrod dilatometer, the differential expansion between the sample and a known standard reference material is measured as a function of temperature. The expansion of the sample is computed from this differential expansion and the expansion of the standard. The measurements are made under computer control, and linear expansion is calculated at preselected temperature intervals. The expansion can be monitored with the visual display during the measurement process. Seven standard reference materials for expansion are available from the National Institute of Standards (NIST, formerly the National Bureau of Standards), including materials with low, moderate, and large expansion. For purposes of calibration and checkout, one NIST standard is measured against another NIST standard.

Specific Heat. Measurements of the specific heat of TBCs can be easily performed using differential scanning calorimetry (ASTM E 1269). Reference and sample holders are equipped with heaters and temperature sensors that detect temperature fluctuations of the sample holder with respect to the reference holder as both are heated. A high-gain, closed-loop electronic system provides differential electrical power rate that can be read out directly in millicalories per second and that is equivalent to the rate of energy absorption or evolution of the sample. The specific heat is calculated by comparing this rate with the rate measured during the heating of a known mass of sapphire. The experiments are performed under computer control, and specific heat is automatically calculated at equal temperature intervals.

The procedure is to measure the differential power required to heat the empty pan at the same rate as the reference empty pan (blank amplitude). The data are collected and stored in the computer. The sapphire standard (whose mass and specific heat are known) is then placed in the empty pan, and the differential power required to heat this pan at the same rate as the reference empty pan is measured to obtain the standard amplitude. Next, the sample is substituted for the sapphire standard and the sample amplitude is determined. The computer then calculates the specific heat. The results for ZrO_2-8wt%Y_2O_3 coatings are very close to those predicted from the rule of mixtures, as calculated using values for the pure oxides (Ref 10).

Thermal Transport Properties. Thermal conductivity can be calculated from:

$$\lambda = q/A\,(dT/dx) \qquad \textbf{(Eq 4)}$$

where λ is the thermal conductivity, *q* is the heat flux, *A* is the cross-sectional area conducting the flux *q*, and *dT*/*dx* is the temperature gradient. Alternatively, conductivity can be determined from:

$$\lambda = \alpha C_p \rho \qquad \textbf{(Eq 5)}$$

where α is the thermal diffusivity, C_p is the specific heat, and ρ is the density. It should be noted that thermal conductivity cannot be measured directly. Equation 4 involves steady-state determinations, and Eq 5 involves transient determinations. Relatively large errors have been documented for steady-state determinations, even under good conditions (Ref 11). Because specific heat and density (expansion) measurements are straightforward, and because diffusivity measurements involve only length and time, transient techniques are more attractive, especially for the small samples associated with coatings in the through-thickness direction. In addition, the diffusivity technique is much faster and costs less.

A particularly useful diffusivity technique (Ref 12) is the laser flash method, ASTM E 1461-92. It is shown schematically in Fig. 8. The sample, normally the size of a nickel, is held at the desired measurement (e.g., room temperature, 100 °C, 200 °C, etc.). The front surface receives a pulse of energy from the laser, which soon raises the back face temperature a degree or two. The rear face temperature response is normalized and compared with the theoretical model based on Carslaw and Jaeger's solution to one-dimensional heat flow (Ref 13). Using that model, diffusivity values can be obtained at any percent rise of the curve. For example, at 50% rise, the diffusivity is calculated from:

$$\alpha = 0.1338\, l^2/t_{0.5} \qquad \textbf{(Eq 6)}$$

where *l* is the sample thickness and $t_{0.5}$ is the elapsed time needed for the rear-face temperature to reach one-half of its maximum rise (Fig. 8).

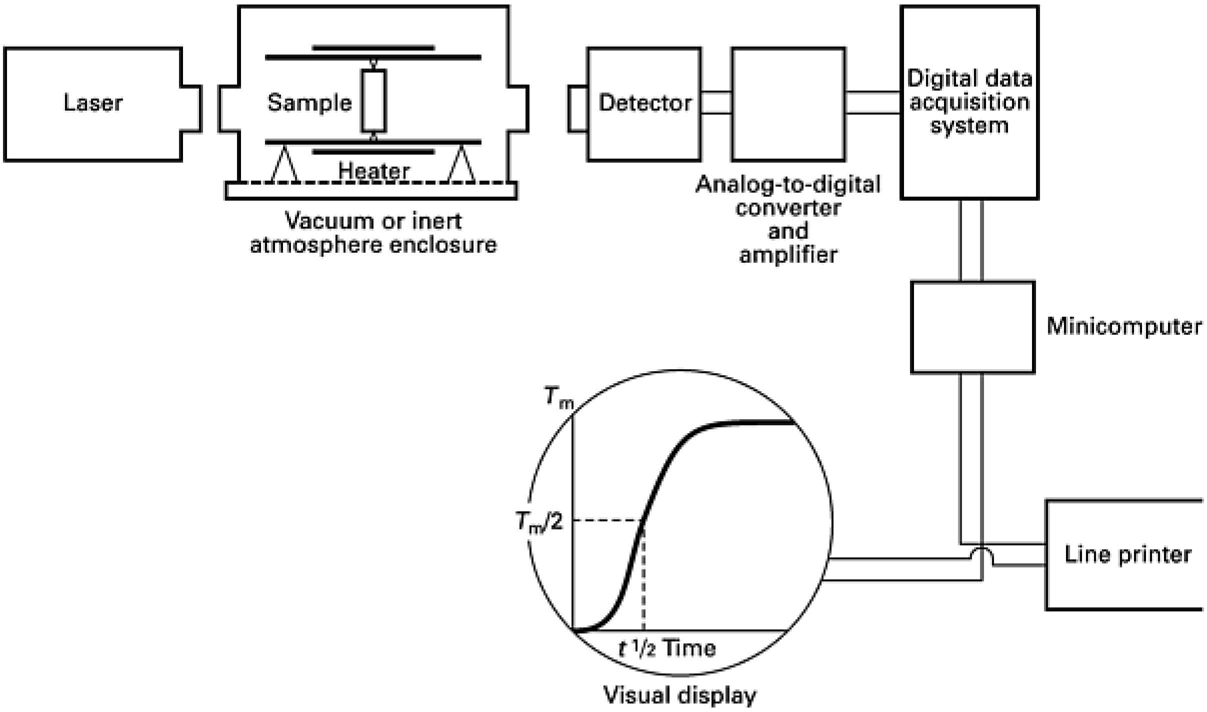

Fig. 8 Schematic diagram of laser-flash method for thermal diffusivity measurement. T_m**, maximum temperature measured by the liquid nitrogen-cooled infrared detector**

It is possible to measure freestanding coatings, but it is also possible to measure the coatings on the substrate. In the latter case, the effects of any interfacial resistance are included in the calculated diffusivity/conductivity of the coating. Because TBCs may be translucent, part of the laser beam could penetrate significantly into the sample, violating an assumed boundary condition. Thus, for freestanding coatings, it is necessary to put a very thin opaque layer on at least one surface. In the case of TBCs on substrates, this is not a problem because the substrate side faces the laser.

Thermal conductivity values in the literature have rarely been corrected for thermal expansion, because the expansion correction has been within the accuracies of steady-state determinations of conductivity. This general practice is usually followed when computing thermal conductivity from transient measurements: density and diffusivity values are not corrected for expansion. If one does correct density for expansion by dividing by $(L_0 + \Delta L)^3$, one must also correct the diffusivity values by multiplying by $(L_0 + \Delta L)^2$, where L_0 is the length at the reference (room) temperature and ΔL is the length change at any temperature from that at the reference temperature. Thus the total correction is a factor of $(L_0 + \Delta L)^{-1}$. For TBCs at operating temperature, this correction is less than 2%.

Thermal diffusivity and conductivity values may increase after thermal cycling (Ref 10, 14) or upon heat treatment to progressively higher temperatures (Fig. 9). These effects may be due to closing of horizontal microcracks. In addition, the conductivity/diffusivity of the TBCs can be thickness dependent due to the somewhat cone-shape structure. It should also be noted that the in-plane conductivity values of TBCs are different from the through-thickness values because of the lamellar nature of thermally sprayed coatings and the columnar structure of zirconia deposited by physical vapor deposition. In general, the in-plane values are relatively unimportant for TBC applications.

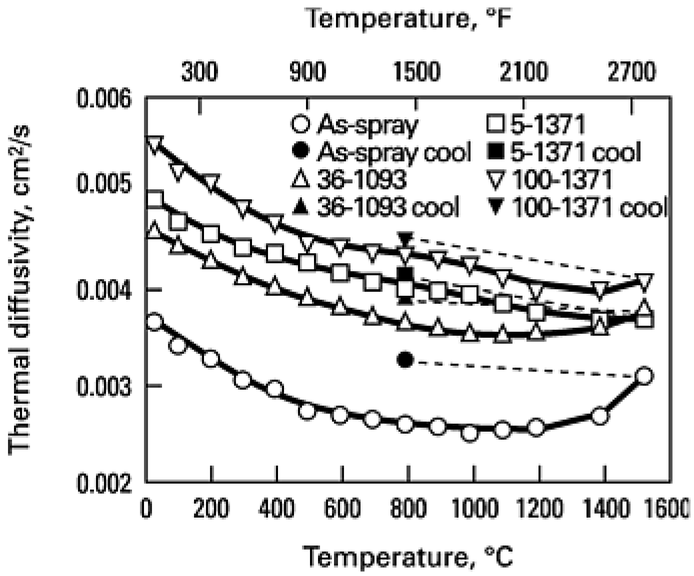

Fig. 9 Thermal diffusivity of plasma-sprayed ceramic coatings subjected to selected heat treatments

Microstructural Characterization of Coatings and Thin Films

S.J. Bull, AEA Technology

Introduction

BOTH METALLURGY AND MATERIALS SCIENCE are concerned with the relationship between structure and the macroscopic properties of materials. Structure can be important at different levels. For example, on the atomic scale, structure dictates the strength of grain boundaries. On a larger scale, extending over many grain diameters, structure influences more complex phenomena, such as contact at surfaces or optical properties. For coatings, structure-property relationships are further complicated by the fact that coating microstructures are generally highly anisotropic and contain concentrations of defects that can vary from grain to grain for some coatings (e.g., plasma-sprayed coatings). Clearly, the ability to characterize coating microstructures is important in understanding the properties and behavior of coatings in many applications.

This article describes the structure of coatings produced by plasma spraying, vapor deposition, and electrodeposition processes. It also introduces the main techniques that can be used for microstructure assessment. Although examples are given for a limited range of deposition technologies, they are widely applicable to coatings produced by other processes.

Microstructure of Coatings

The microstructure of a coating is critically dependent on the deposition technology used to produce it (Ref 1). In some technologies, such as physical vapor deposition (PVD), the structure of the coating can be controlled to a certain extent by the choice of deposition parameters. In other technologies, such as weld surfacing or diffusion treatment, it is the thermal history of the component surface that dictates microstructure. Good process control is needed to ensure the production of a layer with the correct microstructure and the required properties for the application. A number of microstructural factors are important in dictating the properties of the coating:

- Phase composition
- Size and shape of grains
- Size and distribution of porosity
- Defects (vacancies, dislocations, etc.)
- Presence of cracks and pin holes
- Anisotropy
- Stress and strain

In most cases, the first three factors are the most important. However, the others can be critically important for certain applications. Stresses and strains occur when the microstructural units of the coating (e.g., columnar grains in PVD coatings or splats in plasma-sprayed materials) are moved with respect to their equilibrium positions by externally applied forces, which can be due to mechanical or thermal loading or the mismatch of properties with the substrate. Stresses can lead to bending of the coating, distortion of the microstructural units, and generation of defects within microstructural units where they contact (e.g., dislocation loops are created by compressive stresses forcing columnar grains together in PVD films). Strains usually manifest themselves as changes to the lattice parameter of the material. There are two types: macrostrains (changes that affect the whole coating, produced by thermal expansion mismatch) and microstrains (highly localized distortions of the structure around defects). Described below is the evolution of microstructure in several important deposition technologies.

In the thermal spraying process, the powder form of a coating material is injected into a flame, where it melts and is ejected against the component surface to build up the coating. Thermal spraying is actually a generic term for a number of processes that all produce coatings with similar microstructures, ranging from flame spraying and high-velocity combustion processes to plasma spraying. The structure and properties of the coatings depend on the stability of the particles within the flame and the choice of process parameters. Ideally, the powder particles are completely melted, but not vaporized, in transit between the injection point and the substrate surface. The molten particles then strike the substrate surface, where they flatten and freeze. Succeeding particles acquire the same lenticular shape over material that has already been deposited, so that the coatings develop an anisotropic lamellar structure parallel to the interface (Fig. 1). The extent of flattening depends on factors such as degree of melting, viscosity of the liquid, and wetting of the surface. Coatings may contain voids that are due to outgassing, shrinkage, or topographical effects (e.g., shadowing). Metal coatings processed in air will also probably contain oxide inclusions.

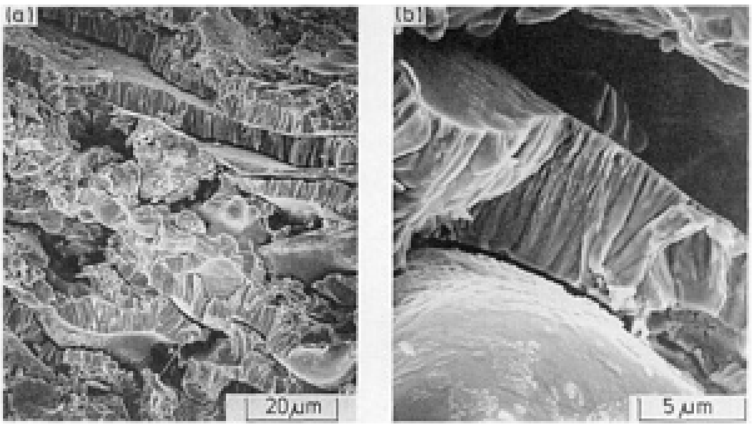

Fig. 1 Scanning electron micrographs of fracture cross sections of air plasma-sprayed tungsten coatings. (a)

Lamellar structure. (b) Presence of columnar structure within the splats

Cooling rates can be very high (as much as 10^6 K/s) for plasma-sprayed particles. This produces a very fine microstructure within the lenticular splats (Ref 2), as shown in Fig. 1(b). The rapid solidification can form amorphous deposits from some ferrous alloys (Ref 3), whereas metastable or nonstoichiometric phases can be observed in some ceramics. For instance, alumina coatings contain an increasing proportion of the λ phase as the energy of the spraying process increases or the particle size decreases (Ref 4).

Vapor Deposition Processes. The structure of coatings deposited from the vapor phase is controlled as much by the nucleation of the coatings as by the way in which they subsequently grow. One feature common to vapor-deposited coatings is that solid material is distributed in an array of fairly closely packed columns that run perpendicular to the substrate. It is this anisotropy in structure that controls many of the properties of the films.

A number of factors can influence the nucleation of vapor deposited coatings. The surface structure of the substrate is critically important, including grain size, defect density, texture, roughness, and surface composition, and it is often necessary to pretreat materials prior to coating to enhance nucleation. Surface contaminants introduced in the coating process can promote or inhibit nucleation, as can ion bombardment in PVD processes. In many cases a chemical or physical activation step is required to get the best surface structure for coating (e.g., a chemical etch is required to remove surface magnesium from aluminum alloys). This needs to be followed by careful control of the early stages of coating to ensure that reliable structures are produced.

Structure Zone Models. An essential feature of the structure of these thin films is that they are formed from a flux of atoms that approaches the substrate from a limited range of directions. This generates the columnar microstructure, but can lead to problems, because there are many boundaries running perpendicular to the interface that can act as planes of weakness (e.g., as short-circuit diffusion paths).

Movchan and Demchishin (Ref 5) were the first to classify thin-film microstructures. They identified three distinct structure zones as a function of the homologous temperature T/T_m, where T represents the substrate surface temperature and T_m represents the coating melting point. A low-temperature zone 1 structure (T/T_m < 0.25-0.3) corresponds to low adatom mobility and consists of tapered columns with domed tops. In a zone 2 structure (T/T_m = 0.3-0.5), surface diffusion becomes increasingly important, and the structure consists of straight columns with a smooth surface topography. With increasing temperature (T/T_m > 0.5), bulk diffusion becomes a dominant process. The zone 3 microstructure therefore consists of equiaxed grains, as are observed in recrystallized metals. For sputtered coatings, Thornton (Ref 6) later suggested that the presence of a sputtering gas could modify the model, and a further region was identified between zone 1 and zone 2. This region consists of poorly defined fibrous grains and is named zone T.

At the temperatures used in the chemical vapor deposition (CVD) process, surface diffusion of adatoms is actuated and structures of the zone 2 type are produced, in the case of most coating materials. However, the structure of the coating is often controlled by the nucleation density. In the early stages of coating, a very high density of small nuclei is established, which becomes constant after a time, that is, no new nuclei are formed, but newly deposited adatoms move to the existing nuclei and are trapped there. For longer deposition times, the nuclei grow until they eventually coalesce to form the film. In the case of some CVD coatings (e.g., diamond on silicon), the nuclei grow in both height and width, and the coalescence process may result in pores at the interface. Because porosity at the interface decreases adhesion, it is necessary to maximize the density of nuclei formed in order to obtain optimal adhesion. Porosity also remains at the triple points created as the nuclei grow together. These nuclei provide the seeds for the columnar units that compose the coating. Maximizing the nucleation density also reduces the size and extent of this through-thickness porosity.

Because the typical deposition temperatures in PVD processes is very low, many coatings are deposited with a zone 1 microstructure. Instead of increasing the deposition temperature, the occurrence of this microstructure can be overcome by bombarding the growing films with particles having sufficient energy so that the resulting momentum transfer will cause the coating atoms to fill the voided boundaries. Messier (Ref 7) has suggested a modification to the structure zone models that accounts for the evolution of morphology with increasing film thickness, as well as the effect of both thermal and bombardment-induced mobility. The model draws attention to the fact that ion bombardment promotes a dense structure of the zone T type, but it also indicates that the atomic rearrangement can have either thermal or ion-bombardment-induced origins.

Increasing the energy (or the flux) of ion bombardment, by applying a substrate bias, for example, has a significant effect on the structure of PVD films (Ref 8, 9). The coating on an unbiased substrate shows an open columnar structure (zone 1, Fig. 2a), whereas the film on a biased substrate appears more dense, because the individual columns are less well defined (zone T, Fig. 2b). The two coatings will have different properties that are due primarily to changes in the packing density of the columns.

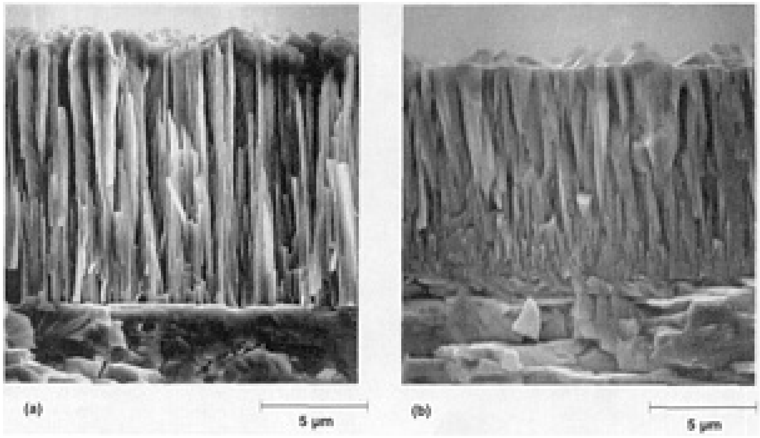

Fig. 2 Scanning electron micrographs of fracture cross sections of sputtered tungsten films on a tungsten substrate. (a) Unbiased (zone 1 structure). (b) -100V bias (zone T structure)

The deposition of predominantly covalent coatings, such as silicon carbide or diamond-like carbon, causes a further complication. Because of bonding directionality, it becomes very difficult to incorporate adatoms into their correct crystallographic location at low deposition temperatures. For this reason, amorphous coatings are produced with smooth, featureless, fracture cross sections. At a critical deposition temperature, some crystallization occurs, and structures of the zone T or zone 2 type can be produced. However, identifiable zone 1 structures are not usually observed.

Zone 1, zone T, and zone 2 microstructures are all associated with the development of texture in PVD films. For titanium nitride coatings, for example, a {111} orientation is commonly reported, although both {200} and {220} orientations have also been observed (Ref 10, 11, 12). The development of texture occurs in three stages:

- Nucleation, where crystallites are nucleated on the substrate from the vapor phase, the distribution and orientation of which depend on the substrate surface structure and deposition parameters
- Competitive growth, where certain favorably oriented nuclei will grow into the vapor phase faster than others, but which may not constitute the majority of the nuclei population
- Steady growth, which occurs once a preferred orientation has achieved dominance

The detailed deposition conditions in any PVD process can change any or all of the above stages and will also affect the morphology of the coating. At the interface region, a very fine grain size is established initially, but with increasing thickness, the columnar structure becomes established and the grain size increases. During the competitive growth phase, intercolumnar voids will open up because of shadowing processes. These voids will be increasingly closed up once the steady-state growth conditions are achieved. Clearly, if porous coatings are to be avoided, it is advisable to know in which thickness range these changes are taking place, as well as how to minimize their effects.

Electrodeposition was one of the earliest plating processes developed for depositing one metal onto another. The method is now widely used for both decorative and engineering purposes. The process involves the reduction of metallic ions at the surface of the substrate, which acts as the cathode of an electrolytic cell. The electrodeposit structure is controlled by the composition of the electrolyte, by the plating conditions, and, in particular, by the presence of growth-inhibiting substances and by the substrate itself (Ref 13). In solution, the metal ions (surrounded by their solvation sheath) migrate toward the deposit, where they lose their sheath and accept electrons to become atoms. The atoms are adsorbed onto the surface and migrate until they encounter a site where they can be incorporated into the existing structure. Impurities or bath additions (inhibitors) may block such sites and can thereby control the structure of the deposit. Under

growth-inhibiting conditions (i.e., when the current density is high and the bath temperature is low, so that atoms cannot readily diffuse), the deposit is finely grained and there is essentially continuous nucleation. Under other conditions, extended three-dimensional crystallite networks can grow.

The growth rate perpendicular to the surface is not the same for all grains, because the adsorption of inhibiting substances is anisotropic. As the deposit thickness increases, the slower-growing grains can become covered, and a texture will develop in the film. Slight misorientations between the grains lead to the need for misfit dislocations at boundaries. This is the reason for the high dislocation densities associated with coatings deposited under inhibited conditions. The microstructure of hard electrodeposits used for tribological applications (such as hard chromium) is equiaxed, and extremely finely grained, and it contains some oxide inclusions and microcracks, which give the coating some porosity (Fig. 3). Tensile residual stresses can be produced in the coating during plating and can lead to a network of larger cracks on the material. Similar structures are observed for autocatalytic coatings, such as electroless nickel, where phosphorus-containing reducing agents are present in the plating solution and get incorporated in the coating. Both electrolytic and autocatalytic coatings can be modified to incorporate fine particles (typically, 0.5-5 μm, or 20-200 μin. in size) into the growing film. They can be hard particles, such as silicon carbide, as well as solid lubricants, such as polytetrafluoroethylene. A nonuniform distribution of codeposited substances can lead to crevices or a banded structure (Ref 13).

Microstructure / Property Relationships

In the preceding section, it was shown that although the same coating materials can be deposited by a number of different processes, the tructure of the coatings produced will be very different. Whereas a very fine equiaxed grain structure is produced by electrodeposition, a columnar structure is produced by vapor-deposition processes (grain boundaries perpendicular to the interface), and a splat structure is produced by plasma spraying (splat boundaries parallel to the interface). Thus, it should be intuitive that the coatings will not have the same properties, and this is what is observed in practice. Considerable attention should be paid to the microstructure of the coating if performance is to be understood. There are numerous techniques that can provide relevant information.

Structure/property relationships have been determined empirically for many deposition processes for a restricted range of coating materials (e.g., Ref 13, 14). However, theoretical modeling of coating properties based on microstructure is not well advanced. A characterization of the structures and properties of commercially available coatings produced by different deposition technologies is often necessary to aid in coating selection and specification. Because some control of coating structure is possible for most deposition technologies, optimizing the microstructure of the coating for a given application is also a possibility. Structural characterization is a necessary step in achieving this rather ambitious goal.

Experimental Techniques for Microstructural Characterization

It is not possible to determine all the structural features of a material using any one analysis technique. Therefore, many techniques that can be used to provide information about specific microstructural features have been developed. It is important to know what factors are important in any application before undertaking a program of structural analysis.

For coatings, many of the techniques are applicable, but somewhat more care must be taken in preparing representative samples, because the volume of material to be investigated is relatively small. Table 1 identifies the most important microstructural features and defines what techniques can be used to assess them. However, other, more unusual techniques can also provide the same information.

Table 1 Techniques for microstructural analysis

Coating property	Technique
Phase composition	X-ray or electron diffraction
Phase distribution	Metallographic sections, SEM, TEM, optical microscopy
Grain size	X-ray diffraction, SEM, TEM (plus image analysis)
Grain shape	SEM, TEM (plus image analysis)
Preferred orientation	X-ray diffraction, TEM
Surface morphology	SEM

Porosity	TEM, mercury intrusion porosimetry, metallographic section (plus image analysis)

Note: SEM, scanning electron microscopy; TEM, transmission electron microscopy

Brief descriptions of some of the most frequently used techniques are described below, as are some of the factors that need to be considered when applying them to coated systems.

Metallography. Most standard metallographic preparation techniques can be applied to coatings, and polished cross sections are commonly used to determine coating thickness and uniformity. Samples are generally cut from a coated component using a low-deformation saw and are mounted in a resin medium prior to polishing. Components should be rigidly clamped and sectioned so that the abrasive wheel enters from the coating side. For most coating-substrate combinations, a hot mounting medium is preferred, but for temperature-sensitive or porous coatings, better results are obtained when a cold-setting resin is used. The section should then be ground back until a flat surface is produced. When dealing with coated samples, it is often observed that some chipping of the coating occurs next to the saw cut. It is therefore essential to grind the section well back to remove any damage prior to polishing. For thin, hard coatings, a large grit size should be avoided during grinding, because it can result in coating detachment (Ref 15). The preferred direction of grinding is from the substrate into the coating because this maintains the best edge sharpness.

After grinding, the section can be prepared using metallographic polishing techniques similar to those used for bulk materials. However, for porous plasma-sprayed coatings, better results can be achieved using more advanced metallographic techniques, as described in Ref 16. The twofold aim of the polishing process is to remove the damage introduced during grinding and to produce the high surface finish needed for metallography. For thin coatings, it is particularly important to use an edge-retaining mount, because edge rounding of the sample can occur during polishing in cases of differential polishing of the coating and the substrate or of sample tilting. For very thin or fragile coatings, the sample can be encapsulated with a thick protective layer prior to sectioning and mounting in order to prevent damage of the coating during preparation. Porous coatings, such as air plasma-sprayed coatings, are best mounted by vacuum infiltration, because the resin can then penetrate the porosity in the coating and will prevent collapse of the coating around the porosity during polishing (Ref 16).

For measuring the thickness and uniformity of the coating, a simple polished cross section may be sufficient. However, particular care must be taken to ensure that the coating has not been damaged during preparation. The importance of grinding back from the cut surface cannot be emphasized enough. Similarly, the porosity revealed in the coating may be an artifact of the preparation process, because grain pullout often occurs in the final stages of polishing materials that have weak boundaries, such as air plasma-sprayed metals. Although there is no simple technique for avoiding these problems, the measurement of thickness or porosity by other techniques can give some indication of whether the measurements obtained from metallography are consistent. A material-specific preparation technique can then be developed for the coating material and process combination of interest.

When dealing with very thin coatings, more detail can be revealed by using a taper section. A taper angle of 5.7°, for example, will give a 10× magnification in the plane of the section. In this case, the sample is mounted in the resin with one edge supported by a spacer, the height of which is chosen to give the required tilt angle, and then prepared in the same way as a cross section (Ref 15). Figure 4 shows a taper section of a PVD titanium nitride coating on stainless steel with a 400 nm (16 μin.) titanium interlayer that is not visible in the polished cross section, but which can be easily resolved in the taper section. Because of nonuniform polishing, the initially planar interface has become irregular in the taper section. This is almost impossible to avoid in practice.

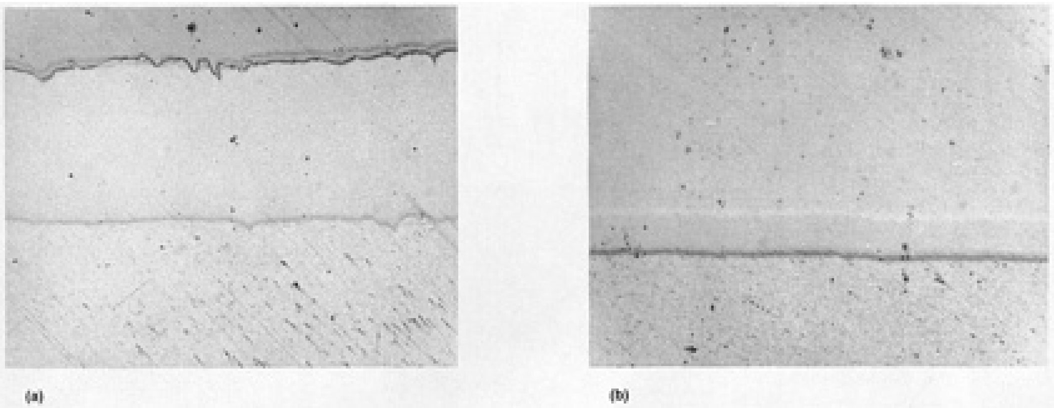

Fig. 4 Micrographs of a PVD titanium nitride coating on stainless steel. (a) Cross section. (b) Taper section showing the presence of a 400 nm (16 μin.) titanium interlayer

The grain structure of the substrate and coating and, sometimes, even the presence of the coating itself can be revealed by etching with an appropriate reagent, as is done for bulk materials. Because it is often difficult to choose an etch that will attack both coating and substrate, a multistage etching process may be needed. It is important to determine whether an etch used for the coating will badly attack the substrate, because that could lead to the observation that there is interfacial porosity, when this is really just an artifact of etch selection. Figure 5 shows the structure of a PVD Fe-Cr-Al-Y coating on stainless steel after 100 h of oxidation at 1000 °C (1830 °F). The structures of both coating and substrate have been revealed by electrolytic etching in CrO_3/H_2O. Image analysis can be used to determine grain size and shape, along with porosity, in a quantitative manner (Ref 16).

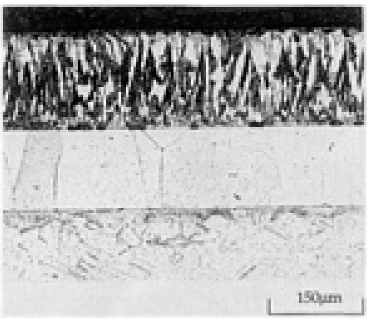

Fig. 5 Polished cross section of a Fe-Cr-Al-Y coating on austenitic stainless steel after 100 h at 1000 °C (1830 °F), electrolytically etched in CrO_3/H_2O to reveal grain structure of coating and substrate

X-ray Diffraction. In most cases, diffraction analysis is used to identify the structure of a deposited film from a list of known possibilities, rather than to identify the structure of a completely unknown or new substance. The analysis is thus essentially limited to the comparison of an experimentally observed diffraction pattern with patterns of substances, the structures of which are already known. This is made considerably easier if the composition of the coating can be determined, because the number of possible structures is then limited. In a typical x-ray diffraction experiment, a monochromatic beam of x-rays, wavelength λ, hits the coated surface from which it is diffracted. The intensity of the diffracted beam is recorded as a function of the diffraction angle, θ. The intensity of the beam will be nonzero only at those diffraction angles at which the Bragg condition is satisfied (Ref 17):

$$\lambda = 2d_{hkl}\sin\theta \quad \textbf{(Eq 1)}$$

where d_{hkl} is the spacing of the lattice planes with Miller indices *hkl*. All elements or compounds consist of atomic arrays with a unique combination of geometry and spacing. The smallest repeatable unit that completely defines the structure is

called the unit cell, and the spacing of these unit cells is defined by one or more lattice parameters (depending on crystal structure). The position of the diffraction maxima gives information about the size and shape of the unit cell, whereas the width of the maxima can be used to evaluate the size, orientation, and strain in grains of polycrystalline materials.

The intensity of the diffracted beam depends on several factors:

- Structure of the material
- Volume of irradiated material
- Diffraction geometry
- Sample alignment

For a more detailed discussion of the x-ray diffraction technique, readers are referred to Ref 17.

Once an experimental diffraction pattern has been obtained, the position and intensities of the peaks can be easily measured. It is then possible to calculate the intensities and positions for all candidate structures and compare these to the measurements to determine the structure of the film. However, a much easier way is to rely on powder diffraction standards (Ref 18), which represent a collection of experimentally determined relative intensity values for a large number of substances. These are available in book, microfilm, or card form, and can also be retrieved from disks or data bases. A typical card, for example, contains information on the structure of the material as well as the relative density data (Fig. 6). Information is available for both stoichiometric and nonstoichiometric compounds.

Fig. 6 Powder diffraction standard card for stoichiometric titanium nitride

The data on peak positions for titanium nitride (from Fig. 6) are represented as vertical lines in Fig. 7, which also shows an experimental diffraction pattern obtained for a titanium nitride film produced by sputter ion plating. It is clear that the observed peaks line up with the standard peak positions, but the measured pattern is slightly shifted to higher angles because of the presence of residual stress within the coating. The intensities, however, differ considerably from the values of the card shown in Fig. 6 because of the preferred orientation of the film. To fully assess the preferred orientation, it is necessary to compare the intensity of the measured line with that of the standard. A texture coefficient, T^*, can be defined as:

$$T^*(h'k'l') = \frac{I_{h'i'l'} / I^0_{h'k'l'}}{l/n \sum_0^n (I_{hkl} / I^0_{hkl}} \qquad \textbf{(Eq 2)}$$

In this equation, h' k' l' are the Miller indices of the plane of interest, I is the measured intensity, and I^0 is the intensity of the standard, which is randomly oriented. A value of unity corresponds to a random texture, and values greater than this show an increasing level of preferred orientation. For the data presented in Fig. 7, a {111} preferred orientation is observed, because $T^*_{\{111\}} = 4$.

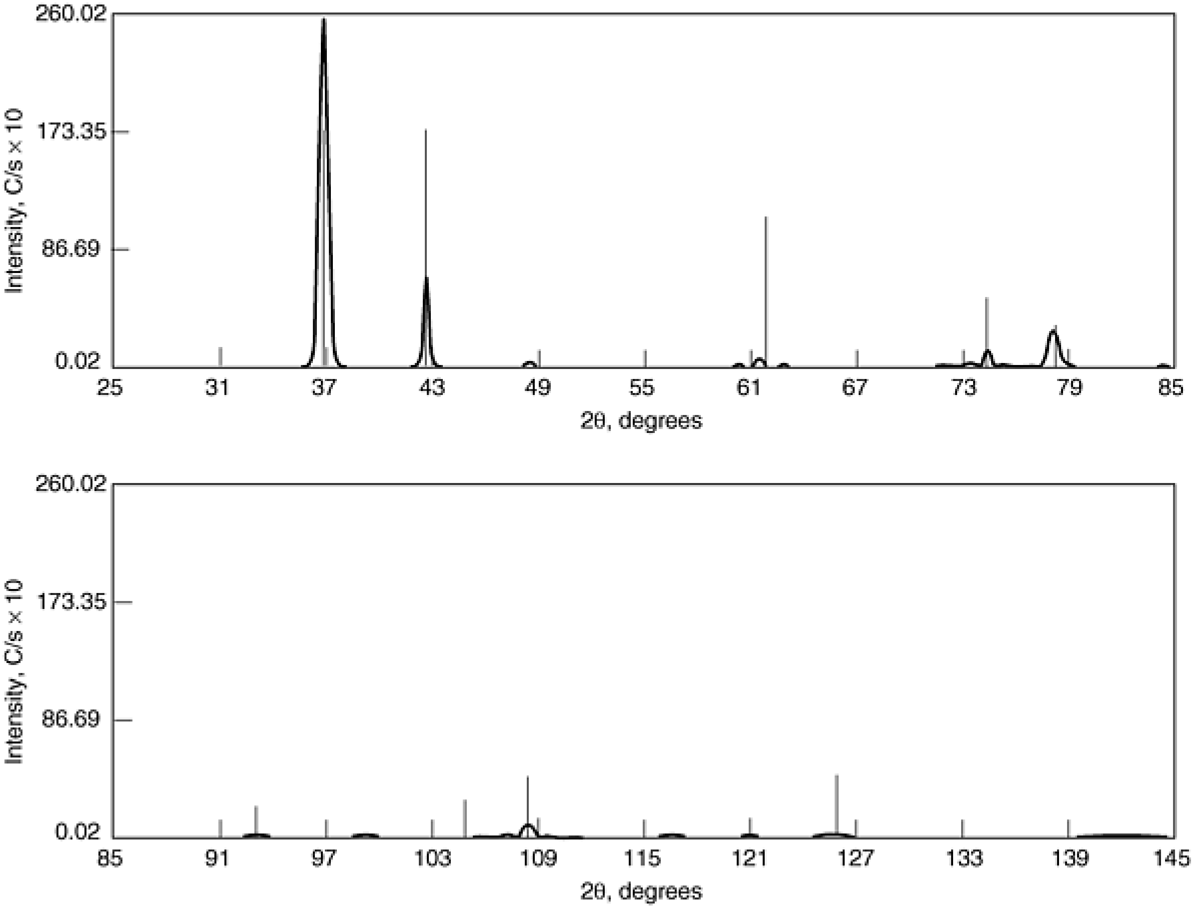

Fig. 7 Measured x-ray diffraction pattern for sputter ion plated titanium nitride. Vertical lines represent data peak positions for titanium nitride from Fig. 6. Film shows a [111] preferred orientation. C/s, counts per second

Once the phase composition of the coating has been identified, lattice parameter measurements can be undertaken. This is particularly important if measurements of residual stress are to be made or if there is a need to assess either the stoichiometry of a material or the composition of a solid solution. Because the accuracy of measurement increases as the Bragg angle increases, high angle reflections of sufficient intensity should be used for stress measurements. For the accurate measurement of peak position, it is necessary to fit a function to the peak profile (Ref 19). It is often assumed that a Gaussian profile provides a good description of peak shape, but, in many cases, a Pearson 7 function will provide a better fit. If the film is under stress, then measurements of the lattice parameter from a single reflection can be misleading, because of anisotropy constants. It is therefore important to use an extrapolation function, such as the Nelson-Riley or cosθ cotθ function, to improve reliability (Fig. 8). In this operation, the lattice parameter determined for a number of reflections is plotted against cosθcotθ, and a line through the points is extrapolated to θ= 0° to determine a_0. The deviations of some reflections from the line that are due to pseudo macrostresses can be revealed by this approach (Ref 19), which has the added advantage of minimizing alignment errors.

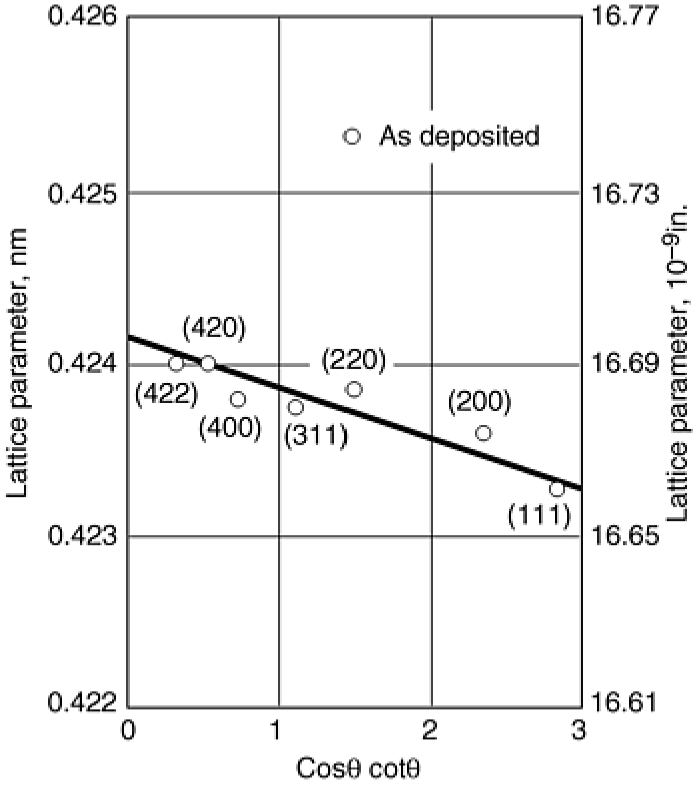

Fig. 8 Variation of lattice parameter with cosθcotθ for sputtered titanium nitride in order to extrapolate a lattice parameter, a_0, corrected for measurement errors

The width of a diffraction line is determined by the grain size and strain in a material, as well as by instrumental factors. A typical diffractometer will have an angular resolution of approximately 0.01°, which means that line broadening can be observed if the grain size *D* is lower than approximately 1 μm (40 μin.). This is easily achievable by various coating techniques, and x-ray diffraction can be used to give a measure of grain size for these technologies, averaged over the penetration depth of the x-ray (Ref 20).

If βis the full width at half-maximum intensity of the diffraction peak (for the case of a Cauchy peak shape, α_2 stripped and corrected for instrumental broadening), then (Ref 19):

$$\frac{\beta \cos\theta}{\lambda} = \frac{1}{D} + \frac{4\varepsilon \sin\theta}{\lambda} \quad \textbf{(Eq 3)}$$

where ε is the average strain in the material. Thus, by plotting βcosθ/λ against sinθ/λ, which is the so-called Hall-Williamson plot (Ref 21), it is possible to determine both *D* and ε. Figure 9 compares the Hall-Williamson plots for titanium nitride coatings produced by several deposition technologies. The broadening is dominated by strain, because the intercept is close to zero, implying a grain size greater than 1 μm (40 μin.).

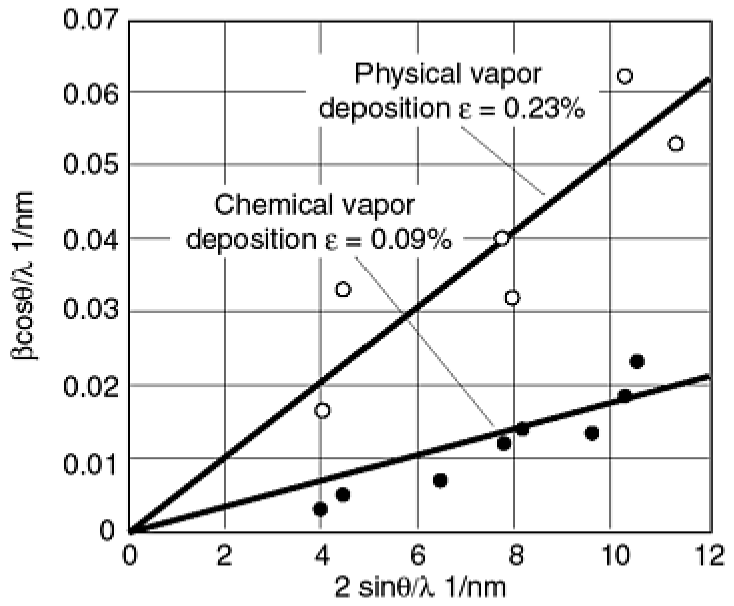

Fig. 9 Hall-Williamson plots for physical and chemical vapor deposited titanium nitride, showing increased strain in the physical vapor deposited films

Electron Microscopies. Perhaps the most useful techniques for characterizing thin films are scanning electron microscopy and transmission electron microscopy, because they can be used to investigate morphology, crystal structure, grain structure, and porosity. Both techniques depend on good sample preparation. Samples are relatively easy to produce for the former technique, but they are time-consuming and often difficult to prepare for the latter technique.

Scanning Electron Microscope (SEM). Numerous signals are available for SEM imaging (Ref 22). When coupled with energy-dispersive x-ray spectroscopy (EDS), the SEM can be used to obtain a wide range of information about surface topography, composition, crystallography, and electronic properties (Table 2). For example, the SEM can be used to assess the grain size, packing density, and porosity of a coating if a fracture cross section is imaged. The chamber of many SEMs is large enough that many components can be imaged nondestructively, and the surface topography induced by surface treatment, together with damage to the coating (after deposition or after service) can be determined.

Table 2 Scanning electron microscope imaging modes

Mode	Detected emission	Best resolution	Information available
Emission	Secondary electrons	5-15 nm (0.2-0.6 μin.)	Topographic
Reflection	Primary electrons (back scattered)	50-250 nm (2-10 μin.)	Topographic, atomic number
Leakage	Specimen current	>1 μm (>40 μin.)	Topographic, defects in some materials
X-ray	X-ray fluorescence	>1 μm (>40 μin.)	Chemical analysis (*Z* >5)
Cathodoluminescence	Luminescence	>1 μm (>40 μin.)	For some materials, quantitative chemical analysis or defect imaging

Crystallographic	Electron channeling	0.05° from 1 μm (40 μin.)	Lattice parameter selected area and defect density

In a typical SEM, an electron beam from a tip or filament is accelerated by the anode (typically, by 5 to 30 kV) and focused by two magnetic lenses to a fine spot on the sample. At the same time, the beam is scanned in the *x* and *y* direction. The electrons that are emitted from the sample are then either collected by a back-scattered electron detector, or, more generally, by a detector for secondary electrons. After amplification, the signal is fed to a cathode-ray tube, which is deflected in the same manner as the microscope electron beam. The magnification of the image is fixed by the *x*-*y* deflection coils.

The primary electron beam generates a tear-drop-shape interaction volume with the specimen. Elastically reflected electrons emerge from the surface with energies close to those of the primary beam. The proportion of back-scattered electrons depends on the material. As the atomic number of the element increases, the back-scattering coefficient increases and such atomic number contrast can be used to distinguish between phases in coatings and substrates. However, back-scattered electron emission is highly directional, and strong topographic contrast is visible for rough surfaces, depending on the position of the detector.

Secondary electrons leave from the near-surface region of the sample when energies are less than approximately 50 eV and show no such directional effect, because they are collected by a positively biased detector from all points on the sample. Their emission intensity is not strongly materials dependent. The secondary electron image clearly shows topographic features, such as cracks in electroplated coatings (Fig. 3). However, it should be realized that these images should not be interpreted like reflected light micrographs, because shadows are not generally caused by topography effects.

The primary electron beam can excite core electrons in the sample, which relax by the emission of an x-ray, as is characteristic of the excited atom. Such x-rays typically escape from 0.5 μm or greater depths. X-ray analysis can be achieved by energy-dispersive or wavelength-dispersive spectroscopies (EDS or WDS, respectively). The EDS system generally uses a lithium-doped silicon detector in conjunction with a beryllium window for analysis of elements with atomic number, Z, greater than 9 (i.e., neon and heavier atoms), although the range can be reduced to $Z = 5$ (boron) with a windowless detector. The WDS method uses a range of crystals with different lattice parameters that can be rotated to focus x-rays from elements where $Z > 6$ into a detector. The EDS system is faster than WDS but has poorer energy resolution. Both EDS and WDS can be quantitative methods of evaluating elemental composition if care is taken in correcting for instrumental, chemical, and physical factors. This is a standard feature in most commercial analysis systems.

Fracture sections provide a very good means for assessing the structure of thin PVD coatings. Figure 2 shows fracture sections through PVD tungsten coatings deposited under unbiased conditions (zone 1), with an applied bias voltage of -150 V (zone T). The columnar structure is clearly visible for both coatings, but the columnar packing density increases with applied substrate bias (i.e., energy of ion bombardment). Because each column consists of an array of grains, a true measure of grain size is not generally possible using the SEM, but an indication of relative grain size may be possible from the column dimensions. The coatings are deposited onto a ferritic steel substrate that was cut through from the back side with a saw until it reached approximately 1 mm (0.04 in.) below the coating. The sample was then immersed in liquid nitrogen to cool below the substrate ductile-brittle transition temperature. After 10 min, the sample was removed and half placed in a vise. Then, the free end was struck with a hammer to fracture the sample in two. The coated side was struck so that the section was not put into compression during fracture, in order to avoid excessive coating damage. The cracks started in the saw cut and ran through the coating without damaging it. Similar results can be achieved for coatings on brittle substrates, such as silicon wafers, by using a diamond scribe to initiate fracture on the back of the substrate.

Insulating substrates or coatings will become charged in the electron beam, which quickly reduces image quality and occasionally damages the material. Charging can be avoided by depositing a thin carbon or gold film on the specimen surface. However, this will reduce the accuracy of any subsequent microanalysis and should only be used if necessary. Alternatively, a low accelerating voltage can be used for the primary beam, because when voltages are less than 3 kV, the sum of the secondary and back-scattered electrons generated can equal the number of primary electrons, and no charging occurs. Such low-voltage SEMs have the added advantage of better resolution, but their poorer signal-to-noise ratio means that some image processing may be necessary to obtain the best results.

Relatively poor resolution can also be encountered with magnetic coatings or substrates. For high-resolution work, it is recommended that a nonmagnetic substrate, such as silicon or stainless steel, be used wherever possible.

Transmission electron microscope (TEM) studies require very thin specimens (5-500 nm, or 0.2-20 μin.), depending on the material. These specimens of foil must be prepared from the bulk of the coating or substrate. With such foils, it is possible to visualize structures on the nanometer level, and when specialized techniques are used, it is even possible to see the presence of single-atom columns and to locate dislocations in the crystal (Ref 23). Grain boundaries and interfaces can also be studied using this technique. When the crystallites range in size from micrometers to nanometers, the TEM can be used for electron diffraction studies to identify phase composition, as well (Ref 24).

The preparation of TEM samples is a skilled operation, and considerable effect is often required to develop the technique for a specific coating-substrate system. Plan-view TEM samples are by far the easiest to produce and consist of sections of the coating parallel to the interface (Fig. 10). In general, plan-view sample preparation takes place in two stages. The first is mechanical thinning, in which a parallel slice of material is cut from the coating and machined to a 3 mm (0.12 in.) disk using a punch or ultrasonic drill. The disk is then polished to approximately 0.1 to 0.2 mm (0.04 to 0.08 in.) in thickness. Finally, the center of the disk is further reduced in thickness by dimpling, that is, grinding with a spherical abrasive tool, which leaves a depression in the center that can be 20 μm (800 μin.) thick.

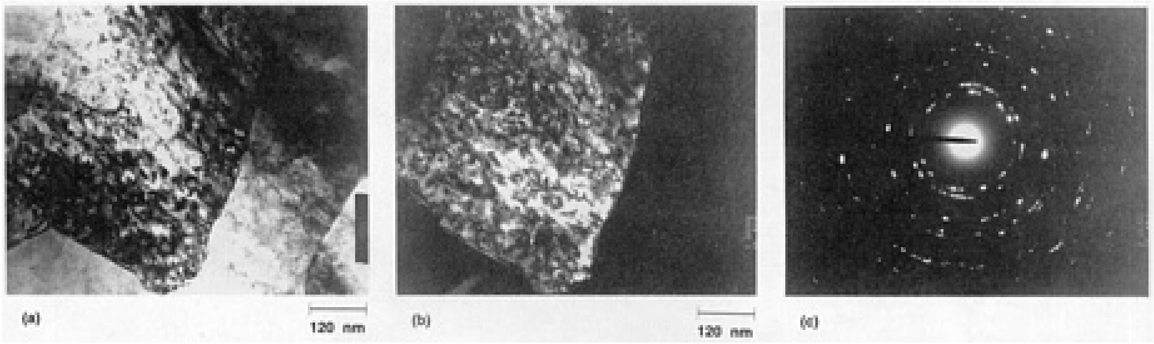

Fig. 10 Plan-view transmission electron microscope images of sputtered titanium nitride coatings. (a) Bright-field image. (b) Dark-field image obtained by putting an aperture over two bright {200} diffraction spots. (c) Corresponding diffraction pattern

The second stage involves final thinning to perforation, which occurs by either electropolishing, using a fine jet of etchant, or ion beam milling, using an argon ion beam of approximately 3 kV, which is directed at the surface at a low angle (5-20°). For metals and semiconductors, the electropolishing route is preferred, whereas for ceramic materials, ion beam milling is usually necessary. Depending on whether the area of interest in the coating is near the substrate interface or further out in the film, thinning of the sample will occur on the film side or the substrate side, respectively, before final perforation is achieved by thinning from both sides. Using this approach, a section can be produced from any level within the coating, but it is difficult to ascertain how far from the interface any plan-view sample lies.

Another method used to produce foils is to deposit a sufficiently thin coating onto a soluble substrate, such as aluminum (soluble in sodium hydroxide) or sodium chloride (soluble in water). After dissolution of the substrate, the film is transferred to a copper grid for imaging. However, in some cases, the film will collapse when the substrate is removed, leaving a fine powder, which can be captured on a copper grid in order to study individual grains (or columns, for PVD coatings) in more detail, but which gives no information about columnar packing.

More information can be obtained from cross-sectional TEM samples, which are considerably more difficult to produce. Usually, the sample is cut in two and joined, coating side to coating side, with a good epoxy adhesive. The assembly is then cut into thin slices and prepared in a similar manner to plan-view samples. However, the differential thinning rates of coating, substrate, and adhesive mean that it is often difficult to prevent the sample from collapsing during thinning. A number of workers have used this technique to study the interfacial regions of hard coatings in some detail (Ref 25, 26).

A TEM consists of an electron gun (typically, 100 to 400 kV for analytical configurations) and an assembly of lenses, all enclosed in a column evacuated to about 1.3 × 10^{-3} Pa (10^{-5} torr). The optical arrangement is similar to that of a light

microscope, but additional stages of magnification are used. Condenser lenses collimate the electron beam, which passes through the specimen, and an objective lens is then used to form a first image in the object plane of the first projector lens. This image is magnified about 40 times. A small area from this image is then projected as an intermediate image, magnified about 40 times by the first projector lens. A small area of this image is then projected onto a fluorescent screen or photographic plate by another projector lens. The image is formed from the intensity distribution of the electrons leaving the bottom surface of the specimen. A total magnification ranging from 10,000 to 1,000,000 is achievable.

In addition to imaging, the TEM can be used for diffraction patterns. The diffraction pattern is formed at the back focal plane of the objective lens, and can be imaged by adjusting the projector lens excitation, which is an automatic function for most modern TEMs. The resolution of the TEM increases with electron-beam energy, and is approximately 0.19 nm (0.008 μin.) at 400 kV.

Contrast in the images is generated in two different ways. For amplitude-contrast imaging, an aperture is used to select either the primary transmitted electron beam (bright field) or one of the diffracted beams (dark field). The aperture is placed in the back focal plane of the objective lens, and the beam is focused to form an image with a further lens. Dark-field imaging is particularly useful when several phases are present. The formation of a dark-field image using a diffracted beam from one of the several phases present highlights the locations in the sample where that phase can be found. Microcracks, grain boundaries, stacking faults, and other defects can also be identified using dark-field imaging techniques (Ref 27).

For phase-contrast imaging, the primary and diffracted beams are allowed to interfere with one another. Local phase shifts of the electron waves are created by voids, defects, heavier atoms, and other phenomena. Phase contrast is the principle underlying lattice imaging (Ref 23). In addition, phase-contrast imaging under defocus conditions is used to identify voids or density variations (Ref 14, 28).

The combination of selected-area diffraction with imaging makes the TEM a very powerful tool. Phase identification and morphological characteristics can be achieved on the same areas of a sample. State-of-the-art analytical TEMs can focus the beam to a spot that is only several nanometers in diameter. The use of an x-ray detector on the column allows the analysis of chemical composition with nanometer-range spatial resolution. However, it should be realized that only a very small volume of material is sampled, because of the high magnifications used and the thin samples needed for imaging. Many microstructural variations occur on a larger scale. Therefore, x-ray diffraction is a more appropriate analytical technique for the study of large-scale structural features such as these, because it samples larger volumes of the sample.

Porosimetry. Porosity can be measured by the mercury intrusion porosimetry (MIP) technique, tests that use corrosive gases to decorate defects, density bottle methods, or optical or electron micrographs. These methods measure different types of porosity, namely open porosity for MIP and gas methods, closed porosity for the density bottle methods and total porosity (including sample preparation artifacts) for the microscopy measurements. No technique is particularly suitable when the porosity levels are low or the pores very small. In these cases, only electron micrographs can be used, and these sample a rather small volume of material.

MIP is very suitable for measuring the intersplat porosity for plasma-sprayed coatings. The determination of pore size distribution by MIP is based on the physical principle that mercury will not penetrate fine pores until sufficient pressure is applied to force its entry. The relationship between the applied pressure, *P*, and the pore radius into which mercury will intrude, *r*, is:

$$Pr = -2\gamma\cos\theta \qquad \textbf{(Eq 4)}$$

where γ is the surface tension of mercury and θ is the contact angle between mercury and the pore wall. Varying the externally applied pressure results in changes in the intruded volume that can be related to pore-size distribution. The method assumes an ideal model in which the specimen pore structure is represented by a labyrinth of interconnected cylindrical pores of sequentially diminishing size. Most natural materials diverge from this. Completely closed pores will not be assessed, and pores accessed through a narrow neck will have their size underestimated. However, as a method of quality-control testing or to compare materials produced by different processes, this is a valuable technique. It cannot be used for materials with which mercury forms an amalgam.

The visibility of porosity can be enhanced by filling pores with a colored mount or metal. For instance, if a plasma-sprayed alumina coating is deposited onto a metal substrate, then copper can be electroplated into the pores, which will

make them extremely easy to identify in polished cross sections. This minimizes the effects of grain pullout on the accuracy of porosity measurements.

Property/Technique Synopsis

As already noted, any single technique cannot provide all the information needed to completely categorize a coating material. For phase identification, x-ray diffraction is the primary technique used, although electron diffraction can also be used. The volume of material sampled by the x-ray technique is much larger, and a more representative picture of the complete coating phase composition is produced. However, very thin coatings or phases with very small volume fractions may be difficult to detect with x-rays, in which case electron diffraction would be preferred.

Coating thickness and surface morphology can be determined from fracture or polished cross sections using either light or scanning electron microscopy. Some estimates of grain size or porosity can also be made in these cases, if an appropriate sample preparation method is used. Etching may be necessary before polished cross sections can reveal grain or phase boundaries. For coatings that are less than 10 μm (400 μin.), scanning electron microscopy is necessary to determine the structure in cross section. For films that are considerably less than 1 μm (40 μin.) in thickness, only transmission electron microscopy is capable of giving cross-sectional images that can be used to determine grain size, phase distribution, or porosity. This is particularly true when interfacial structures are to be examined.

The importance of good specimen preparation for all structural analysis techniques cannot be overemphasized. In many cases, apparently featureless fracture or polished cross sections have been taken to indicate amorphous or single-phase coating. Subsequent etching or diffraction analysis has shown the presence of grain or phase boundaries.

It is also important to correlate the structure of coatings with their composition, which can vary through the coating thickness. The article "Surface and Interface Analysis of Coatings and Thin Films" in this Section of the Volume provides information on coating analysis.

Surface and Interface Analysis of Coatings and Thin Films

S. Hofmann, Max-Planck-Institut für Metallforschung, Institut für Werkstoffwissenschaft, Stuttgart, Germany

Introduction

SURFACE AND INTERFACE ANALYSIS TECHNIQUES have been among the paramount characterization methods since the beginning of modern, scientifically based thin film and coatings technology in the seventies, and their use very often has led to substantial progress in new fabrication techniques and devices (Ref 1, 2). This is obvious because the structure and composition of surfaces and interfaces is decisive for many properties of thin films, such as chemical reactivity, friction and wear, film adhesion, and electronic and diffusional properties. Of course, any of the large variety of physical characterization methods is more or less surface sensitive, but this article refers mainly to the "classical" methods of surface chemical analysis, namely electron spectroscopies (Ref 3) and ion spectroscopies (Ref 4), of which the most important techniques are Auger electron spectroscopy (AES), x-ray photoelectron spectroscopy (XPS or ESCA, electron spectroscopy for chemical analysis), and secondary ion (and neutral) mass spectroscopy (SIMS and SNMS) (Ref 5, 6). Glow discharge optical emission spectroscopy (GDOES) or glow discharge mass spectroscopy (GDMS), ion scattering spectroscopy (ISS), and Rutherford backscattering spectroscopy (RBS) are becoming of increasing importance, as is total reflection x-ray fluorescence spectroscopy (TRXF) (Ref 7) in special applications. All these techniques were emerging in the late 1960s and early 1970s (Ref 5) and have been developed since then into often sophisticated instruments for local microanalysis down to the nanometer scale (Ref 3, 4, 6). A survey of the most important surface analysis techniques and their relative frequency of application is shown in Fig. 1.

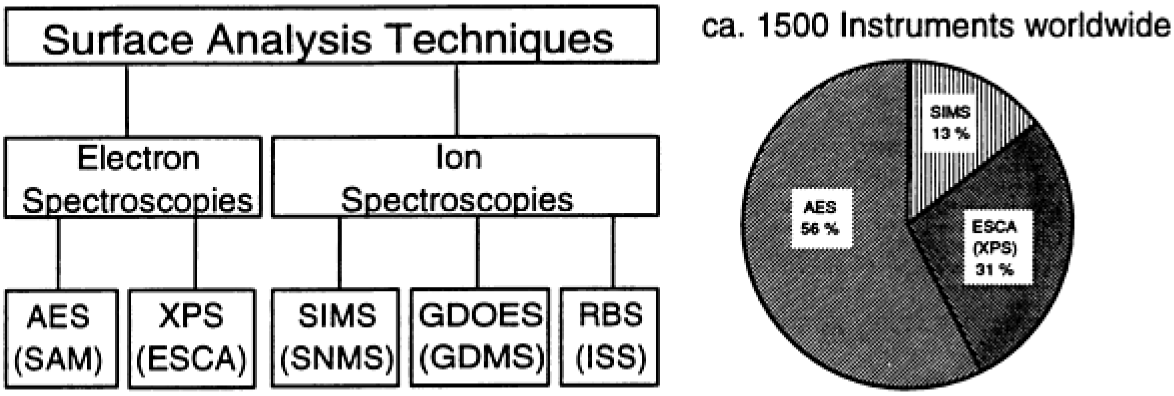

Fig. 1 Survey of the most important surface analysis techniques. AES (SAM), Auger electron spectroscopy (scanning Auger microscopy). XPS (ESCA), x-ray photoelectron spectroscopy (electron spectroscopy for chemical analysis). SIMS (SNMS), secondary ion mass spectroscopy (secondary neutral mass spectroscopy). GDOES (GDMS), glow discharge optical emission spectroscopy (glow discharge mass spectroscopy). RBS (ISS), Rutherford backscattering spectroscopy (ion scattering spectroscopy). Source: Ref 3

Coatings and thin films can be studied with surface analysis methods because their inherently small depth allows characterization of surface composition, interface composition, and the in-depth distribution of composition. This provides an indispensable method for the control of fabrication parameters as well as for the study of property/composition relationships. The full potential of surface analysis is further enhanced if the methods are applied in combination with other characterization methods including phase and structural identification (x-ray diffraction, transmission electron microscopy, and scanning tunneling microscopy) and stereochemistry (infrared and Raman spectroscopy). Recent trends are the development of increased spatial resolution (e.g., toward the 10 nm region and below in AES and SIMS) and improved databases and evaluation software for quantitative analysis.

With the exception of RBS, any of the above-mentioned surface analysis methods involves the use of an ion sputtering facility, which allows destructive depth profiling. Therefore, these methods can also be used for chemical analysis of the "bulk" of thin films and for the characterization of interfaces. Nondestructive depth profiling can be performed with RBS up to a few micrometers in depth, and with angle-resolved XPS up to about 5 nm thickness. Another method of interface analysis is based on brittle fracture or cleavage of the sample along internal interfaces, which exposes two surfaces to be studied by surface analysis. Following are the most important phenomena and structures that can be studied by the above-mentioned methods, the majority of which are relevant for coatings and thin films:

Surfaces, studied directly

- Segregation
- Diffusion
- Contamination
- Adsorption
- Oxidation
- Catalysis
- Friction and wear

Interfaces, studied by fracture and/or profiling

- Segregation
- Diffusion
- Embrittlement
- Intercrystalline corrosion
- Sintering
- Adhesion
- Composites

Thin films, studied by depth profiling

- Interdiffusion
- Ion implantation
- Reaction layers (oxides, passivation layers, etc.)
- Evaporation layers
- Protective coatings
- Microelectronic devices

From the more than 50 different existing techniques in surface analysis (Ref 6), this article only considers the main methods that have broad applicability and for which commercially available instruments exist (AES, XPS, SIMS, SNMS, GDOES, ISS, and RBS). They are characterized by the ability to provide quantitative analysis of all elements (except hydrogen and helium in AES and XPS) and intrinsic information depth in the nanometer range or below.

The latter point is the important difference to (spatially resolved) bulk analysis methods such as x-ray analysis in the electron microprobe. It should be mentioned that high-resolution, analytical scanning transmission electron microscopy (STEM) can also be used for surface and interface analysis (see the article "Microstructure/Characterization of Coatings and Thin Films" in this Volume).

A survey of the lateral and in-depth dimensions of the analyzed volume of typical microanalytical techniques is given in Fig. 2. For surface analyzing techniques with depth resolution below 5 nm, the depth of information is an intrinsic, physical parameter determined by the mean escape depth of photoelectrons or Auger electrons or that of the sputtered particles (SIMS, SNMS). In contrast, the lateral resolution depends mainly on instrumental capabilities, such as primary beam diameter or optical imaging facility.

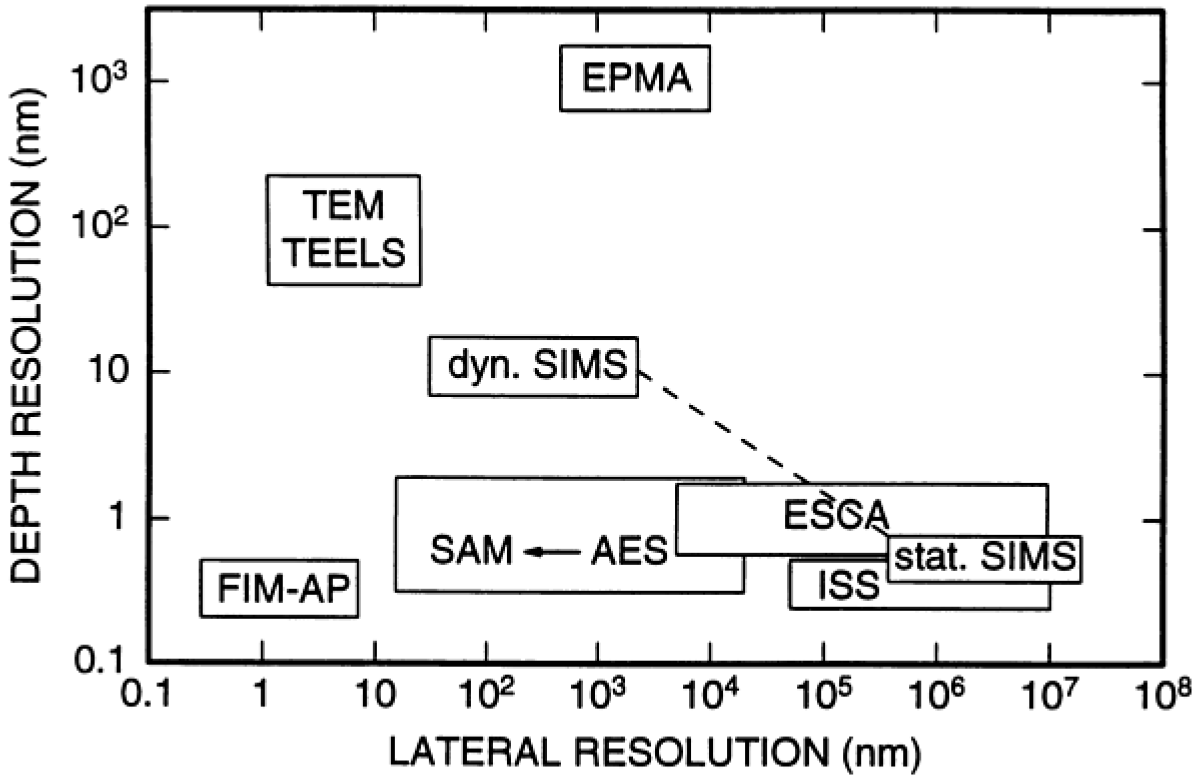

Fig. 2 Depth of information (depth resolution) and lateral resolution of surface and microanalysis techniques. AES, Auger electron spectroscopy. EPMA, electron probe microanalysis. ESCA, electron spectroscopy for chemical analysis. FIM-AP, field ion microscopy - atom probe. ISS, ion scattering spectroscopy. SAM, scanning Auger microscopy. SIMS, secondary ion mass spectroscopy. TEELS, transmission electron energy loss spectroscopy. TEM, transmission electron microscopy.

The principal components of an analytical surface analysis instrument are schematically shown in Fig. 3. They are: an excitation source (electrons, ions, or x-rays), an auxiliary ion gun for depth profiling, and a spectrometer (energy or mass) with particle detector, data acquisition, and processing facility. Together with the sample, the main components are in an ultrahigh vacuum chamber (UHV, $\leq 10^{-9}$ mbar). Therefore they can often be used for process control, as in modern molecular beam epitaxy or physical and chemical vapor deposition methods (Ref 7, 8) which work under UHV base pressure conditions (Ref 7). The principles of the main analysis methods are outlined in the following sections of this article. (For a quick survey and comparison of their most important features, see Table 1.)

Table 1 Comparison of surface and thin-film analysis techniques

Parameter	**Technique**					
	AES	**XPS**	**ISS**	**RBS**	**SIMS**	**GDOES**
Excitation	Electrons	X-rays	Ions	Ions	Ions	Ions
Emission	Electrons	Electrons	Ions (*E*)	Ions (*E*)	Ions (*m*/*e*)	*h*ν (optical)

Electron Spectroscopies (AES and XPS)

AES and XPS determine the energies of electrons emitted from a surface. Those with specific energies usually are photoelectrons or Auger electrons. For detailed information, the reader is referred to Ref 3, 5, and 6. Principles for basic understanding are briefly characterized in the following and illustrated by some examples.

X-ray Photoelectron Spectroscopy. Irradiation of the sample with x-rays of energy $h\nu$ (e.g., characteristic radiation of AlKα: $h\nu$ = 1486.6 eV; or MgKα: $h\nu$ = 1253.6 eV, often combined with a monochromator for narrower line width) causes emission of photoelectrons with kinetic energy E_{kin} according to:

$$E_{\mathrm{kin}} = h\nu - E_{\mathrm{B}} - j_{\mathrm{A}} \quad \textbf{(Eq 1)}$$

where E_B is the binding energy of the respective electron level and j_A is the work function of the electron energy analyzer (Fig. 3). Because hu is the energy of the x-ray source used, the binding energy can be determined directly in most usual instruments if j_A and the analyzed energy E_{kin} are empirically calibrated with standard samples. Tables of binding energies are available (Ref 9).

The terminology of XPS follows that of atomic physics. Each electronic level is characterized by its orbital number *n* (= 1, 2, 3, 4 . . .), the orbital momentum *m* (= *s, p, d, f*), and the total spin quantum number *I* (= 1/2, 3/2, 5/2 . . .).

Chemical Effects and Compound Analysis. In general, chemical bonding changes the electron binding energy of valence band and core levels, which for core levels is recognized in XPS by a distinct "chemical shift" of the elemental peak with respect to the pure element (Ref 3). An example is shown in Fig. 4 for the 2*p* 3/2 and 2*p* 1/2 doublet of the Ti-2*p* XPS spectrum of a native oxide layer on a titanium nitride (TiN) coating (Ref 10). If the characteristic binding energies are known from measurements of standard samples or, often less precisely, from data banks (e.g., the National Institute of Standards and Technology the XPS database in Ref 9), the relative amount of a compound can be directly determined by peak fitting of peaks at the respective energies and subsequent determination of the Ti-2*p* 3/2, 1/2 respective peak areas. This was done for the Ti-2*p* 3/2, 1/2 doublet in Fig. 4, which is decomposed into two doublets, one for TiO_2 and the other for TiN. Comparison of the peak areas in this case gives $X_{TiO_2}/X_{TiN} = 0.49$. With the emission angle θ= 45° and an electron attenuation length of $\lambda_0 = 1.2$ nm, this value corresponds to a 1.8 nm thick TiO_2 layer on TiN.

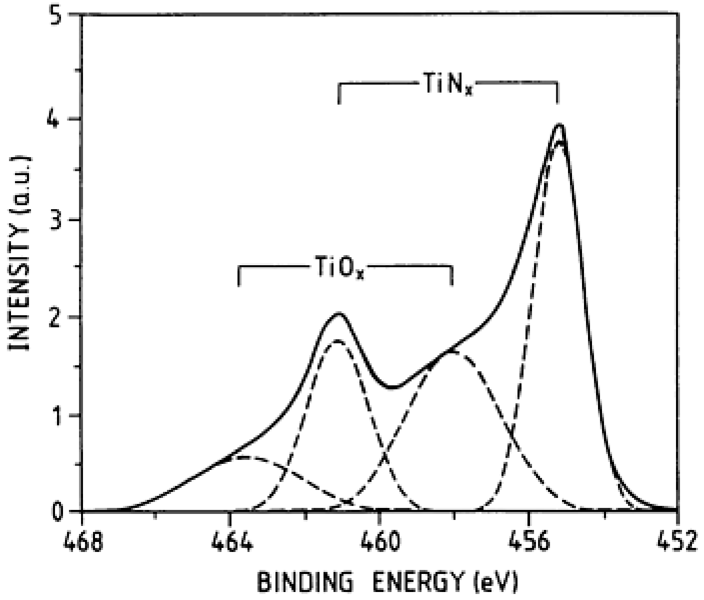

Fig. 4 X-ray photoelectron spectroscopy of the Ti-2*p* 1/2, 3/2 doublet in TiN and TiO_2 obtained with a thin oxide layer on TiN. Source: Ref 10

Usually, the chemical shift of compounds such as nitrides and oxides is of the order of a few electron volts (see Fig. 4) (Ref 3, 9). In many compounds, different valency states have a characteristic shift of the core level. For example, the Ta-4*f* doublet in Ta_2O_5 shows a shift of the binding energy of 5 eV from Ta^0 to Ta^{5+}, whereas for TaO a shift of 2 eV (corresponding to Ta^{2+}) is obtained (Ref 11).

Auger Electron Spectroscopy. The most important method for chemical microanalyses of a surface is electron-beam-excited AES, which is based on the Auger effect (Ref 3, 5, 6). It is a radiationless transition, competing with x-ray fluorescence when an atom is ionized (e.g., by electron impact) in an inner shell (e.g., *K*-shell). The generated electron vacancy can be filled by an electron from an outer shell (e.g., *L*-shell), and the energy gain of this transition causes the

emission of another electron from the outer shell. According to the net energy of the described Auger transition involving K, L_1, L_2 levels, the kinetic energy of the emitted Auger electron is given by:

$$E_{kin}\,(KL_1L_2) = E_K - EL_1 - EL_2 - \Delta E - j_A \qquad \textbf{(Eq 2)}$$

where E_K, EL_1, and EL_2 are the respective electron binding energies, ΔE is a small correction term for the relaxation of the twofold ionized state, and j_A is the work function of the analyzer.

Equation 2 gives a characteristic kinetic energy--independent of the excitation energy--for any specific Auger transition of an element and therefore is the basis of qualitative analysis. Because three electron levels are involved, hydrogen and helium cannot be detected. For elements with higher atomic number, transitions such as *LMM*-, *MNN*-, and so on are used for Auger analysis. In general, the derivative spectrum $d[N(E) \cdot E]/dE$ is recorded as shown in Fig. 5 for TiN (Ref 10).

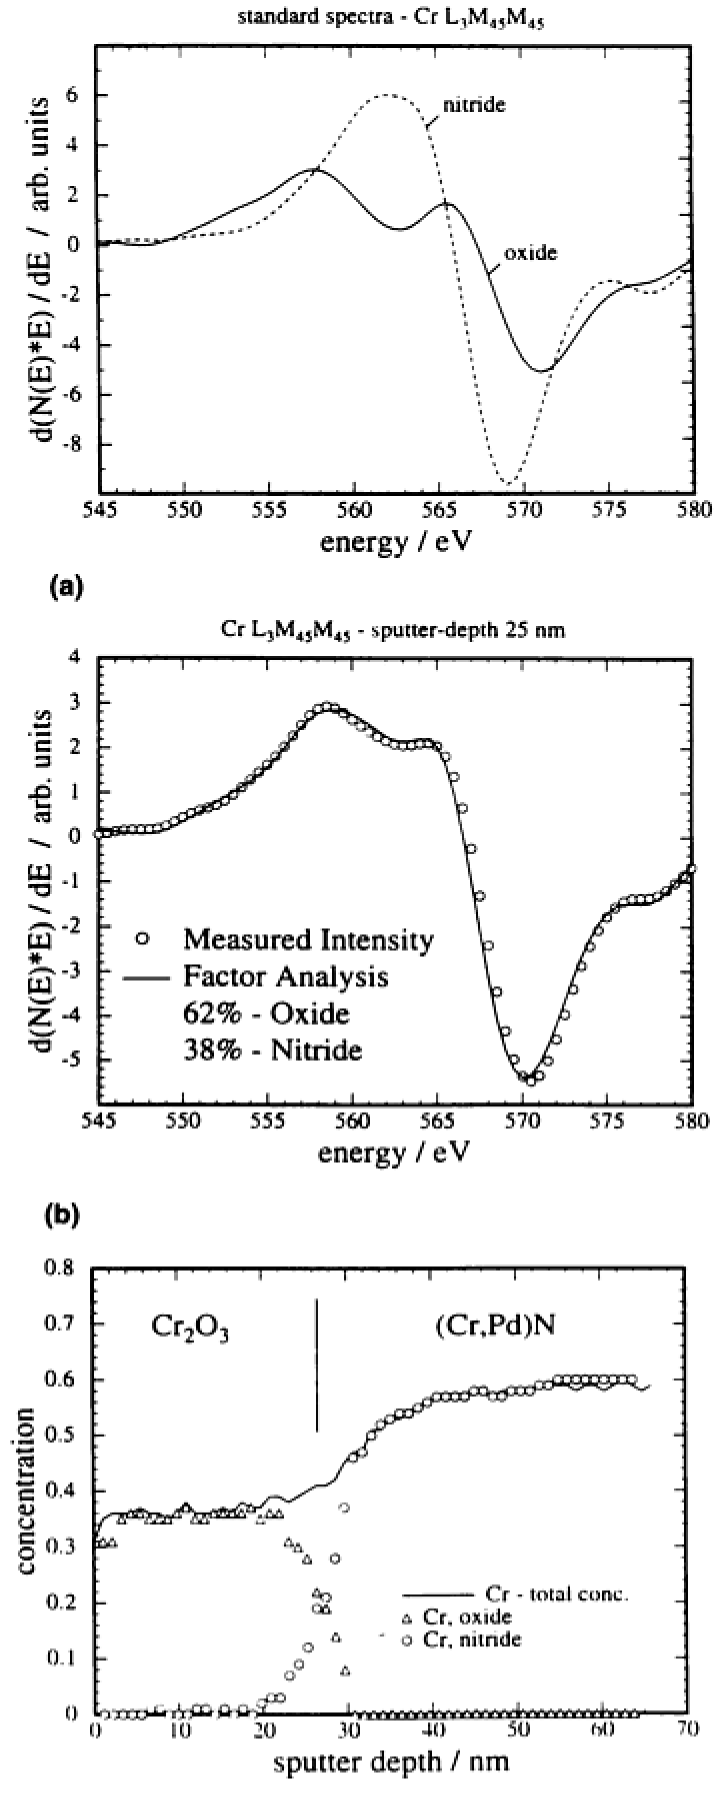
Chemical Effects and Compound Analysis. Because of the three electron levels involved in AES, the chemical bonding effect is much more complex than in XPS and is most often recognized as a peak shape change that impedes elemental quantification (Ref 3). However, the knowledge of standard spectra of the relevant factors (or principal components) allows the decomposition of a measured depth profile into quantitative contributions, as shown in Fig. 6 for Cr_2O_3 and CrN in an oxidized (Cr,Pd)N coating (Ref 12).



(a) (b) (c)

Fig. 6 Factor analysis in Auger electron spectroscopy depth profiling of an oxidized (Cr,Pd)N coating. (a)

Standard spectra of the components chromium nitride and chromium oxide. (b) Comparison of measured and synthesized spectra. (c) Depth profile of the principal components. Source: Ref 12

Applying the mathematical method of factor analysis (Ref 13) to a series of spectra, for example in a depth profile (Ref 14, 15) enables the assessment of the number of principal components and a test of the validity of the otherwise obtained standard spectra, as well as the determination of one unknown component *n* if *n*-1 components are known. For more details of this powerful method, the reader is referred to Ref 13, 14, and 15 (see also the section "Thin Film and Interface Analysis" in this article).

Information Depth. Whenever an Auger electron or photoelectron is generated, its characteristic energy can be analyzed outside the sample only if it leaves the surface without any inelastic scattering event by which it loses some amount of energy and contributes then only to the lower-energy background of the spectrum. The probability of inelastic scattering increases exponentially with the traveled distance and is described by the inelastic mean free path λ_0 or, more precisely, attenuation length, which additionally includes elastic scattering (Ref 16). Depending on electron energy and material, the attenuation length is typically between 0.4 and 3 nm and increases with the kinetic energy. Although physical theories for predictions of λ_0 have recently been developed (Ref 17), the semiempirical relation of Seah and Dench (Ref 18) is still useful and gives the right order of magnitude for elements as well as for many inorganic compounds for the energy range of 30 to 3000 eV:

$$l_o = \left[\frac{534}{E^2} + 0.41.(a.E)^{1/2}\right].a \qquad \textbf{(Eq 3)}$$

where λ_0 is in nanometers, E is the kinetic electron energy in electron volts, and a is the mean atomic distance in nanometers. The atomic mass number, M, the density, ρ, and Avogadro's number, N_0, determine $a = [M/(\rho \cdot N_0)]^{1/3}$. Values of λ_0 are typically between 0.4 nm ($E \approx 100$ eV) and 2 nm ($E \approx 1500$ eV), meaning that 63% of the measured intensity of Auger electrons or photoelectrons stems from a surface layer with the thickness λ_0 for emission perpendicular to the surface (θ = 0). This fact is the reason for the surface-specific information of the electron spectroscopies. If the emission angle θ increases, the electron escape depth λ is smaller than λ_0 and given by $\lambda = \lambda_0 \cdot \cos\theta$(Ref 18).

Quantification Principles of Electron Spectroscopies. The signal intensity, given by the number of Auger electrons or photoelectrons in an elemental peak, is a measure of the number of atoms of this element in the analyzed volume and therefore of its concentration. Usually, the signal intensity is given by the area under the measured peak [$N(E)$] after background subtraction (Ref 3). Whereas background subtraction is generally used in XPS, the much larger electron background in AES causes relatively large errors. Therefore it is still customary to use the Auger peak-to-peak height in the differentiated [$d[N(E) \cdot E]/dE$] spectrum in AES to characterize the elemental signal intensity I_i, as shown in Fig. 5 for the Auger spectrum of TiN (Ref 10). For both AES and XPS we may write:

$$I_i = k_0 \cdot (1 + r_B) \cdot S_i \cdot X_i \cdot l_0^2 \cdot \cos\theta \qquad \textbf{(Eq 4)}$$

where k_0 is an instrumental constant given by the analyzed area, excitation intensity (primary current or x-ray intensity), and the total analyzer transmission; r_B is the backscattering factor in AES, mainly dependent on the atomic number, and is typically between 0.1 and 1.5 (however, $r_B = 0$ for XPS); S_i is the relative elemental sensitivity factor (generally defined with respect to pure silver in AES and with respect to pure carbon in XPS); X_i is the mole fraction in the analyzed volume (analyzed area times l_0^2); l_0^2 is the inelastic mean free path for the peak energy of element *i* or, more precisely, the attenuation length (Ref 16, 17), and θ is the angle of emission of the detected electrons with the normal to the sample surface.

For a complete spectrum with I_i the intensity of the most intense peak of every detected element *i*, k_0, and θ are constant. Assuming that r_B (in AES) and λ_i are approximately constant, it follows from Eq 4 that:

$$X_i = \frac{I_i / S_i}{\sum_{j=1}^{n} (I_j / S_j)} \qquad \textbf{(Eq 5)}$$

which gives the mole fraction X_i for the chosen element i of a total of n elements. Note that Eq 5 is only a first-order approximation, because the matrix dependence of l_0^2, and of r_B in AES, are neglected. This expected deviation can be taken into account by a correction factor F_{AB} of element A in matrix B, by which every I_A/S_A has to be multiplied in Eq 3 (Ref 3, 10, 19):

$$F_{AB} = \frac{(1+r_B^A).l_0^A}{(1+r_B^A).l_0^A} \quad \textbf{(Eq 5a)}$$

where l_0^A and l_0^B are the electron attenuation lengths and r_B^A and r_B^B are the AES electron backscattering coefficients of the pure element A and of element A in matrix B, respectively. The F_{AB} correction factor depends on the difference, mainly with respect to density and mean atomic number, of matrix and pure element. In favorable cases, F_{AB} is of the order of a few percent; for strong differences, F_{AB} can be between 0.5 and 2 (Ref 3). According to Eq 5a, these values are a measure of the error margin contained in quantification of homogeneous samples using Eq 5.

Depth-Dependent Composition. Homogeneous composition in electron spectroscopies means constant composition within about 5λ from the surface, because the intensities contributing to the signal decay exponentially with depth z, that is, $I_i = I_i^0 \exp(-z/\lambda)$. For $z = 5\lambda$, I_i is about 0.7% of I_i^0 of a pure element at the surface and is therefore approximately at the limit of detection for most elements. Because λ_0 is between 0.4 and 2 nm, the above condition means a required homogeneity in a range between 2 and 10 nm. This is the maximum information depth or the intrinsic sampling depth in AES and XPS.

For example, if λ_0 is 2 nm ($\lambda_0 = \lambda$ for emission perpendicular to the surface, $\theta = 0$) in an AB composition and the first monolayer d = 0.25 nm composed of pure A ($X_A = 1$) with the rest being pure B, then $I_A/I_A^0 = 1 - \exp(-0.25/2) = 0.12$ and $I_A/I_B^0 = \exp(-0.25/2) = 0.88$, which corresponds to $X_A = 0.12$ homogeneously distributed in a region of ≥10 nm. From the measured intensity alone, both possibilities or intermediate cases are indistinguishable. If λ_0 is 0.4 nm, $X_A = 0.46$ is obtained. Figure 7 shows the relation between the ratio $\overline{X}_A(5 \cdot \lambda)/X_A(d)$, of the measured $\overline{X}_A(5 \cdot \lambda)$ and the true $X_A(d)$ homogeneously distributed within a layer of thickness d. It is easily recognized from Fig. 7 that because of matrix effects with respect to the elemental standard, changing λ changes the sampling depth and therefore the sensitivity factor, as outlined above (Ref 19).

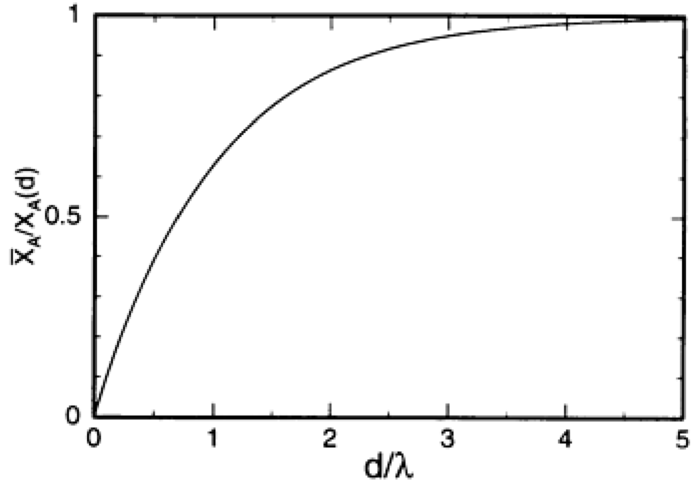


Fig. 7 Ratio of the average concentration $\overline{X}_A$, assuming a constant $\overline{X}_A$ with depth of an A-B alloy, to the concentration $X_A(d)$ of a thin layer of thickness d of A on a substrate B

Because the relative change in λ with composition should be the same for any elemental peak, the sensitivity factor, S_A/S_B, which is decisive for correct quantification of homogeneous samples, should not change with changing composition (except for r_B in AES, Eq 5a). Therefore, any matrix has a characteristic set of elemental sensitivity factors that can be best evaluated by the use of standards (Ref 3, 4, 19, 20).

Microanalysis and Lateral Resolution. The technique of scanning a focused electron beam and simultaneous plotting the peak-to-background intensity of an elemental signal using scanning Auger microscopy (SAM) allows elemental mapping (Ref 21). A secondary electron image of an electronic thin-film device is shown in Fig. 8(a), whereas Fig. 8(b, c, d) show the silicon, aluminum, and fluorine maps. In this case, the device was etched by a fluorine-containing reactive gas. It is clearly recognized that fluorine remained only at the aluminum contact layers and not on the silicon structures (Ref 22).

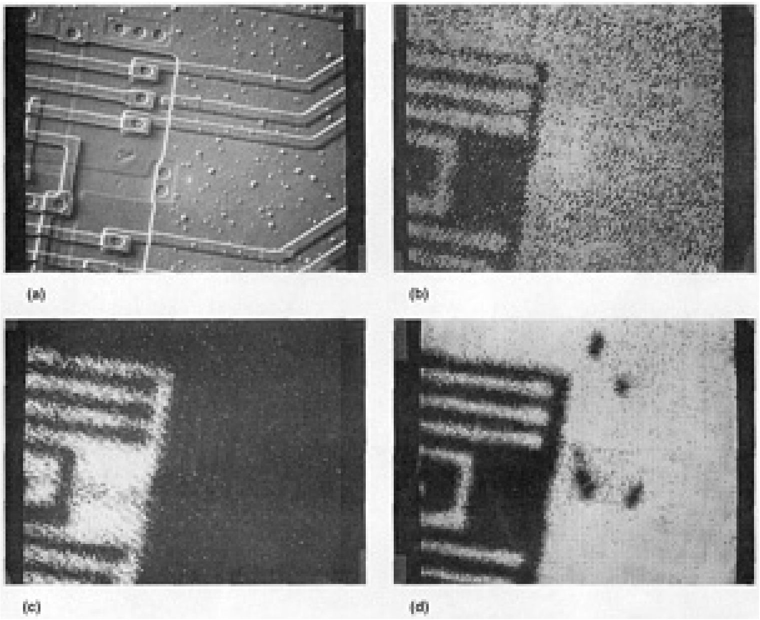

Fig. 8 Integrated circuit after cleaning treatment with a fluorine-containing compound analyzed with Auger electron spectroscopy/scanning Auger microscopy. (a) Secondary electron image. (b) Chemical map of aluminum. (c) Chemical map of silicon. (d) Chemical map of fluorine. Note that fluorine is removed by electron-stimulated desorption from focusing spots of the electron beam. Source: Ref 22

A lateral resolution in SAM of about 0.1 μm can be routinely obtained. Modern instruments with field emission cathodes provide primary beam diameters of 15 nm at 1 nA beam current, suitable for the analysis of microelectronics devices. Limitations in quantification and detrimental effects such as beam heating are discussed in Ref 22.

XPS offers somewhat less spatial resolution than SAM, about 70 to 5 μm. Small-spot XPS can be performed either by excitation of a restricted sample area (e.g., a focused x-ray beam by a bent monochromator crystal) or by an electron optical lens in front of the analyzer, which selects a limited area of the sample for analysis (Ref 23). Imaging XPS uses monochromatic electrons and a multichannel parallel detection device to generate an elemental image (Ref 23).

Limitations and Special Problems. High-spatial-resolution AES of small particles, protrusions, or precipitates in micrometer dimensions is difficult to analyze quantitatively because of distortions by backscattered primary electrons that excite Auger electrons from the surrounding material. The achievable resolution is limited by the amount of current in a small-diameter beam that is necessary for a sufficient signal-to-noise ratio and by the temperature increase that is due to the high current density (up to 10^3 A/cm^2), which may cause diffusion and even evaporation processes in thin films on substrates with low thermal conductivity (Ref 21, 22). Furthermore, electron-stimulated desorption may lead to decomposition of compounds at the surface. For both cases of sample damage, lowering the current density (e.g., by enlarging the beam diameter or scanning the electron beam over a certain area) is a remedy, but at the cost of decreasing spatial resolution. The usually much lower power density greatly reduces this problem in XPS.

Charging of insulating materials is a severe problem in both AES and XPS. However, whereas negative charging of the sample in AES is difficult to overcome in practical analysis, even though a number of special techniques can help (Ref 24, 25), XPS causes positive surface charging, which can often be successfully compensated by low-energy electron flooding with an auxiliary electron source (Ref 26).

Ion Spectroscopies

When ions are used as a probe, there are several possibilities for surface chemical analysis: the characteristic energy loss of scattered primary ions (ISS, RBS), the mass of secondary (sputtered) particles (SIMS, SNMS, GDMS), or their optical emission (GDOES). Primary ion energy spectroscopy is performed either at low energy (<10 keV) (Ref 27) or at high energy (>300 keV) (Ref 28). The term *low-energy ion scattering* (LEIS) is often used synonymously with ISS. The term *high-energy ion scattering* (HEIS) is akin to RBS. SIMS (Ref 29) and SNMS (Ref 30) or GDMS (Ref 31) are based on mass spectrometric detection of the sputtered species, while GDOES (Ref 32) measures optical emission lines characteristic for specific elements.

Energy Analysis of Scattered Primary Ions

Ion Scattering Spectroscopy. The principle of ISS is the collisional elastic momentum and energy transfer of a primary ion of mass m_1 and energy E_0 (1 to 5 keV) with an atom of mass m_2 in the topmost layer of the sample (Ref 27). For a given scattering angle, the energy E_1 of the backscattered primary ion (generally He^+) is a unique function of the ratio m_2/m_1. For example, at 90° scattering angle the relation

$$E_1 = E_0 \cdot \left(1 - \frac{m_1}{m_2}\right) / \left(1 + \frac{m_1}{m_2}\right) \quad \textbf{(Eq 6)}$$

is valid and shows how the energy scale (E_1) can be calibrated in a mass scale (m_2). The single-collision binary scattering described by Eq 6 occurs only at the surface. Therefore ISS is unique in determining the composition of only the topmost surface layer. However, the limitations in sensitivity and mass resolution at higher masses (see Eq 6), along with its difficult quantification, have confined ISS to more fundamental research.

Rutherford backscattering spectroscopy is one of the techniques first applied to thin-film analysis (Ref 28). The reason is that due to their high energy (>300 keV, up to several MeV), the primary ions penetrate between several 100 nm and some 10 μm of a solid until they lose their energy and are stopped. Along their way, a considerable fraction undergoes Rutherford backscattering, provided that the nuclei in the target have a higher mass than the primary ions. (These are usually He^+ ions, so hydrogen and helium cannot be detected by RBS.) However, forward ejection of these atoms, that is, elastic recoil detection, can be applied to detect hydrogen (Ref 33). The backscattered primary ions lose a specific amount of energy, which is determined by both the mass m_2 of the scattering atomic nuclei in the sample and by the well-known energy loss that occurs mainly through electronic interaction, which is proportional to the totally traveled distance z and the loss rate dE/dz. The measured energy $E_1/(m_2, z)$ of the primary ion (m_1) after backscattering is given by the following two terms:

$$E_1(m_2, z) = f(m_2, E_0) - z \cdot f(m_2, E_0, dE/dz) \qquad \textbf{(Eq 7)}$$

Because of the second term, the width of the peak due to scattering at m_2 is a measure of the thickness of the respective material, and its intensity is proportional to the (areal) concentration. It is obvious that the achievable depth resolution depends on the energy resolution of the analyzer. Thin-film analysis with high depth resolution is enabled by modern electrostatic energy analyzers. An example is shown in Fig. 9, where the measured and calculated intensity-energy relations for a 10.4 nm thick niobium layer on sapphire is depicted (Ref 34). The notch of the measured profile is due to a native niobium oxide layer of about 2 nm thickness. The main advantages of RBS are that it is a nondestructive and quantitative method. The main disadvantages are the relatively large analyzed spot (typically 1 mm diameter), the necessity of expensive particle accelerators, and the lack of chemical information. For a summary of the typical features of RBS in comparison with other methods, see Table 1.

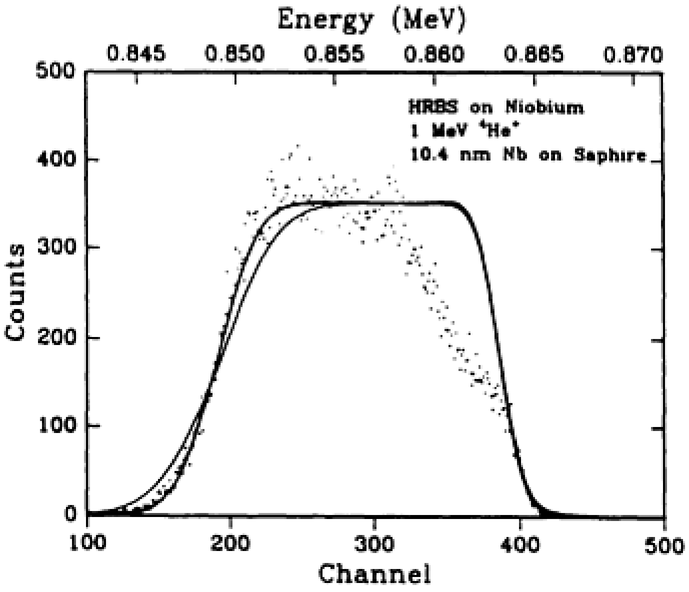

Fig. 9 High-resolution Rutherford backscattering spectroscopy of a 10.4 nm niobium layer on sapphire (calculated solid lines) that was oxidized in air (shoulder in the experimental points distribution). 1 MeV $^4He^+$. Source: Ref 34

Detection of Sputtered Particles

Secondary ion mass spectroscopy (SIMS) is probably the first technique used for depth profiling (Ref 29). A primary ion beam of about 0.5 to 15 keV energy causes sputter erosion of the surface by emission of neutrals and ions. The ejected secondary ions are separated in a mass spectrometer (electric quadrupole or magnetic sector or, in time-of-flight SIMS, by flight time measurements of pulse-accelerated secondary ions). The precision of identification of atomic

and molecular species depends on the mass resolution, ($m/\Delta m$), which typically is 500 to 2000 for quadrupole, up to 10,000 for magnetic sector, and up to 15,000 for time-of-flight spectrometers. The basic equation for quantitative SIMS can be written as (Ref 29):

$$I_I^{\pm} = I_0^{\pm} \cdot T_i \cdot Y_i \cdot b_i^{\pm} \cdot X_i \qquad \textbf{(Eq 8)}$$

where the measured count rate at mass *i* of the positive or negative secondary ions, $I_I^{\pm}$, is determined by the primary ion intensity $I_0^{\pm}$, the total instrumental transmission T_i, the sputter yield Y_i (atoms/ion), the ionization probability $b_i^{\pm}$ (≤ 1) of the sputtered particles (*i*), and their mole fraction X_i in the sample.

The main advantages of SIMS are its:

- Ability to detect all elements, including hydrogen
- Ability to detect elements in the parts-per-billion range
- Ability to perform microanalysis and imaging in the submicrometer range
- High dynamic range of up to 8 orders of magnitude in concentration

Besides its intrinsic destructiveness, the main disadvantage of SIMS is its difficult quantification. The strong matrix dependence of the ionization probability $b_i^{\pm}$ (up to 5 orders of magnitude) is the main reason for the notorious difficulty of quantifying SIMS in a multicomponent matrix with varying composition. Because the sputter yield Y_i is much less matrix dependent, ionization of practically all sputtered neutrals (i.e., $b_i^{\pm}$ approaching unity) would drastically reduce the matrix effect. Indeed, this is done in the so-called SNMS method, where the sputtered neutrals are ionized by a low voltage of plasma or an electron beam ("positonization") (Ref 30). The simplest way to achieve enhanced ionization is a direct-current glow discharge on the sample surface, which at the same time generates sputtered particles and ionizes them (GDMS method) (Ref 31).

A similar method that also uses a direct-current glow discharge is GDOES (Ref 32), where the excitation of optical emission is used as a means to analyze the sputtered species. As in GDMS, the main advantages are the high sputter rate due to the high current density and therefore the speed of thin-film depth profile analysis and high sensitivity. However, lack of spatial resolution and a generally lower depth resolution than with SIMS and SNMS are disadvantageous.

Table 1 compares the most important surface and thin-film analysis methods: AES, XPS, SIMS, and ISS, together with the generally non-UHV methods for thin-film analysis, RBS and GDOES.

Surface Analysis Applications

Surface Adsorbates and Contamination. The most obvious application of surface analysis methods is the study and control of the surface composition prior to further treatment, as in the production of thin-film structures in microelectronics (Ref 35) (see Fig. 8). Trace elements on flat, larger surfaces, for example silicon wafers, can be investigated with total reflection x-ray fluorescence spectroscopy at glancing incidence angle (Ref 7) with high

sensitivity. Different chemical species can be observed. For example, the detection of residues after etching of a silicon surface with a (CHF_3 + O_2) plasma in semiconductor fabrication is enabled by the carbon 1*s* XPS spectrum, which allows the recognition of different peaks attributable to several compounds. Further Ar^+ ion etching removes the fluorine-containing compounds (Ref 35). Any kind of surface contamination can be detected. For example, friction and wear often is accompanied by transfer of materials from one part to the other, which can be monitored by surface analysis.

Thin Film and Interface Analysis. Analysis of internal interfaces with surface analysis methods can be principally performed in either of two ways: in-situ fracture of a sample along the interface (e.g., coating-substrate) and subsequent surface analysis of one or both parts (Ref 36, 37, 38), or by depth profiling through the interface (Ref 39, 40). A special method is angle lapping of the sample and taking a line scan across the interfacial region (Ref 3).

Coating-substrate interfaces are often prone to accumulation of impurities (e.g., by segregation or oxidation) that lead to a change in adhesive properties. These can be disclosed by a scratch test, by which a part of the interface is exposed due to peeling of the coating. For example, sulfur segregation was shown to have a detrimental effect on the adhesion of thin films, as determined by an in-situ scratch test in an AES instrument (Ref 41).

Whereas sputter depth profiling is a destructive method, nondestructive methods make use of the known energy-range relation of ions (RBS) or electrons (AES, XPS) in solids. A particularly important nondestructive method to disclose the in-depth distribution of composition is angular resolved XPS, which is, however, restricted to a probing depth of 2 to 3 times the electron attenuation length (i.e., to <5 nm for conventional XPS). By tilting the sample around an axis perpendicular to the analyzer axis and away from the latter, relatively more and more intensity from the species in the top layer is obtained as compared to deeper layers. An example is given in Fig. 10 for the determination of the thickness of an oxide layer (Al_2O_3) on aluminum. The peak area I_{ox} of the Al-2*p* peak indicating Al_2O_3 (75.7 eV) increases relative to that of pure aluminum (72.3 eV, I_{met}) with increasing takeoff angle φ. The thickness *d* of the Al_2O_3 layer is given by (Ref 42, 43, 44):

$$d = \lambda \cdot \sin \varphi \cdot \ln(1 + k \cdot I_{ox}/I_{met}) \qquad \textbf{(Eq 9)}$$

where λ is the electron attenuation length (2.0 nm) and *k* is a sensitivity correction factor of the order of unity. Figure 10(b) shows a plot of the ratio I_{ox}/I_{met} from Fig. 10(a) as a function of the emission angle $\theta = 90° - \varphi$. Using a more general formulation of the angular dependence $I(\varphi)$ being a Laplace transform of $I(1/\lambda)$, more detailed layer profiles can be revealed, as shown by Bussing and Holloway (Ref 45) for the altered layer of sputtered Ga-As surfaces. Recently, multilayer samples were successfully studied by using grazing incidence XPS, which combines the low penetration depth of x-rays at $\varphi < 3°$ incidence angle to the surface (and its variation with φ) with all the XPS features (Ref 46).

(b)

Fig. 10 Angle-resolved x-ray photoelectron spectroscopy spectrum of a 2.3 nm thick Al_2O_3 layer on aluminum. (a) Al-2*p* peak as a function of the takeoff angle *j*. (b) Ratio of the peak areas of Al_2O_3 and aluminum as a function of the emission angle θ= 90° - *j*. Source: Ref 47

Most common and straightforward is depth profiling by ion sputtering in combination with a surface analysis method. This technique discloses the elemental distribution as a function of the sputtered depth, including the composition of interfaces. Important is the attainment of a high depth resolution (Ref 3, 39, 47), which can be achieved by a rastered beam of Ar^+ ions with less than 3 keV energy, a small analyzed area, and a high angle of incidence (e.g., 70°) of the ion beam (Ref 39). Sample rotation during profiling has been shown to give optimum results with respect to high depth resolution (Ref 40, 48). With this technique, a depth resolution of Δz = 6 nm was achieved for Ni-Cr multilayer thin films (even at a sputtered depth of about 0.5 μm) employing AES and SIMS profiling in a study involving four laboratories (Ref 48).

SIMS depth profiling is particularly useful for determining dopant profiles (e.g., implantation profiles) in semiconductors or detecting impurity segregation at interfaces. The profile obtained from less than a monolayer ("delta layer") of aluminum in Ga-As is shown in Fig. 11 (Ref 49, 50), demonstrating the advantageous sensitivity and high depth resolution of SIMS. Other examples of thin-film depth analyses are given in previous sections of this article.

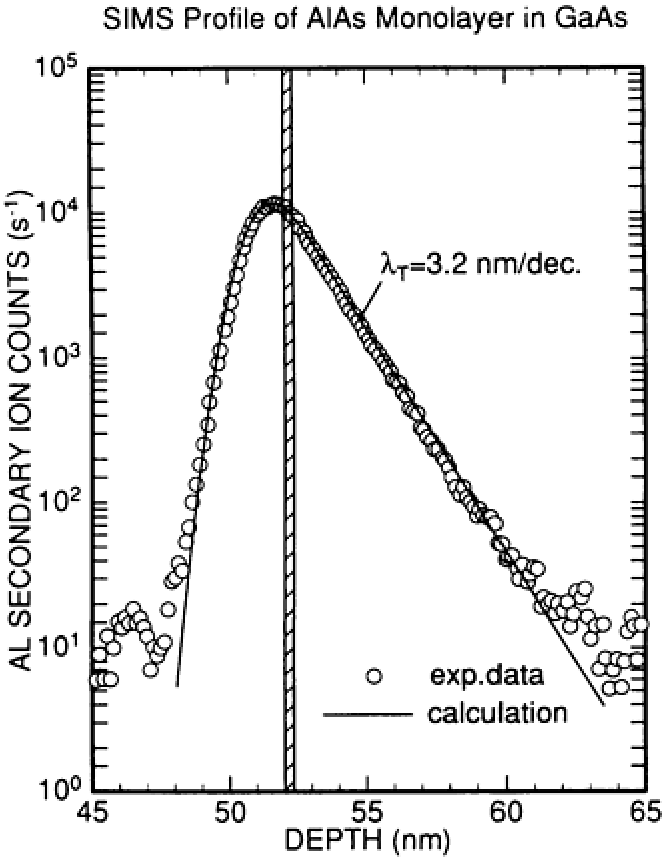

Fig. 11 Secondary ion mass spectroscopy depth profile of an AlAs monolayer doping in GaAs. Comparison between measured points (circles) (Ref 49) and calculations (solid line). Source: Ref 50

The result of chemical reactions at the gas-solid or liquid-solid interface often are specific layer structures, and further reaction behavior depends on their chemical composition. Passive layers on stainless steels (Ref 51) and oxide layers on different alloys and nitride coatings (Ref 52) have frequently been studied. An example of the composition of a passive layer on an Fe-Cr alloy is shown in Fig. 12. Figure 12(a) shows the AES depth profile obtained by using factor analysis and least-squares fitting of the four different standard spectra of metallic and oxidized iron and chromium (Ref 53). Figure 12(b) gives the result of a "convolution" procedure employed in order to calculate the original depth distribution (Fig. 12b) from the measured profile (Fig. 12a). Profile broadening schemes are used to account for the effects of sputtering and information depth influences on the assumed profile in Fig. 12(b) until an optimal fit with the profile in Fig. 12(a) is obtained (Ref 34, 39).

sputtering time. (b) Concentrations of the alloy elements in metallic and oxidic states after fitting all fractions of the respective components with a sequential-layer sputtering model. Source: Ref 53

High-resolution AES (i.e., scanning Auger microscopy) is another way to obtain the in-depth composition at interfaces by line scanning the focused electron beam (of ≤ 1 μm diameter) across the rim of the crater generated by sputter profiling (Ref 39, 54). An example of such a "crater edge profile" is shown in Fig. 13 for a TiN coating on a high-speed steel interface characterized by the iron Auger intensity (Ref 55). It is clearly seen, by comparison of the traces of the oxygen signal and the titanium signal, that oxygen varies with titanium and not with iron. This means that only titanium oxide, no iron oxide, is contained in the interface.

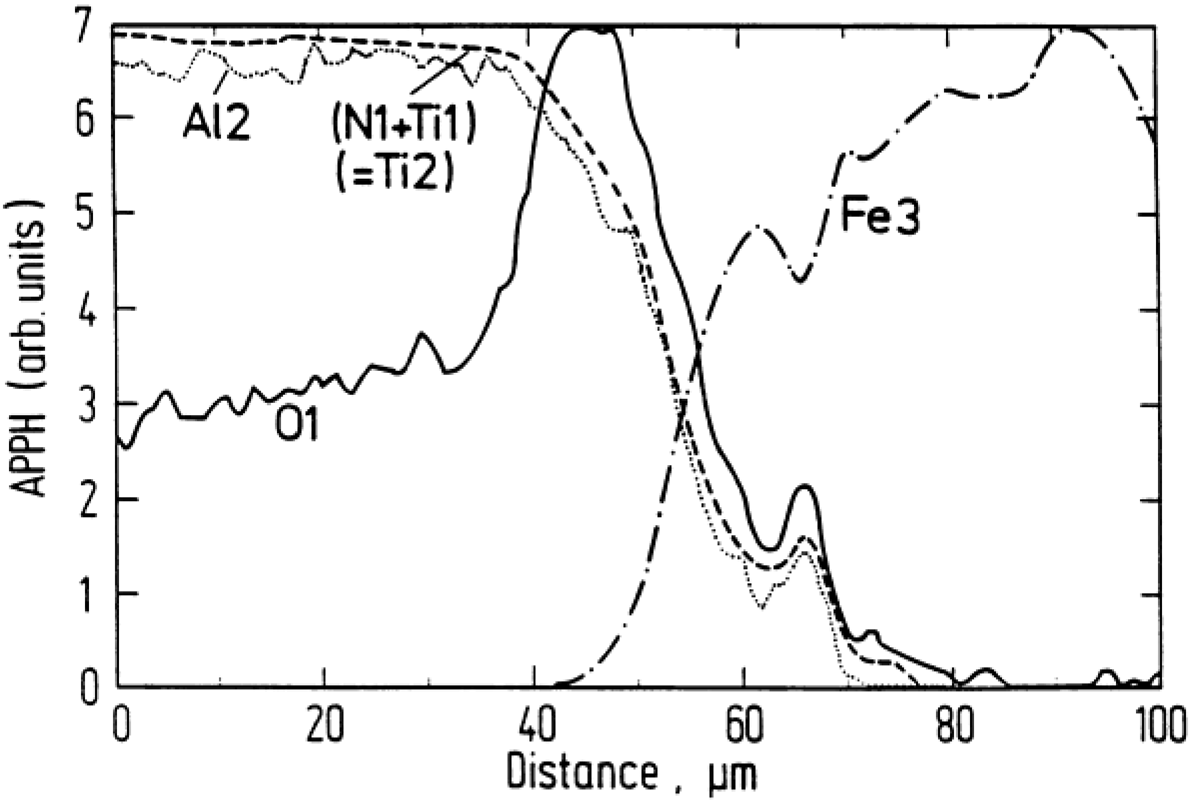

Fig. 13 Oxide layer at the interface between an (Al,Ti)N coating and a high-speed steel substrate (Fe), disclosed by using crater edge profiling with scanning Auger microscopy. Source: Ref 54

The chemical shift in XPS can be used to disclose different chemical bonding states at interfaces. For example, the two phases ZrO_2 and ZrN were found at the interface ZrN-Fe of a ZrN coating on a high-speed steel substrate (Ref 54). Another example is that different SiO_x suboxides in the interface of ultrathin SiO_2 layers on silicon were disclosed by high-resolution XPS (Ref 56).

Reactions at interfaces can be directly studied by AES and XPS depth profiling. An example is shown in Fig. 14 for a thin-film structure of Si-Ni-Si (each layer about 50 nm thick) sputter deposited on a Si(111) substrate (Ref 57). Figure 14(a) shows the Auger depth profile for the as-deposited sample. Although the apparent interface width increases with depth, the small peak of oxygen at a sputtering time of about 9 min indicates the native SiO_2 layer of about 2 nm thickness on the silicon substrate. The shape of the profile after thermal treatment, with a linear temperature increase up to 205 °C at a heating rate of 40 °C/min, shows that mainly nickel was migrating into the adjacent silicon layers and that mainly a Si_2Ni phase was formed, which was confirmed by selected area diffraction in TEM (Ref 57). Evaluating the increase of the measured interface width, $\Delta z = z\,(0.84\,I_0) - z\,(0.16 \cdot I_0)$, with increasing temperature, T, and time, t, $\Delta z(T) - \Delta z(T_0) \approx 2 \cdot (D \cdot t)^{1/2}$, allows determination of the interdiffusion constant, in this case $D = D_0 \cdot \exp(-Q/kT)$ with $D_0 = 2.5 \cdot 10^{-2}$ m^2/s and the activation energy $Q = 0.5$ eV (Ref 57). The error in this evaluation is mainly due to a change of the sputtering rate with composition (about +50% from pure nickel to pure silicon).

Introduction

WEAR AND EROSION TESTS have traditionally been used by materials engineers and scientists to optimize materials selection or development for a given application. Standardization, repeatability, convenience, short testing time, and simple measuring and ranking techniques are desirable in these tests. Currently, more demanding and complex methods

of wear testing are being used by mechanical and reliability engineers to determine wear parameters that can project performance and establish the influence of various factors on these parameters.

Wear is closely related to friction and lubrication. The study of these three subjects is known as *tribology*. The apparatus used for one tribological test can frequently be used for another, but friction, wear, and lubrication are distinct phenomena, and test procedures and interpretations vary. For example, a lubricant test evaluates the ability of a lubricant to withstand temperature, speed, or load and still provide protection against wear. The degree or amount of wear is a measure of lubricant response. In contrast, the area of interest in a wear test, which can be conducted lubricated or dry, is the wear response of the material.

No general-purpose wear test exists that can establish a unique wear parameter or rating of a material. Consequently, a general discussion of wear testing must encompass overall methodology. This article presents a brief review of wear testing methods. Detailed information about significant wear mechanisms, tribological phenomena, and test methods appear in *Friction, Lubrication, and Wear Technology*, Volume 18 of the *ASM Handbook*, and in the article "Wear Testing" in *Mechanical Testing*, Volume 8 of the *ASM Handbook.*

Wear and Erosion Test Equipment

In the 1960s the American Society for Lubrication Engineers (ASLE) listed more than 200 types of wear tests and equipment in use (Ref 1), and the list has since grown. This wide variety is the result of a desire to ensure appropriate controls, make tests convenient, and simulate the wear conditions of the intended application.

The equipment described in Ref 2 includes apparatuses specifically designed for laboratory use. Although many of these test configurations are one-of-a-kind machines, others are available as commercial units.

Standards related to wear and erosion testing are listed in Ref 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, and 15. These standards do not suggest adequate test methods for wear or erosion resistance, but they relate to the testing of metals, plastics, refractory materials, and organic coatings. Reference 12 describes an abrasion tester that is essentially an air-blast erosion rig. Reference 13 describes an erosion tester that is similar but different in detail. References 14 and 15 describe air-blast erosion test rigs for coatings.

References 16, 17, 18, 19, 20, 21, 22, and 23 give design details of the three most commonly used erosion test rigs: air-blast rigs (Ref 16, 17, 18, 19), whirling arm rigs (Ref 20, 21, 22), and wind tunnel rigs (Ref 23). Reference 24 contains a general discussion of these erosion test methods.

Elements of a Wear Test

General elements of a wear test are simulation, acceleration, specimen preparation, control, measurement, and reporting. Simulation is the most critical, but no element of the application should be overlooked. Wear and wear phenomena can be influenced by load, environment, geometry, motion, the wearing mediums and counterface, and other factors.

Simulation ensures that the behavior experienced in the test is the same as in the application. Given the complexity of wear and the current incomplete understanding of wear and its phenomena, test development is subject to trial and error and is dependent on the capability of the developer. The ideal test exactly duplicates a wear situation. Generally, this is not practical, but any modifications in the test procedure should be carefully evaluated to obtain the most useful wear data.

General knowledge and experience can aid in assessing the differences between test and application, but correlations between test and application should also be studied. The most helpful correlation in developing a test is comparison of the worn surface and wear debris produced in the test to those produced in the application. For example, the morphology of the scar, the presence or absence of oxidized surface layers, changes in the microstructure of the material, and wear debris size, shape, and composition can be compared. If major features of the wear scar and debris are different, valid simulation is unlikely. Wear mechanisms frequently result in characteristic wear particles.

Measurement. Common direct measures of wear are mass or weight loss, volume loss or displacement, and scar width, depth, or other geometrical measures. Examples of indirect measures are the time required to wear through a coating, the load required to cause severe wear, and the load required to change surface reflectance. The selection of variables to measure wear is often based on convenience, the nature of the wear specimens, available techniques, and the amount of wear.

Material wear behavior can be compared by determining a wear curve or measuring wear at a single point in the test. Wear behavior frequently is complex, and a wear curve provides more information and allows evaluation of more complex behavior than single-point measurement. For example, the wear behaviors of two materials in the same test are plotted as functions of the number of sliding cycles (Fig. 1).

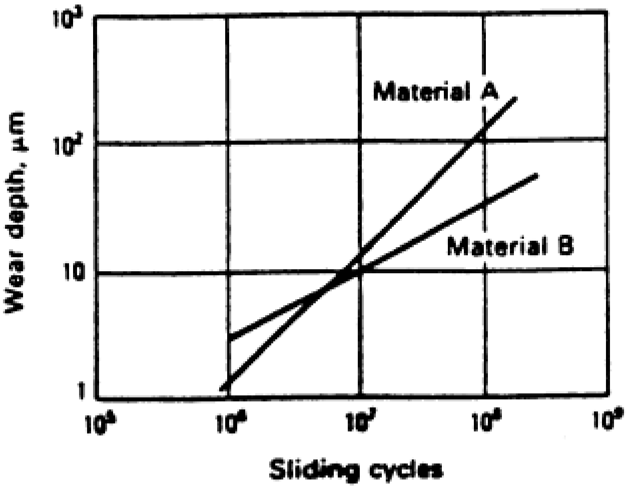

Fig. 1 Wear behavior of two materials in the same test

Reporting. Wear is a system response. When wear data are reported, a description of the wearing system must be supplied, including apparatus, geometry of contact, type of motion, load, speed, environmental condition, condition of wearing mediums, description of materials, description of lubricant and lubrication, description of wear-in period, and unusual observations, such as evidence of transfer.

Surface Engineering of Cast Irons

J.R. Davis, Davis & Associates

Introduction

THE TERM "CAST IRON," like the term "steel," identifies a large family of ferrous alloys. Cast irons primarily are alloys of iron that contain more than 2% carbon and from 1 to 3% silicon. Wide variations in properties can be achieved by varying the balance between carbon and silicon, by alloying with various metallic or nonmetallic elements, and by varying melting, casting, and heat-treating practices.

Cast iron is produced by adding excess amounts of carbon to an austenite structure. During solidification, a portion of this carbon separates from the melt as either iron carbide or graphite. The form that the excess carbon takes is determined by the rate of cooling. If the cooling is rapid, the carbon will solidify as iron carbide. If the cooling is slow, the carbon will solidify as graphite. The type of carbon present and its shape will determine the type and, in particular, the properties of the cast iron.

Following a brief review of the classification and characteristics of cast irons, this article will review the processes used to clean iron castings as well as surface treatments used to extend casting life when resistance to corrosion, wear, and erosion is required. Additional information on the cleaning and coating processes described herein can be found in the cited articles appearing elsewhere in this Volume.

Classification of Cast Irons

There are six basic types of cast irons and several varieties of each. The types of iron are classified as to how the excess carbon occurs in the microstructure. The correspondence between commercial and microstructural classification, as well as the final processing stage in obtaining common cast irons, is given in Table 1.

Table 1 Classification of cast iron by commercial designation, microstructure, and fracture

Commercial designation	Carbon-rich phase	Matrix[(a)]	Fracture	Final structure after
Gray iron	Lamellar graphite	P	Gray	Solidification
Ductile iron	Spheroidal graphite	F,P,A	Silver-gray	Solidification or heat treatment
Compacted graphite iron	Compacted vermicular graphite	F,P	Gray	Solidification
White iron	Fe_3C	P,M	White	Solidification and heat treatment[(b)]
Mottled iron	Lamellar Gr + Fe_3C	P	Mottled	Solidification
Malleable iron	Temper graphite	F,P	Silver-gray	Heat treatment
Austempered ductile iron	Spheroidal graphite	At	Silver-gray	Heat treatment

(a) F, ferrite; P, pearlite; A, austenite; M, martensite; At, austempered (bainite).

(b) White irons are not usually heat treated, except for stress relief and to continue austenite transformation.

White iron is essentially free of graphite, and most of the carbon content is present as separate grains of hard Fe_3C. White iron exhibits a white, crystalline fracture surface because fracture occurs along the iron carbide plates. White cast iron contains 2.0 to 3.6% C and 0.5 to 2.0% Si with high-alloy grades containing as much as 7% Ni, 28% Cr, and 3.5% Mo.

White cast irons have high compressive strength and good retentions of strength and hardness at elevated temperature, but they are most often used for their excellent resistance to wear and abrasion. The massive carbides in the microstructure are chiefly responsible for these properties.

Malleable iron contains compact nodules of graphite flakes. These are called "temper carbon" because they form during an extended annealing of white iron of a suitable composition. Malleable cast iron contains 2.2 to 2.9% C and 0.9 to 1.9% Si. Tensile strengths can range from 275 MPa (40 ksi) to 725 MPa (105 ksi).

Gray iron, the most commonly used cast iron, contains carbon in the form of graphite flakes. Gray iron exhibits a gray fracture surface because fracture occurs along the graphite plates (flakes). Gray irons usually contain 2.5 to 4.0% C, 1 to 3% Si, and 0.1 to 1.2% Mn. Tensile strengths range from 140 to 415 MPa (20 to 60 ksi) with higher strengths possible in high-alloy gray irons.

Gray cast iron has several unique properties that are derived from the existence of flake graphite in the microstructure. Gray iron can be machined easily at hardnesses conducive to good wear resistance. It resists galling under boundary-lubrication conditions (conditions wherein the flow of lubricant is insufficient to maintain a full fluid film). It has outstanding properties for applications involving vibrational damping or moderate thermal shock.

Ductile iron, also known as spheroidal graphite or nodular iron, contains spherulitic graphite in which the graphite flakes form into balls as do cabbage leaves. Ductile iron is so named because in the as-cast form it exhibits measurable ductility. Ductile iron typically contains 3 to 4% C, 1.8 to 2.8% Si, and 0.1 to 1.0% Mn. Alloying additions are sometimes made to ductile irons to improve heat and corrosion resistance. These alloyed grades may contain 1 to 6% Si, 0.7 to 2.4% Mn, 18 to 36% Ni, and up to 5.5% Cr.

The chief advantage of ductile iron over gray iron is its combination of high strength and ductility--up to 18% minimum elongation for ferritic ductile iron with a tensile strength of 415 MPa (60 ksi) as opposed to only about 0.6% elongation for a gray iron of comparable strength. Martensitic ductile irons with tensile strengths of about 830 MPa (120 ksi) exhibit at least 2% elongation.

Austempered Ductile Iron. If ductile iron is austenitized and quenched in a salt bath or a hot oil transformation bath at a temperature of 320 to 550 °C (610 to 1020 °F) and held at this temperature, transformation to a structure containing mainly bainite with a minor proportion of austenite takes place (Fig. 1). Irons that are transformed in this manner are referred to as austempered ductile irons. Austempering generates a range of structures, depending on the time of transformation and the temperature of the transformation bath. The properties are characterized by very high strength, some ductility and toughness, and often an ability to work harden, giving appreciably higher wear resistance than that of other ductile irons. Austempered ductile irons exhibit in excess of 5% elongation at tensile strengths exceeding 1000 MPa (145 ksi).

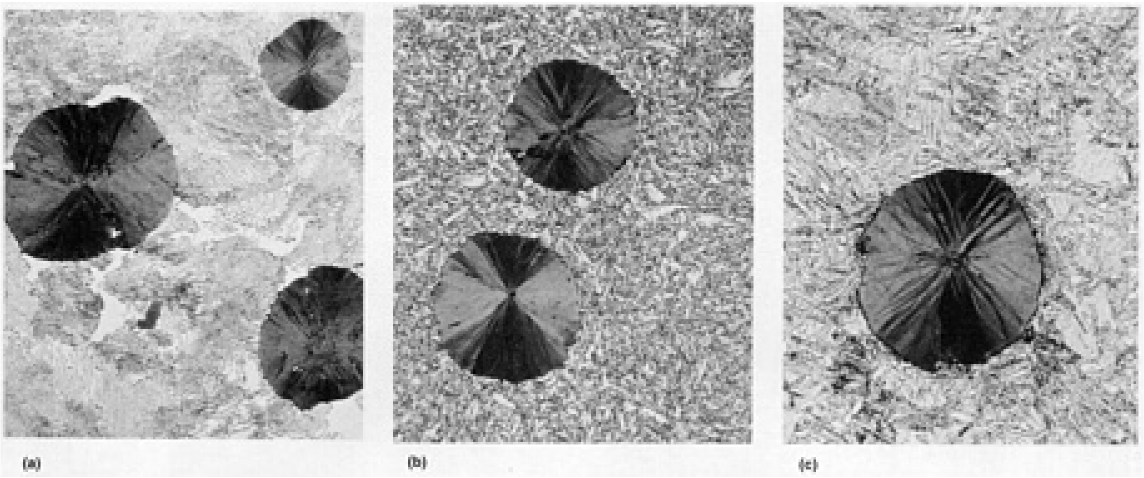

Fig. 1 Comparison of ductile iron microstructures. (a) Microstructure of normalized ductile iron showing pearlite matrix. (b) Microstructure (tempered martensite) of hardened-and-tempered ductile iron. (c) Microstructure of austempered ductile iron showing matrix of upper bainite and retained austenite. All etched in picral. 500×

Compacted graphite (CG), or vermicular graphite, irons have structures and properties that are in between those of gray irons and ductile irons. The graphite forms interconnected flakes as in a gray iron, but the flakes are shorter and thicker. The CG irons contain 2.5 to 4.0% C, 1.0 to 3.0% Si, with manganese contents varying between 0.1 and 0.6%, depending on whether a ferritic or pearlitic structure is desired.

High-alloy iron contains over three percent alloy content and is commercially classified separately. As indicated above, high-alloy irons may be a type of white iron, gray iron, or ductile iron. The matrix may be ferritic, pearlitic, martensitic, or austenitic, depending upon which alloying element dominates the composition. Table 2 lists approximate ranges of alloy content for various types of alloy cast irons used for abrasion-resistant, corrosion-resistant, and heat-resistant applications.

Table 2 Ranges of alloy content for various types of alloy cast irons

Description	Composition, wt%[(a)]									Matrix structure, as-cast[(c)]
	TC[(b)]	Mn	P	S	Si	Ni	Cr	Mo	Cu	
Abrasion-resistant white irons

Nickel-chromium-silicon iron[j]	1.8-2.6	0.4-1.0	0.10	0.10	5.0-6.0	13-43	1.8-5.5	1.0	10.0	A
High-aluminum iron	1.3-2.0	0.4-1.0	0.15	0.15	1.3-6.0	. . .	20-25 Al	. . .	. . .	F

Heat-resistant ductile irons										
Medium-silicon ductile iron	2.8-3.8	0.2-0.6	0.08	0.12	2.5-6.0	1.5	. . .	2.0	. . .	F
Nickel-chromium ductile iron[h]	3.0	0.7-2.4	0.08	0.12	1.75-5.5	18-36	1.75-3.5	1.0	. . .	A
Heat-resistant white irons										
Ferritic grade	1-2.5	0.3-1.5	. . .	. . .	0.5-2.5	. . .	30-35	. . .	. . .	F
Austenitic grade	1-2.0	0.3-1.5	. . .	. . .	0.5-2.5	10-15	15-30	. . .	. . .	A

(a) Where a single value is given rather than a range, that value is a maximum limit.

(b) Total carbon.

(c) CP, coarse pearlite; M, martensite; A, austenite; F, ferrite.

(d) Can be produced from a malleable-iron base composition.

(e) Copper can replace all or part of the nickel.

(f) Such as Duriron, Durichlor 51, Superchlor.

(g) Such as Ni-Resist austenitic iron (ASTM A 436).

(h) Such as Ni-Resist austenitic ductile iron (ASTM A 439).

(i) Such as Silal.

(j) Such as Nicrosilal

Cleaning of Castings

Cleaning of the surface is the most important prerequisite of any coating process. Suitable levels of cleanliness and surface roughness are established by various mechanical and nonmechanical methods. Foundries deliver castings that have been shot or grit blasted (see the discussion on blast cleaning below). Supplementary nonmechanical cleaning may be needed to reach interior passages or to remove heat-treating scale or machining oil.

The choice of cleaning process depends not only on the types of soils to be removed but also on the characteristics of the coating to be applied. The cleaning process must leave the surface in a condition that is compatible with the coating process. For example, if a casting is to be treated with phosphate and then painted, the cleaning process must remove all oils and oxide scale because these inhibit good phosphating.

If castings are heat treated before they are coated, the choice of heat treatment conditions can influence the properties of the coating, particularly a metallic or conversion coating. In most cases, heat treatment should be done in an atmosphere that is not oxidizing. Oxides and silicates formed during heat treating must be removed before most coating processes.

Mechanical Cleaning and Finishing

Mechanical cleaning and finishing methods most commonly employed for processing iron castings include abrasive blast cleaning (the most commonly used method for cleaning cast irons), abrasive waterjet cleaning and finishing, vibratory finishing, barrel finishing, and shot peening.

Blast cleaning of castings is a process in which abrasive particles are propelled at high velocity to impact the casting surface and thereby forcefully remove surface contaminants. The contaminants are usually adhering mold sand, burned-in sand, heat treat scale, and the like.

The usual methods of imparting high velocity to abrasive particles are by the use of either centrifugal wheels (Fig. 2) or compressed air nozzles. Centrifugal wheels are the most widely used method because of their ability to propel large volumes of abrasive efficiently. For example, a 56 kW (75 hp) centrifugal wheel can accelerate steel shot to 73 m/s (240 ft/s) at 55,800 kg/h (123,000 lb/h) flow. To do the same with 13 mm ($\frac{1}{2}$ in.) direct pressure venturi nozzles at 45 kg (100 lb)/min per nozzle would require approximately 20 nozzles and an air flow of 0.120 m^3/s/nozzle (260 ft^3/min/nozzle) × 20, or a total of 2.45 m^3/s (5200 ft^3/min) at 550 kPa (80 psi). Approximately 700 kW (940 hp) at the air compressor would be required to supply this amount of air, which gives a 700 kW/56 kW = 12.5 to 1 (940 hp/75 hp = 12.5 to 1) efficiency advantage for the centrifugal wheel.

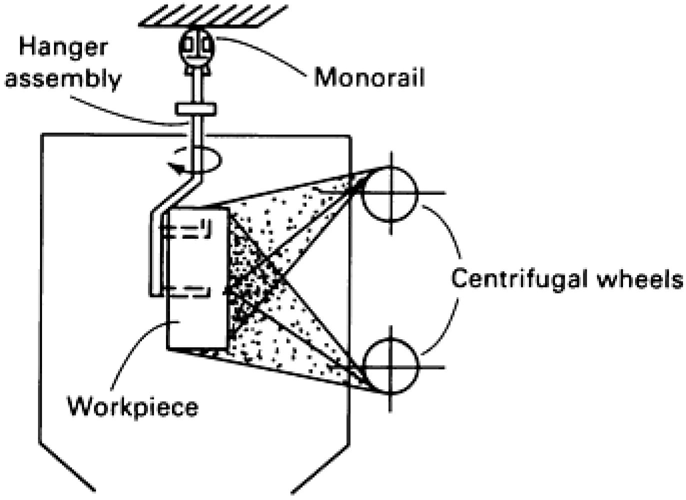

Fig. 2 Front view of a typical rotating hanger blast cleaning assembly. The workpiece is rotated 360° as it is held in position on the monorail track to provide full coverage by the blast pattern produced by the centrifugal wheels.

Even though the nozzle blast is not as efficient overall as the wheel blast, in some applications it may be more efficient because the blast stream can be more efficiently applied, when, for example, blasting into small holes to clean the interior areas of a casting. Other reasons for using a nozzle blast are requirements for:

- Low production
- Portability

- Suitability for very hard abrasives, such as aluminum oxide

More detailed information on the selection and design of blast cleaning equipment can be found in Ref 1 and the article "Mechanical Cleaning Systems" in this Volume.

In the past, chilled iron grit and malleable abrasives were used. Today, however, practically all the shot and grit used is high-carbon cast steel that is heat treated and drawn to give a desired tempered martensite microstructure and hardness. The hardness range of the most commonly used shot and grit is HRC 40 to 50. Harder shot and grit are also produced, with a range of HRC 55 to 65. For faster cleaning or special surface finish requirements, hard abrasive is not often used; but when it is, the wear on machine parts is high, and the abrasive breakdown rate is more rapid. This is especially true of hard grit. Table 3 lists commercially available shot and grit sizes.

Making a choice between shot and grit depends on the surface contaminants or the surface texture required. Grit is used when a chiselling action is required, for example, when removing rust, or perhaps to help remove burned-in sand or provide a good bonding surface for painting, plating, or enameling. Hard grit is used to clean the surface of bathtubs prior to enameling, where a definite tooth is required on the casting surface to provide for better adhesion of the enamel. In some cleaning applications, a shot and grit mixture may be used.

Abrasive Waterjet Cleaning. Although most often used as a cutting or machining process, the abrasive waterjet process has been tested for its use in degating and defining castings, as well as burn-in removal from castings. High-pressure waterjets (without abrasives) have also been tested for cleaning hydraulic passageways in castings. Using this process, coherent fluid jet is formed by forcing high-pressure 200 to 400 abrasive-laden water through a tiny sapphire orifice. The accelerated jet exiting the nozzle travels at more than twice the speed of sound and impinges on the workpiece. Results from a study from a foundry producing castings used in lawn, garden, and farm equipment are given in Ref 2. Detailed information on the use of abrasive waterjets for cutting metals and nonmetals can be found in Ref 3 and 4.

A vibratory finishing machine is an open-topped tub or bowl mounted on springs, usually lined with polyurethane. Parts and media are loaded in a fashion similar to that of a tumbling barrel (see the discussion on barrel finishing which immediately follows). With a vibratory machine, the container can be almost completely filled. Vibratory action is created either by a vibratory motor attached to the bottom of the container, by a shaft or shafts with eccentric loads driven by a standard motor, or by a system of electromagnets operating at 50 or 60 Hz. The action of media against components takes place throughout the load, so that process cycles are substantially shorter than conventional tumbling in barrels.

Vibratory finishing is used to clean the internal passages of cast iron cylinder heads and engine blocks. The internal passages of such components are rather intricate and it is usually difficult to reach all surface areas from any externally propelled form of cleaning. High pressure water, air blast, and shot blasting all would clean the internal surface areas that were located near an external opening; however, most of the internal passageways are hidden from this method of cleaning. Therefore, the vibratory media cleaner was introduced to clean these passages (Ref 5).

The media enters the internal passageways of the castings under the vibration of the vibratory machine and literally scrubs the surface walls of the internal cavities. The in-and-out movement of the media also carries core wash and sand from the internal passages of the castings, allowing removal of the material and providing a clean casting. Additional information on vibratory finishing can be found in the article "Mechanical Cleaning Systems" in this Volume.

Barrel Finishing. The rotary barrel, or tumbling barrel, utilizes the sliding movement of an upper layer of workload in the tumbling barrel, as shown in Fig. 3. The barrel is normally loaded about 60% full with a mixture of parts, media, compound, and water. As the barrel rotates, the load moves upward to a turnover point; then the force of gravity overcomes the tendency of the mass to stick together, and the top layer slides toward the lower area of the barrel. The rotation of the barrel causes the abrasive medium to scour the casting surfaces. Scale, sand, and even fins can be affectively removed during tumbling. Additional information on barrel finishing can be found in the article "Mechanical Cleaning Systems" in this Volume.

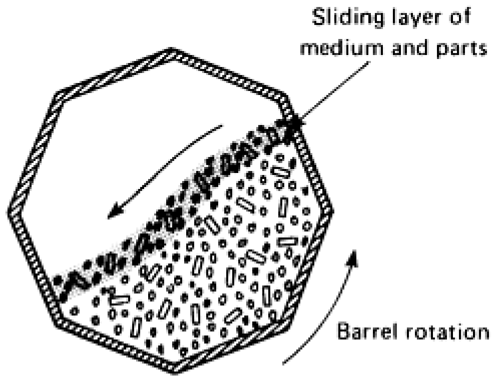

Fig. 3 Action of media and parts within a rotating barrel

Shot peening is a method of cold working in which compressive stresses are induced in the exposed surface layers of cast iron parts by the impingement of a stream of steel shot, directed at the surface at high velocity under controlled conditions. It differs from blast cleaning in primary purpose and in the extent to which it is controlled to yield accurate and reproducible results. Although shot peening cleans the surface being peened, this function is incidental. The major purpose of shot peening is to increase fatigue strength.

Both the benefits in improved fatigue strength and increased surface hardness have been shown in studies on shot peened austempered ductile iron gears (Ref 6). In cases where severe grinding operations are performed on a gear, resultant surface tensile stresses can have a negative impact on part endurance. Peening after the grinding operation can increase the endurance limit even above the original gentle grind design condition, as shown in Fig. 4.

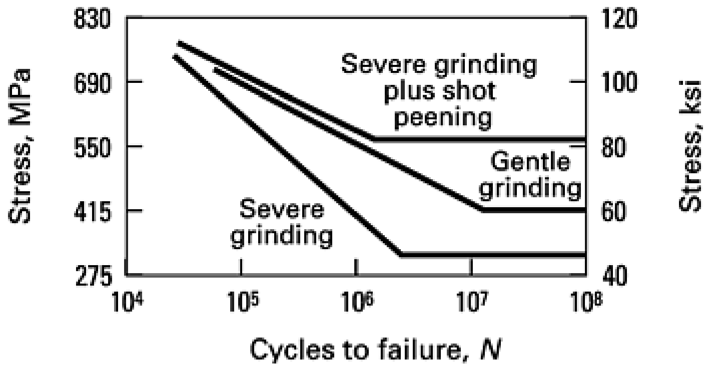

Fig. 4 Effect of shot peening on the fatigue strength of a ground component. A part designed for a gentle grinding operation could be salvaged by shot peening after a severe grinding operation. Source: Ref 6

When fatigue problems occur, one of the solutions is to eliminate stress risers in the part by polishing or other surface refining process. Though the stress riser in the material tends to be reduced, any subsequent scarring of the surface in application can greatly reduce any benefits of the polishing operation. Costs to produce a surface finish finer than a 125 rms will usually increase substantially.

Instead of polishing the surface, shot peening will produce a compressed stress layer below the surface of the material that will prevent crack propagation and increase fatigue strength. Not only can this be used as a salvage technique, but it can be used as a cost reducer by eliminating the need for the added polishing costs.

In cases where uniform casting texturing is required, the controls used in the peening process can impart a finish that is homogenous in appearance. In this situation, the benefits of the compressive stress to produce improved fatigue strength may not be critical, and surface texture selection will most likely determine shot size and application intensity.

To retain the fatigue strength benefits produced by peening, no more than 10% of the depth of compression can be removed by the subsequent machining operation. Shot peening should be performed after heat treating so that the compressive stresses and reduction of fatigue strength are not dissipated as heat treating temperature approaches stress relieving temperature.

Nonmechanical Cleaning

Nonmechanical cleaning methods applicable to cast irons include molten salt bath cleaning, pickling, and chemical cleaning with the latter method including acid cleaning, solvent cleaning, vapor degreasing, and emulsion cleaning. Articles on each of the aforementioned processes can be found in the Section on "Surface Cleaning" in this Volume.

Molten salt baths are excellent for cleaning complex interior passages in castings. In one electrolytic, molten salt cleaning process, the electrode potential is changed so that the salt bath is alternately oxidizing and reducing. Scale and graphite are easily removed with reducing and oxidizing baths, respectively. Molten salt baths are fast compared to other nonmechanical methods, but castings may crack if they are still hot when salt residues are rinsed off with water.

Pickling of cast iron is usually done prior to hot dip coating or electroplating. When pickling is used, the castings are cleaned in solutions containing sulfuric and hydrofluoric acids. The concentration of each acid depends on whether the primary purpose is to remove sand or scale. Increased hydrofluoric acid is needed to remove embedded sand from the casting surface, whereas sulfuric or hydrochloric acids are sufficient for simple scale removal. Table 4 gives the operating conditions for pickling iron castings. Before being pickled, castings must be free of oil, grease, and other contamination. After being removed from the pickling solution, castings are rinsed thoroughly in hot water. Residual heat permits self-drying, but drying may be accelerated by the use of fans. For complex shaped castings, baking ovens may be employed.

Table 4 Operating conditions and solution compositions for pickling cast irons

Operating	Sand	Scale

variable	removal	removal
Sulfuric acid, vol%	5	7
Hydrofluoric acid, vol%	5	3
Water, vol%	90	90
Temperature[(a)], °C (°F)	65-85 (150-185)	50 to over 85 (120 to over 185)
Average immersion time, h	4	4

(a) 50 °C (120 °F) is for slow pickling, 65 to 85 °C (150 to 185 °F) for average pickling speed, and over 85 °C (185 °F) is for fast pickling.

Acid cleaning is a process in which a solution of a mineral acid, organic acid, or acid salt, in combination with a wetting agent and detergent, is used to remove oxide, shop soil, oil, grease, and other contaminants from metal surfaces, with or without the application of heat. The distinction between acid cleaning and acid pickling is a matter of degree, and some overlapping in the use of these terms occurs. Acid pickling is a more severe treatment for the removal of scale from castings, whereas acid cleaning generally refers to the use of acid solutions for final or near-final preparation of metal surfaces before plating, painting, or storage.

Mixtures of 70 wt% phosphoric acid, 5 wt% ethylene glycol monobutyl ether, and 25 wt% water are used for removing grease, oil, drawing compounds, and light rust from iron and steel. This mixture is adaptable to immersion, spray, or wiping methods and leaves a light phosphate coating (100 to 320 mg/m^2, or 10 to 30 mg/ft^2) that provides a paint base or temporary resistance to rusting if the parts are to be stored.

Acid solutions of 40 to 60 vol% hydrochloric or 6 to 8 vol% sulfuric (often containing up to 1% inhibitor) are used at room temperature for removing soil and light rust. Stronger solutions of these acids are used in electrolytic baths for final cleaning of cast irons before electroplating. Various soils, including light rust, may also be removed by combining acid cleaning and barrel finishing.

Other Chemical Cleaning Methods. Organic solvents that were commonly used in the past include naphtha, benzene, methanol, toluene, and carbon tetrachloride. These have been largely replaced by chlorinated solvents, such as those used for vapor degreasing. Solvents effectively remove lubricants, cutting oils, and coolants, but are ineffective against such inorganic compounds such as oxides or salts. Emulsion cleaners are solvents combined with surfactants; they disperse contaminants and solids by emulsification. Emulsion cleaners are most effective against heavy oils, greases, slushes, and solids entrained in hydrocarbon films. They are relatively ineffective against adherent solids such as oxide scale.

After wet cleaning, short-term rust prevention is accomplished by the use of an alkaline rinse. This can be followed by the application of mineral oils, solvents combined with inhibitors and film formers, emulsions of petroleum-base coatings and water, and waxes. A summary of the temporary coatings used for corrosion protection is given in Table 5.

Table 5 Temporary coatings used for corrosion protection

Type	Coating structure	Thickness, μm (mils)	Removal method	Uses

Oil	Non-drying mineral oil viscosity determines coating thickness	5-7 (0.2-0.3)	Seldom required; solvent rinsing, emulsion spray, or vapor degreasing	Finished automotive parts; galvanized irons
Solvent	Petroleum-based inhibitors and film formers dissolved in petroleum solvents	5-50 (0.2-2.0)	Seldom required; solvent rinsing or alkaline washing	External surfaces of machinery parts and tooling. Can be used outdoors
Emulsified	Petroleum-based coating modified to form a stable emulsion with water	5 (0.2)	Removal seldom necessary; solvent rinsing	Same as above, but suggested for indoor use
Wax	Wax layer applied heated or in a volatile solvent	38-75 (1.5-3.0)	Solvent rinsing or alkaline cleaning	Highly finished parts stored for prolonged periods

Electroplating and Electroless Plating

Cast irons are most commonly plated with chromium, nickel, copper, cadmium, and zinc. In addition, gold, lead, and rhodium are used for specialized applications. Alloy coatings, such as brass, bronze, and tin-base compositions, are used for decorative purposes. As shown in Table 6, each electroplated coating has its own characteristic properties.

Table 6 Properties and characteristics of conventional electroplated metal coatings

Metal	Coating hardness	Appearance	Thickness		Characteristics and uses
			μm	mil	
Cadmium	30-50 HV	Bright white	3-10	0.15-0.5	Pleasing appearance for indoor applications; less likely to darken than zinc; anodic to ferrous substrate
Chromium	900-1100 HV	White--can be varied	0.2-1[(a)] 1-300[(b)]	0.01-0.06[(a)] 0.05-	Excellent resistance to wear, abrasion, and corrosion; low friction and high reflectance

				12.0[b]	
Cobalt	250-300 HK	Gray	2-25	0.1-1.0	High hardness and reflectance
Copper	41-220 HV	Bright pink	4-50	0.2-2.0	High electrical and thermal conductivities; used as undercoat for other electroplates
Lead	5 HB	Gray	12-200[c] 1300[d]	0.5-8.0[c] 50[d]	Resistant to many acids and hot corrosive gases
Nickel	140-500 HV	White	2-40[a] 130-500[c]	0.1-1.5[a] 5-20[c]	Resistant to many chemicals and corrosive atmospheres; often used in conjunction with copper and chromium; can be applied by electroless plating
Rhodium	400-800 HB	Bright white	0.03-25	0.001-1.0	High electrical conductance; brilliant white appearance is tarnish and corrosion resistant
Tin	5 HB	Bright white	4-25	0.015-1.0	Corrosion resistant; hygienic applications for food and dairy equipment; good solderability
Zinc	40-50 HB	Matte gray	2-13[a] 12-50[d]	0.1-0.5[a] 0.5-2.0[d]	Easily applied; high corrosion resistance; anodic to ferrous substrate

(a) Decorative.

(b) Hard.

(c) Wear applications.

(d) Corrosion applications.

Iron castings are electroplated to impart corrosion resistance or to provide a pleasing appearance. Typical applications include many different types of interior hardware, machine parts such as printing cylinders, decorative trim, and casings. Iron castings are also electroplated to enhance their wear resistance; for example, hard chromium plating is applied to the wear surfaces of piston rings (see the discussion below on chromium plating). Areas not requiring a plated surface can be masked or stopped off to prevent coverage. Plating can be applied as a very thin layer for applications requiring only a pleasing appearance or mild corrosion resistance; thicker plating can be applied for more wear resistance, longer corrosion resistance, or to replace lost metal (Table 6).

Electrodeposition is done by making clean iron castings cathodic in an aqueous solution containing a salt of the coating metal and then passing a direct electrical current through the solution. The effective metal content in the plating bath can be replenished by using anodes made of the coating metal to complete the electrical circuit. Variations in the properties of the deposited coating are influenced by the composition, temperature, pH, and agitation of the bath and by current

density. In addition, further variations in the coating can result from the design of the casting, the distance of the casting from the anode, and the preparation of the surface before plating.

This section will review the types of platings applied to cast irons for corrosion or wear resistance. More detailed information on the equipment and plating solutions used for these processes can be found elsewhere in this Volume (see the articles in the Section on "Plating and Electroplating"). Additional information on corrosion and wear characteristics of electroplated coatings can also be found in Volume 13, *Corrosion,* and Volume 18, *Friction, Lubrication, and Wear Technology,* of the *ASM Handbook.*

Chromium Plating. Both hard and decorative chromium electroplates are deposited on cast iron substrates. Commercially, hard chromium is deposited from four types of efficiency etch-free baths. All of the baths contain chromic acid (CrO_3) and sulfate (SO_4^{2-}). The SO_4^{2-} acts as a catalyst. Chromium cannot be electrodeposited from an aqueous CrO_3 solution unless one or more catalysts are present. Depending on which catalysts are present and the plating parameters, between 10 and 45% of the cathodic current will be used to reduce hexavalent chromium (Cr^{6+}) to chromium metal. The properties of the electrodeposits are influenced by the ratio of CrO_3 to the catalysts, plating temperature, and current density. Chromic acid to sulfate ratios vary between 75 to 1 and 120 to 1, plating temperatures range from 45 to 65 °C (110 to 150 °F), and current densities from 10 to 90 A/dm^2 (0.65 to 6 A/in.^{2}).

Hard chromium plating, which is also known as industrial chromium plating, differs from decorative chromium plating in the following ways:

- Hard chromium deposits are intended primarily to increase service life of function parts by increasing their resistance to wear, abrasion, heat, or corrosion. Deposits are also applied to restore dimensions of undersized parts
- Hard chromium normally is deposited to thicknesses ranging from 2.5 to 500 μm (0.1 to 20 mils) and for certain applications to considerably greater thicknesses (up to 6000 μm, or 240 mils) whereas decorative coatings seldom exceed 1.3 μm (0.05 mil)
- With certain exceptions, hard chromium is applied directly to the base metal; decorative chromium is applied over undercoats of nickel or of copper and nickel, and is either buffed or used in the as-plated condition

One of the most prevalent applications for chromium plated cast irons is that of hard plated piston rings. Gray cast iron, with a hardness ranging from 200 to 400 HB, is the most commonly used material for piston rings. Table 7 shows the various types of cast irons used in gasoline engine piston rings. Pearlitic gray iron produced by either centrifugal or sand casting methods has the widest use. In heavy-duty engine applications, alloy cast iron, ductile iron, and malleable iron are used. Harder materials, such as carbon steel or even bearing steels, may also be used.

Table 7 Typical piston ring materials

Type	Approximate specification	Manufacturing method	Range of composition, wt% (balance iron)									Tensile strength		Modulus of elasticity		Hardness HB

Relatively thick coatings (up to 0.2 mm, or 0.008 in.) of plated chromium on the ring periphery provide the best compromise between scuffing, wear, and corrosion resistance and low friction and oxidation resistance at high temperatures. Generally, the use of chromium-plated top rings (with a hardness of 700 to 900 HV) run against cast iron cylinder liners can reduce the ring and liner wear by a factor of 2 to 3 (Ref 8). More detailed information on chromium plating can be found in the articles "Industrial (Hard) Chromium Plating" and "Decorative Chromium Plating" in this Volume.

Electrolytic nickel plating may be categorized as general purpose, special purpose wear-resistant, or bright. General purpose nickel plating is applied for protection against corrosive attack but is also used to build up worn or undersized parts. Wear-resistant nickel plating is used in engineering applications that require abrasion and corrosion resistance as well as surface smoothness. Bright nickel plating is used to provide decorative finishes and is frequently used as a base for a very thin chromium plate. Unless polished occasionally, all nickel plate will tarnish with a yellow cast after long exposure. Severely corrosive atmospheres will turn nickel green. Nickel plating of iron castings does not present any unusual problems, and the cleaning techniques prior to plating often are the same as for low-carbon steel. Three types of general-purpose baths are used for nickel plating: Watts, sulfamate, and fluoborate. A variety of proprietary organic and metallic brighteners, levelers, and antipitting agents are available to tailer the degree of brightness, reflectivity, and hardness desired.

The hardness of nickel deposits can vary from about 150 to 500 HV depending on the plating conditions (current density, solution pH and temperature, and composition). The widest use of electroplated nickel for wear applications is as an undercoat for chromium (Ref 9). If thick deposits are needed, for example, in building up heavily worn parts, it is usually not practical to do so using only chromium plating, because of its low current efficiency and high internal stress. In such cases, most of the deposit thickness is composed of nickel, with chromium constituting only a thin outer layer. For additional information, see the articles "Nickel Plating" and "Nickel Alloy Plating" in this Volume.

Electroless nickel plating is used to deposit nickel without the use of an electric current. The coating is deposited by an autocatalytic chemical reduction of nickel ions by sodium hypophosphite, sodium borohydride, or organic aminoboranes. When sodium hypophosphite is the reducing agent, the deposit generally contains between 3 and 11 wt% phosphorus. The boron contents of electroless nickel range from 0.2 to 4 wt% and from 4 to 7 wt% when the reducing agents are an aminoborane and sodium borohydride, respectively.

The structure of the deposit changes from microcrystalline to amorphous, with increasing alloy content. If the phosphorous content is above about 10 wt%, the coating is amorphous and therefore lacks grain boundaries or other crystalline defects at which corrosion can be initiated. Electroless nickel has some advantage over electrolytic nickel in that its thickness and phosphorus content are uniform over the substrate and independent of substrate geometry.

Electroless nickel can be heat treated to hardnesses comparable to those of electrodeposited chromium. The maximum hardness can be attained in 1 h at about 400 °C (750 °F) or 10 h at 260 °C (500 °F). The hardness of as-plated Ni-P alloys varies from 500 to 650 HV. As-plated Ni-B deposits are generally harder than the Ni-P ones. The ability of electroless nickel deposits to maintain their hardness under elevated-temperature service conditions increases with increasing phosphorus or boron content, but decreases rapidly above 385 °C (725 °F). Nickel-boron coatings tend to better withstand wear at elevated temperatures and are therefore more widely used under these conditions.

Electroless nickel is most frequently used in wear applications in the precipitation-hardened condition. The improved abrasion and wear resistance after heat treating is evident from Fig. 5. Although the greatest hardness was obtained by heat treatment at 400 °C (750 °F), the electroless nickel that was heat treated at 600 °C (1110 °F) showed the least wear. However, the corrosion resistance of as-plated Ni-P coatings, which is one of the main reasons for their use, deteriorates upon heat treating to the maximum hardness, because of cracking. Therefore, under corrosion or corrosive wear applications, the higher hardness should be avoided.

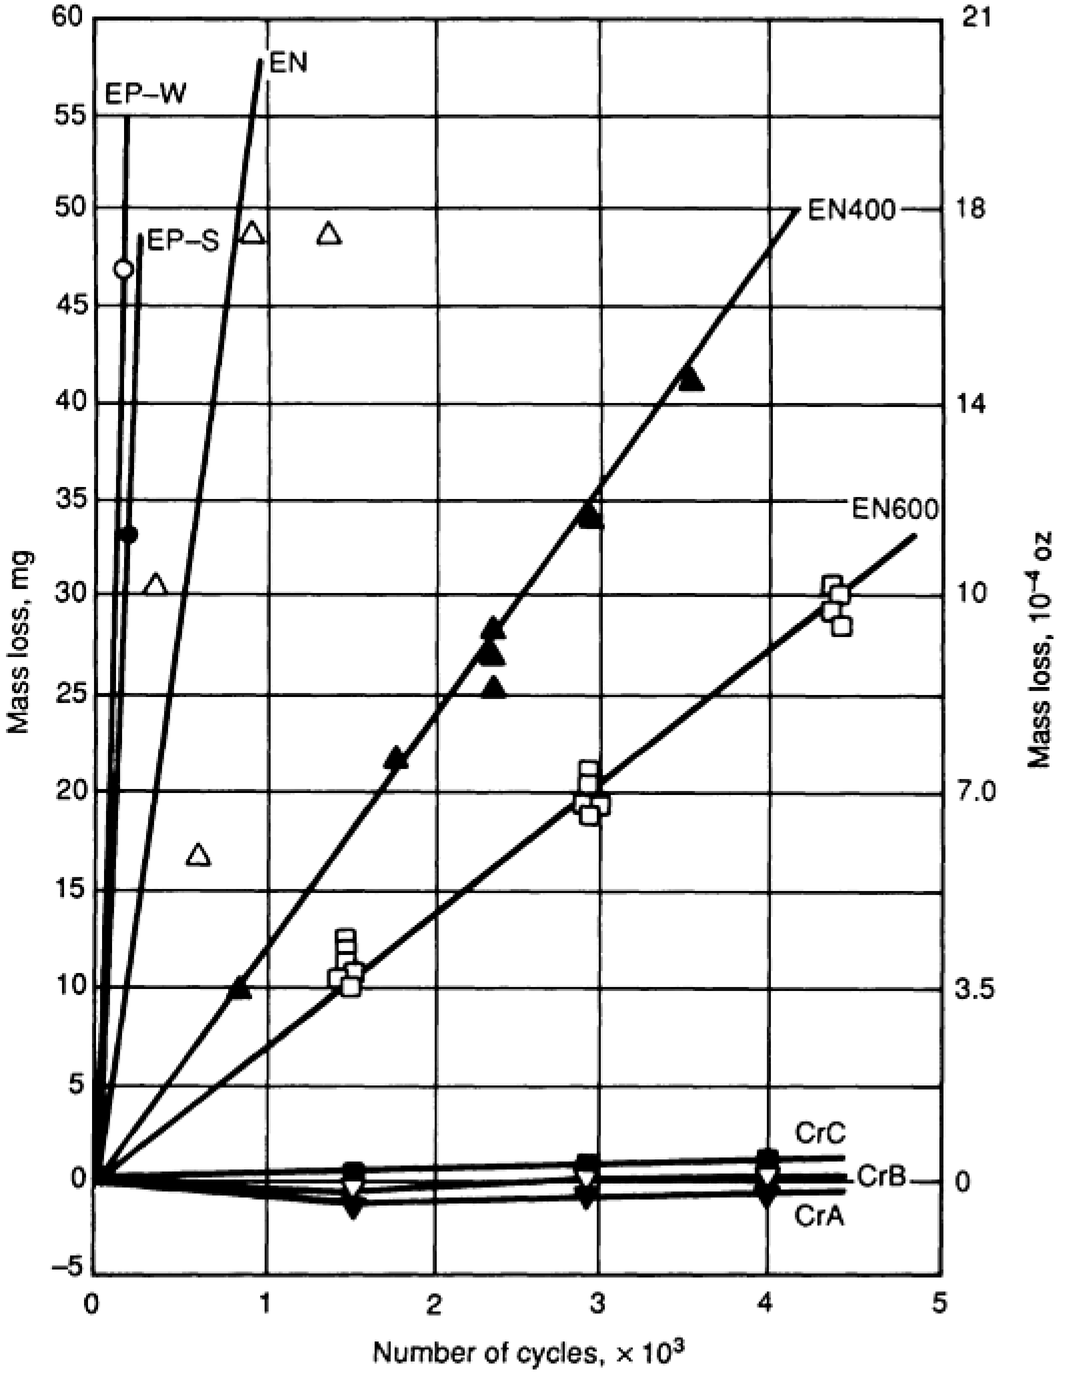

Fig. 5 Effect of number of cycles on wear loss of plated pin versus steel blocks in a Falex test for three chromium deposits (CrA, CrB, and CrC), heat treated electroless nickel deposits (EN400 and EN600), a non-heat-treated electroless nickel deposit (EN), and two electroplated nickel deposits from a sulfamate solution (EP-S) and a Watts solution (EP-W). Source: Ref 9

The widest use of electroless nickel for both corrosion and wear resistance is in complex-shaped cast iron valves that control the flow of either liquids or gases. Another important application for electroless nickel-plated cast irons is printing rolls which must have an especially uniform surface to function properly.

Copper Plating (Ref 7). Electroplated copper usually functions as an underplate for nickel and chromium plating. It provides a desirable base surface because it can be easily deposited in a uniform, pore-free, and ductile condition. Copper underplates also enhance buffing and polishing when multiple-layer plating is used. Copper itself is relatively corrosion resistant, but is subject to tarnishing and staining. It is occasionally used alone for decorative effect, but should be

provided with an overcoat of lacquer. Some use of copper plating is made to facilitate soldering iron to other materials, such as copper tubing.

Anodic Electroplates. Electrodeposits of cadmium and zinc are used extensively to protect cast iron against corrosion. Because these metals are anodic to iron, the underlying ferrous metal is protected at the expense of the electroplate, even if the coating becomes scratched or nicked, exposing the substrate. Cadmium is generally preferred for the protection of cast irons in marine atmospheres and zinc is preferred in industrial environments. Cadmium is much more toxic than zinc, and applications in which its corrosion products may get into the environment should be avoided. The corrosion performance of both cadmium and zinc is greatly enhanced by chromate conversion coatings.

Most cadmium plating is carried out in alkaline cyanide baths prepared by dissolving cadmium oxide (CdO) in a sodium cyanide (NaCN) solution. Sodium hydroxide (NaOH) and sodium carbonate (Na_2CO_3) are formed by reactions within and are part of this bath. Cadmium balls suspended in steel wire cages serve as the plating anodes. Typical bath compositions suitable for various plating methods and workpieces are summarized in Table 8.

Table 8 Alkaline cyanide cadmium plating baths

Total NaCN-to-Cd ratio	Concentration, g/L (oz/gal)				
	Cd	CdO	NaCN	NaOH	Na_2CO_3
4.0	19.5 (2.6)	22.5 (3.0)	77.9 (10.4)	14.2 (1.9)	30-75 (4-10)
4.1	19.5 (2.6)	22.5 (3.0)	80.1 (10.7)	59.9 (8.0)	30-45 (4-6)
4.5	36 (4.8)	41.2 (5.5)	161.8 (21.6)	25.5 (3.4)	30-45 (4-6)
5.0	20.2 (2.7)	22.5 (3.0)	101.1 (13.5)	14.2 (1.9)	30-60 (4-8)
7.2	19.5 (2.6)	22.5 (3.0)	136.3 (18.2)	14.2 (1.9)	30-45 (4-6)

The choice of a plating bath depends on the size and configuration of the workpiece being plated. Large numbers of small parts are most conveniently barrel plated with solutions of a lower NaCN-to-Cd ratio, while larger parts with intricate and recessed surfaces must be coated by still plating techniques of high throwing power. Automatic plating is normally used for intermediate size products which are arranged on racks and then automatically sequenced through a plating procedure.

Organic or metallic compounds are often added to alkaline cyanide cadmium plating baths to influence the formation of the electrodeposited cadmium crystals and thus the brightness of the coating. They are largely proprietary and, among the organics, include:

- Aldehydes
- Coumarin
- Dextrin
- Furfural
- Gelatin
- Milk
- Molasses
- Sugar

- Some sulfonic acids

Metallic brighteners include nickel, cobalt, molybdenum and selenium compounds.

Best results are achieved by a moderate use of both types. Excessive amounts of the organic brighteners are less harmful in that they ultimately hydrolyze and become harmless. Metallic brighteners should never be used unless technical facilities and competent personnel are available. Baths which are used excessively and which contain large amounts of organic brighteners must be filtered frequently or continuously. Other considerations in bath selection for both cyanide and non-cyanide plating baths can be found in the article "Cadmium Plating" in this Volume.

As shown in Table 9, cadmium is usually applied as a thin coating (less than 25 μm, or 1 mil thick) intended to withstand atmospheric corrosion. It is seldom used as an undercoating for other metals, and its resistance to corrosion by most chemicals is low.

Table 9 Recommended minimum thicknesses and corrosion characteristics for zinc and cadmium coatings electrodeposited on cast iron

Service conditions	Coating thickness		Chromate finish	Time to white corrosion in salt spray, h
	μm	mils		
Electrodeposited zinc				
Mild (indoor atmosphere; minimum wear and abrasion)	5	0.2	None	. . .

Thickness specified is after chromate conversion coating, if used.

Source: Ref 11

(a) There are some applications for cadmium coatings in this environment; however, these are normally satisfied by hot-dipped or sprayed coatings.

Zinc, like cadmium, is also anodic to cast iron and therefore offers more protection when applied in thin films of 7 to 15 μm (0.3 to 0.5 mil) than similar thicknesses of nickel and other cathodic coatings. Because it is relatively inexpensive and readily applied in barrel, tank, or continuous plating facilities, zinc is often preferred for coating iron and steel parts when protection from either atmospheric or indoor corrosion is the primary objective. Table 9 lists the recommended minimum thicknesses and corrosion characteristics of zinc electrodeposits.

The adherence of electrodeposited zinc coatings depends on the metal-to-metal bond between the plated coating and the underlying cast iron surface. Therefore, particular attention must be given to the preparation of the surface before plating to obtain a coating in true physical contact with the entire casting surface.

The usual method of removing all rust, scale, and grease from the cast iron surface involves cleaning the surface thoroughly in a hot alkaline bath by soaking the parts for a short period of time. This is often followed by use of an electrolytic alkaline cleaner and a spray alkaline cleaner. An acid dip is then carried out to remove oxides and scale. There must be adequate rinsing between the alkaline/acid baths and the acid/plating baths to avoid contamination of the plating bath by carryover from the cleaning baths.

Zinc plating is done in an acid or an alkaline bath. Although the alkaline-cyanide zinc baths are the most efficient and have the best throwing power, they do create a serious pollution problem. Therefore, more acid zinc baths are being used. Acid bath compositions and operating conditions are described in the article "Zinc Plating" in this Volume.

Various brightening agents may be added to the baths to give a deposit that is more lustrous than that obtained from normal zinc plating baths. The amount of brightening agent requires very careful control, and the bath and the zinc anode must both be kept particularly pure when brighteners are used.

Hot Dip Coatings

Hot dip coating consists of immersing the casting in a bath of molten metal. A flux-coated and/or chemically cleaned surface is necessary to achieve satisfactory results. Aluminum, tin, zinc, and their alloys can be applied from a molten bath. Hot dip coatings are preferred because they are thicker than electroplates and because an alloy layer is formed between the coating metal and the iron. This provides additional durability and adhesion. Castings of complex shape are easily coated by these processes, although air may become trapped in blind holes unless the castings are rotated. More detailed information on hot dip coating is available in the articles "Continuous Hot Dip Coatings" and "Batch Hot Dip Galvanized Coatings" in this Volume.

Hot dip zinc coating (galvanizing) is widely used on iron castings, particularly pipe, valves, and fittings. The uniform and adherent coating provides a barrier against corrosive attack and will further protect an iron casting by acting as a sacrificial anode or by undergoing preferential corrosion. Successful galvanizing depends on surface preparation. Pickling followed by dipping in a bath of zinc ammonium chloride or other flux is done prior to dipping in molten zinc. Excess zinc may be drained or centrifuged from the castings before quenching. Quenching improves the brightness of the coating. Iron castings of any type and any composition can be hot dip galvanized.

Hot dip tin coating (hot tinning) provides a protective, decorative, and nontoxic coating for food equipment, a bonding layer for babbitted bearings, or a precoated surface for soldering. Surface preparation is particularly important, and when maximum adherence is desired, such as when tinning is used to prepare a casting for the application of babbitt, electrolytic cleaning in a molten salt is preferred.

For the hot dip lead coating of iron castings, lead-base alloys are preferred over pure lead; with pure lead, bonding is mechanical rather than metallurgical. Tin is the element most widely used to enhance bonding. Lead coatings are noted for their resistance to fumes from sulfuric and sulfurous acids.

The aluminum coating (aluminizing) of iron castings imparts resistance to corrosion and heat. The coating oxidizes rapidly, thus passivating the surface. The resultant aluminum oxide is refractory in nature; it seals the surface and resists degradation at high temperatures. An aluminized surface has limited resistance to sulfur fumes, organic acids, salts, and compounds of nitrate-phosphate chemicals.

Hardfacing and Weld Cladding

Hardfacing can be used when a casting requires an unusually hard and wear-resistant surface and when it is impractical to produce a hard surface in the casting process or by selective heat treatment. Frequently, hardfacing is used to repair worn castings by building up an overlay of new material.

Hardfacing is basically a welding operation in which an alloy is fused to the base metal by oxyfuel welding, arc welding, laser welding, or thermal spray processes. Hardfacing materials include a wide variety of alloys, carbides, and combinations of these materials. Conventional hardfacing materials, also referred to as weld overlays, are normally classified as steels or low-alloy ferrous materials, high-chromium white irons or high-alloy ferrous materials, carbides, nickel-base alloys, or cobalt-base alloys. A few copper-base alloys are sometimes used for hardfacing applications, but for the most part, hardfacing alloys are either iron-, nickel-, or cobalt-base.

Microstructurally, hardfacing alloys generally consist of hard phase precipitates such as borides, carbides, or intermetallics bound in a softer iron-, nickel, or cobalt-base alloy matrix. Carbides are the predominant hard phases in iron- and cobalt-base hardfacing alloys. Carbon contents of iron- and cobalt-base hardfacing alloys generally range up to 4 wt%. Borides, as well as carbides, are the predominant hard phases in nickel-base hardfacing alloys. Combined carbon plus boron contents generally range up to 5 wt%. The specific carbide and/or boride phases that form are determined by matrix alloying additions.

Hardfacing alloys usually are available as bare rod, flux-coated rod, long-length solid wires, long-length tube wires (with and without flux), or powders. The most popular processes, and the forms most commonly associated with each process, are:

Hardfacing process	**Consumable form**
Oxyfuel/oxyacetylene (OFW/OAW)	Bare cast or tubular rod
Shielded metal arc (SMAW)	Coated solid or tubular rod (stick electrode)
Gas-tungsten arc (GTAW)	Bare cast or tubular rod
Gas-metal arc (GMAW)	Tubular or solid wire
Flux-cored open arc	Tubular wire (flux cored)

Submerged arc (SAW)	Tubular or solid wire
Plasma transferred arc (PTA)	Powder
Laser beam	Powder

Detailed information on hardfacing materials, hardfacing alloy selection, and hardfacing process selection can be found in Ref 12. Producers of hardfacing alloys should also be consulted for technical assistance.

A weld clad is a relatively thick layer of filler metal applied to a cast iron base metal for the purpose of providing a corrosion-resistant surface. Weld cladding is normally carried out by arc welding. Materials deposited on cast irons to improve their corrosion performance include copper-base alloys, stainless steels, and nickel-base alloys.

Problems due to dilution of stainless steel or nickel-base filler metals can be minimized by first depositing a buffer layer of low-carbon nickel prior to the application of the cladding alloy. Dilution of the base iron casting into the weld deposit can also be kept to a minimum by:

- Maximizing the amount of metal deposited per unit length. The beads being deposited should be overlapped as much as possible
- Minimizing the amount of heat input in order to reduce the amount of base metal melting. The use of straight-polarity dc current will help decrease the penetration

Caution must be exercised when considering the reduction in penetration or melting of the cast iron substrate. The deposited weld metal must melt part of the casting to adhere properly. A rule of thumb is that a minimum of 5 to 10% dilution is needed for complete fusion.

Thermal Spraying

Thermal spraying comprises a group of processes in which divided molten metallic or nonmetallic material is sprayed onto a prepared substrate to form a coating. The sprayed material is originally in the form of wire, rod, or powder. As the coating materials are fed through the spray unit, they are heated to a molten or plastic state and propelled by a stream of compressed gas onto the substrate. As the particles strike the surface, they flatten and form thin platelets that conform and adhere to the irregularities of the prepared surface and to each other. They cool and accumulate, particle by particle, into a lamellar, castlike structure. In general, the substrate temperature can be kept below approximately 200 °C (400 °F), eliminating metallurgical change of the substrate material. The spray gun generates the necessary heat for melting through combustion of gases, an electric arc, or a plasma. Figure 6 illustrates a general thermal spraying process. Figure 7 illustrates the microstructure that results from the thermal spray process. As shown in this figure, the molten particles spread out and deform (splatter) as they impact the substrate, at first locking onto irregularities on the roughened surface, then interlocking with each other.

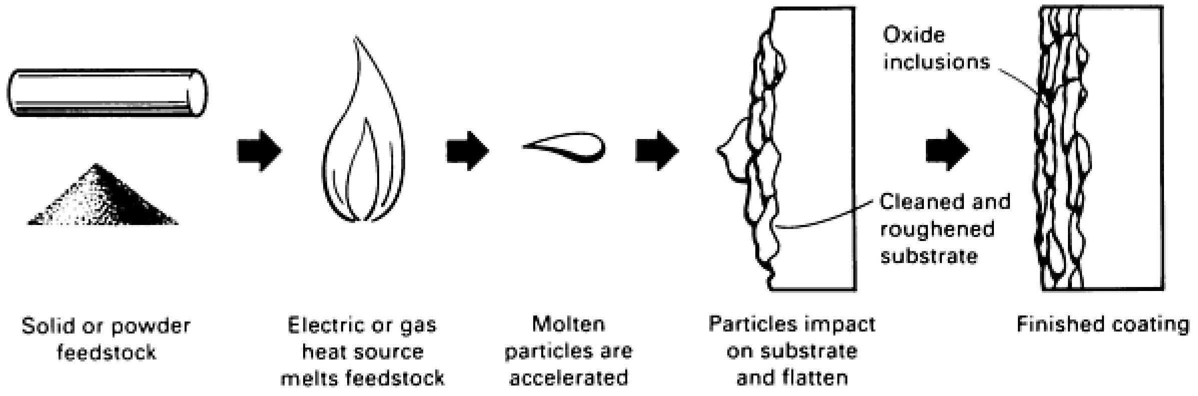

Fig. 6 Schematic of the general thermal spray process. Source: Ref 12

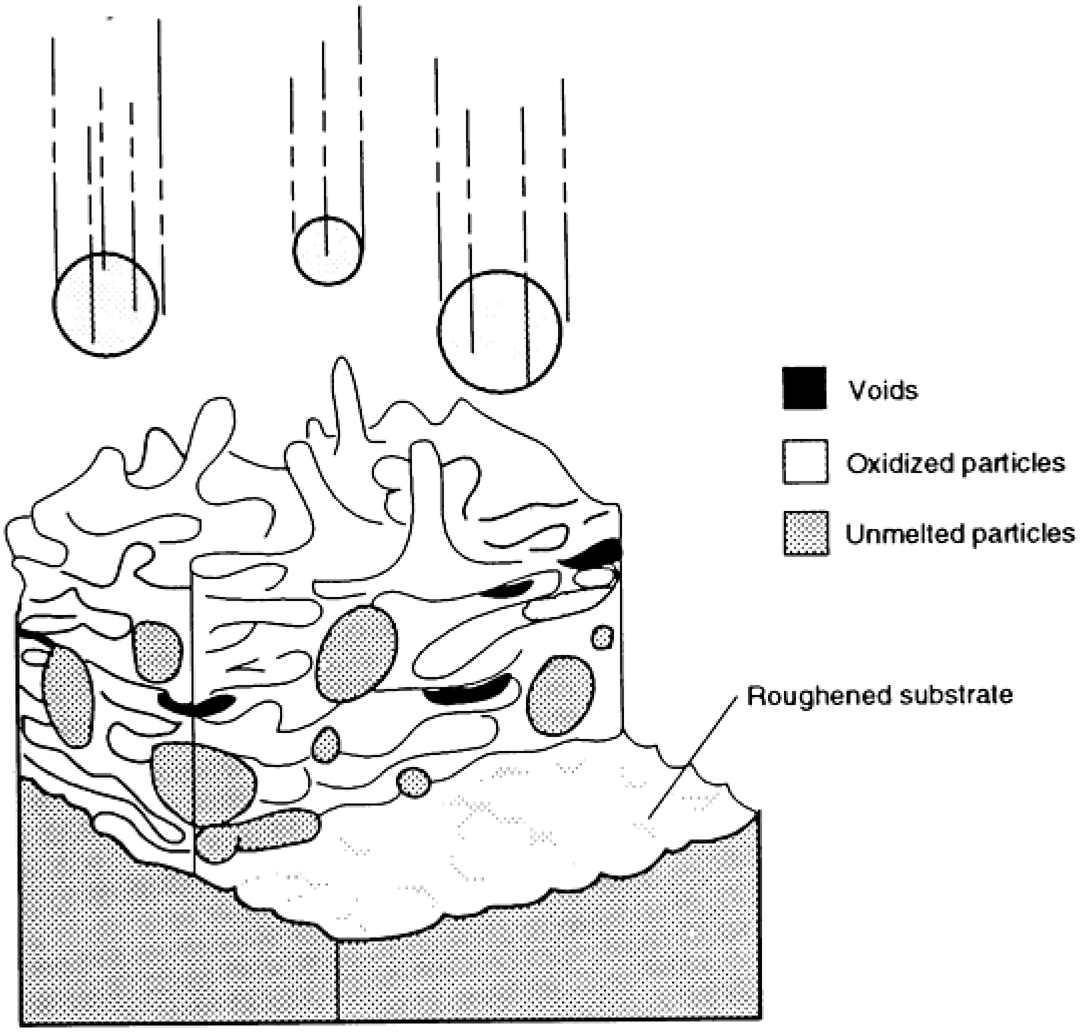

Fig. 7 Schematic showing the buildup of a thermal spray coating. Molten particles spread out and deform (splatter) as they strike the target, at first locking onto irregularities on the substrate, then interlocking with each other. Voids can occur if the growing deposit traps air. Particles overheated in the flame become oxidized. Unmelted particles may simply be embedded in the accumulating deposit. Source: Ref 12

Currently, five different commercially available thermal spray methods are in use:

- Oxyfuel wire (OFW) spray
- Electric arc wire (EAW) spray
- Oxyfuel powder (OFP) spray
- Plasma arc (PA) powder spray
- High-velocity oxyfuel (HVOF) powder spray

Selection of the appropriate thermal spray method is typically determined by the desired coating material, coating performance requirements, economics, and part size and portability. Reference 12 provides detailed information on thermal spray process selection.

Thermal spray coatings are deposited on cast iron substrates for:

- Corrosion resistance
- Wear resistance
- Oxidation resistance
- Dimensional restoration
- Thermal barriers

Corrosion Resistance. Zinc and aluminum and their alloys are the metals most widely used for thermal spray anticorrosion coatings. They are extensively used for the corrosion protection of iron and steel in a wide range of environments and have been shown to provide very long-term protection (over 20 years) in both marine and industrial locations.

Wear coatings are used to resist abrasion, erosion, cavitation, and fretting, and to reduce friction. These coatings consist of a wide range of metals and their alloys, ceramics, cermets, carbides, and even low-friction plastics. Typical coating hardness ranges from 20 to 70 HRC. Metal matrices are hardened by rapid solidification, by dispersions introduced from the spray process, by the addition of separate hard phases (for example, carbides of chromium, tungsten, titanium, and/or tantalum), or by oxide inclusions.

Oxidation protection. Thermal spray coatings are extensively used by industry to protect cast iron components and structures from heat oxidation at surface temperatures to 1095 °C (2000 °F). By ensuring long-term protection, thermal spray coatings show real economic advantages during the service lives of such items. Oxidation-resistant coatings include aluminum, aluminum-iron, nickel-chromium, and MCrAlY materials.

Dimensional Restorative Coatings. Thermal spray is used as a coating to repair or resurface (up to 3 mm, or 0.12 in. thick) worn and/or corroded parts, as well as to repair new part errors (for example, undersize parts), to repair nicks or other blemishes, or to renew surfaces that are corroded or worn in use.

Thermal barrier coatings consist of a low-conductivity (thermal) ceramic deposited over an MCrAlY bond coat. The ceramic of choice is partially-stabilized zirconia (7 to 8 wt% Y_2O_3-ZrO_2) deposited at a thickness of 0.25 mm (0.010 to 0.040 in.) with 10 to 15% porosity. A bond coat of NiCrAlY or CoCrAlY is used at a thickness of 0.125 mm (0.005 in.). Both coatings are used on components used in gas turbine engines and adiabatic engines to improve efficiency and reduce metal temperatures or cooling requirements.

Laser Surface Processing (Ref 13)

High-power lasers have been used to process materials to improve their wear resistance since the late 1960s. Laser surface modification techniques that are used to improve the wear resistance of cast irons include transformation hardening,

melting, and alloying. The processing conditions, examples of microstructures, wear characteristics, and applications associated with each technique are discussed in greater detail in Ref 13.

Laser Transformation Hardening. The wear resistance of highly stressed ferrous alloy components, such as gears and bearings, can be improved by transformation hardening. Because ferrous materials are very good heat conductors, the high heat fluxes generated by lasers are most suitable to heat the surface layer to austenitization levels without affecting the bulk temperature of the sample. The ensuing self-quenching is rapid enough to eliminate the need for external quenching to produce the hard martensite in the heated surface. Because ferrous alloys have high reflectivity, absorptive coatings such as manganese phosphate and graphite are applied to the workpiece for efficient laser heating. Most of these coatings burn off and normally do not affect the microstructure. Processing conditions for laser transformation hardening are typically power densities that range from 5 to 100 MW/m^2 (3.2 to 64.5 $kW/in.^2$) and interaction times ranging from 0.01 to 10 s. Usually, inert gas shielding is used. A rectangular beam is often used for laser transformation hardening. The case depth depends on the hardenability of the material and rarely exceeds 2.5 mm (0.1 in.).

In cast irons, laser heat-treated surfaces appear in light contrast, as shown in Fig. 8(a) for gray iron and in Fig. 8(b) for ductile iron. The microstructure of laser-hardened gray cast iron is generally fine martensite that contains flake graphite, as shown in Fig. 9(a). Acicular bainite can sometimes occur in the martensite matrix. The microstructure of laser-hardened ductile iron is also fine martensite, but contains "bull's eye" graphite nodules, as shown in Fig. 9(b). A closer examination of Fig. 9(b) reveals a narrow region of martensite between the graphite nodule and the ferrite ring, which indicates the extent of carbon diffusion occurring during processing.

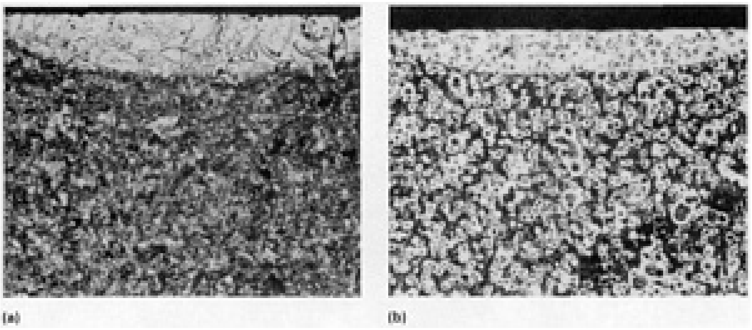

Fig. 8 Cross sections of laser heat-treated surfaces in cast irons. (a) Gray iron. (b) Ductile iron. Source: Ref 13

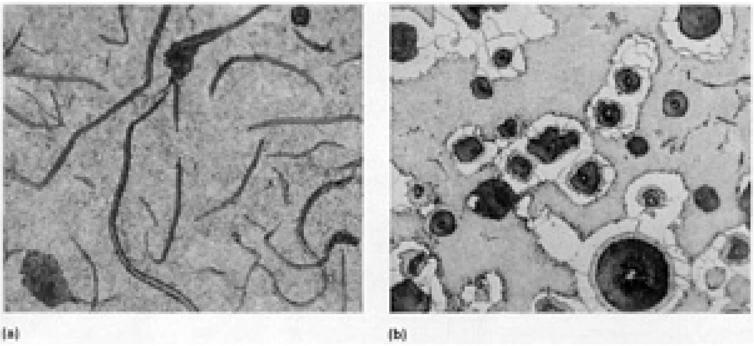

Fig. 9 Microstructures of laser-hardened cast irons. (a) Gray iron. (b) Ductile iron. Source: Ref 13

According to Molian and Baldwin (Ref 14), the extensive case that developed during laser hardening of gray and ductile irons was made up of sequential regions with varying degrees of microstructural modification. The region just below a very thin melt zone contained plate martensite, retained austenite, and graphite, whereas the region just above the base metal contained a mixture of refined martensite and untransformed pearlite.

From their study of pin-on-disk wear behavior of laser-hardened gray and ductile cast irons, Molian and Baldwin (Ref 14) found an improvement in scuffing and sliding wear resistance with an increase in case depth, as shown in Fig. 10. On the same samples, erosive wear test results showed that the erosion rate depended on the surface hardness and the case depth, as shown in Fig. 11, and increased as the matrix microstructure varied from ledeburite to tempered martensite to pearlite (Ref 15).

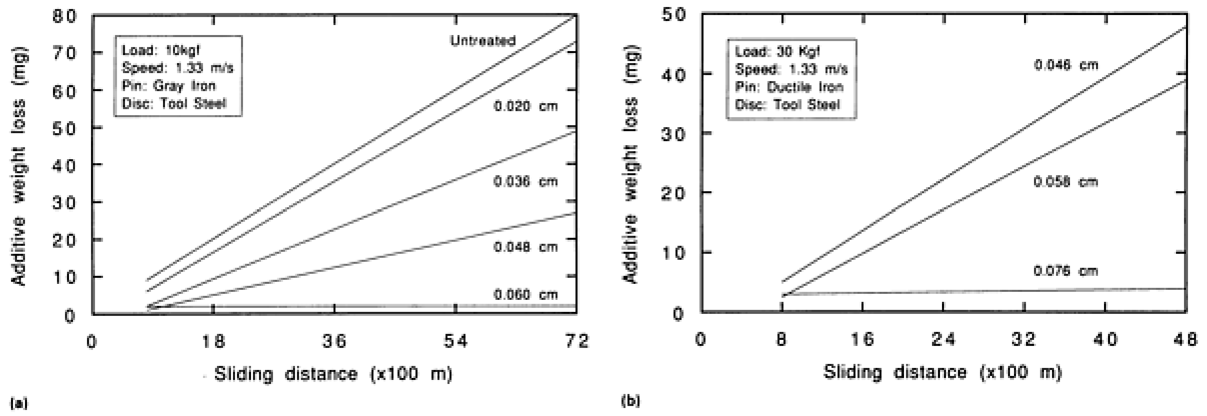

Fig. 10 Sliding wear behavior of laser-hardened cast irons as a function of case depth. (a) Gray iron. (b) Ductile iron. Source: Ref 13

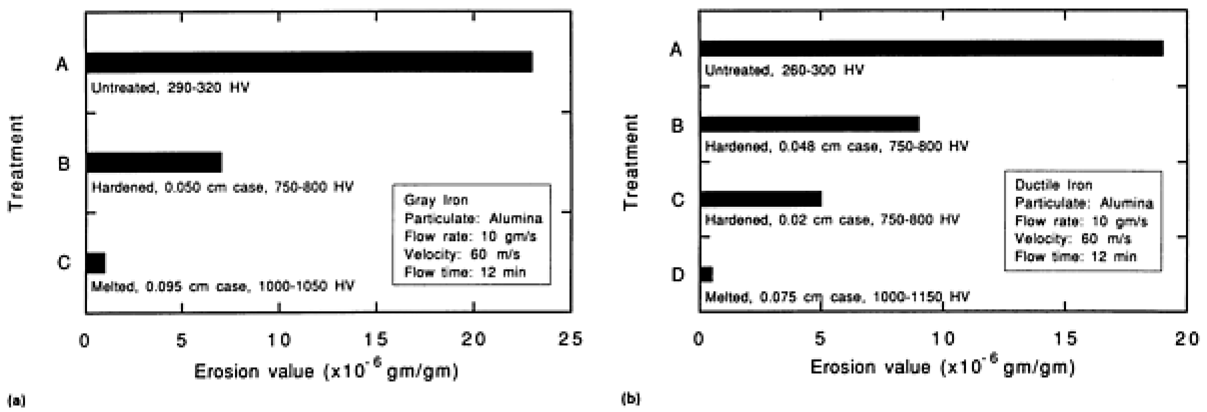

Fig. 11 Erosive wear behavior of laser-hardened cast irons as a function of surface hardness and case depth. (a) Gray iron. (b) Ductile iron. Source: Ref 13

Tomlinson et al. (Ref 16) observed that besides reducing wear, laser hardening of flake graphite iron resulted in very little plastic deformation, no graphite deposition on the opposing metal, and no adhesive damage. Trafford et al. (Ref 17) used a reciprocating pad-on-plate technique to evaluate the wear resistance of laser-processed gray iron and found that fully martensitic and surface-melted ledeburite microstructures had the lowest wear rates (Fig. 12).

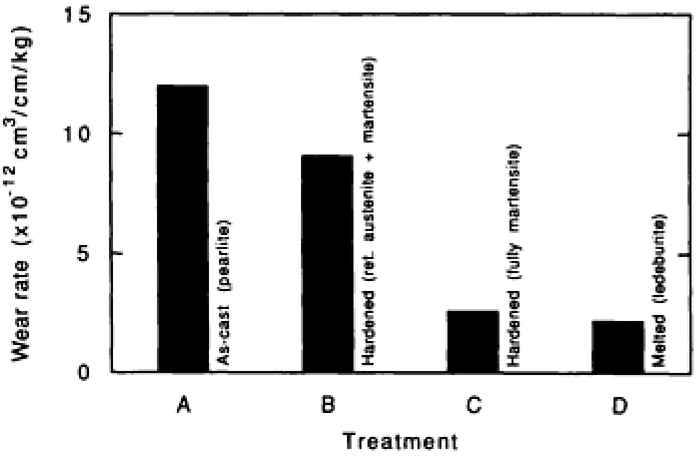

Fig. 12 Abrasive wear rates in gray iron as a function of microstructure arising from various laser-hardening treatments. Source: Ref 13

Example 1: Laser Surface Hardening of Cast Iron Camshaft Lobes

(Ref 18). The surface of the lobes of an automotive camshaft made from ductile cast iron (see Fig. 13) was to be surface hardened to increase wear resistance. The desired case depth, defined as the depth where the hardness was 50 HRC, was 0.5 to 1.0 mm (0.02 to 0.04 in.).

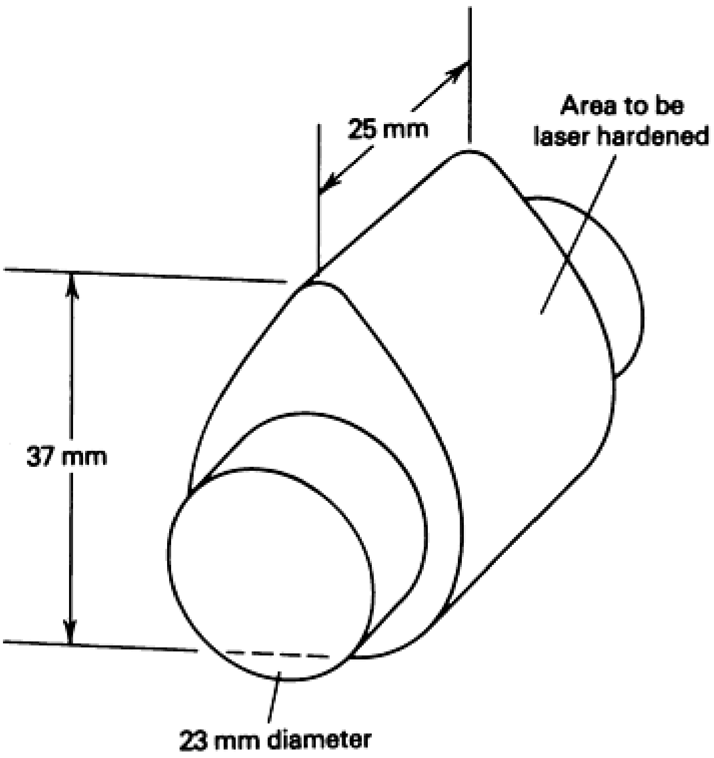

Fig. 13 Ductile cast iron cam from automotive camshaft. Source: Ref 18

A 15 kW CO_2 laser was used for the processing. The optical system delivered a focused spot, with a diameter of 10 mm (0.4 in.) to the workpiece. This spot was scanned over a distance of 22 mm (0.9 in.) normal to the direction of processing. The frequency of scanning was 125 Hz in the normal direction, forming a rectangular spot 22 mm by 25 mm (0.9 by 1.0 in.) on the camlobe surface.

To obtain an even hardened case around the periphery of the camlobe, it was necessary to vary the angular speed of rotation of the lobe under the laser beam. The reason is that the angle of incidence of the laser beam to the workpiece changed during rotation, from nearly normal incidence at the cylindrical portion of the lobe to a grazing incidence of only 20 to 30° at the flat portion. Furthermore, at constant rotational speed, the linear speed of processing would vary as the lobe rotated. This was obtained by mounting the workpiece on a rotary table. The speed of rotation was varied by means of an electromechanical controller in a predetermined manner.

The camlobe was laser hardened using a manganese phosphate coating to increase energy absorption. Because of the design of the workpiece, it was difficult to predict the optimum processing parameters by calculations and the parameters were, therefore, evaluated by trial and error. The results were:

Power input	9 kW
Power density	1600 W/cm^2 (10,300 W/in.^{2})
Linear speed of processing	
at the cylindrical portion	760 mm/min (30 in./min)
at the flat portion	180 mm/min (7 in./min)
Depth of case	0.55 mm (0.022 in.)

The hardness profile of the surface layer of the camlobe is shown in Fig. 14.

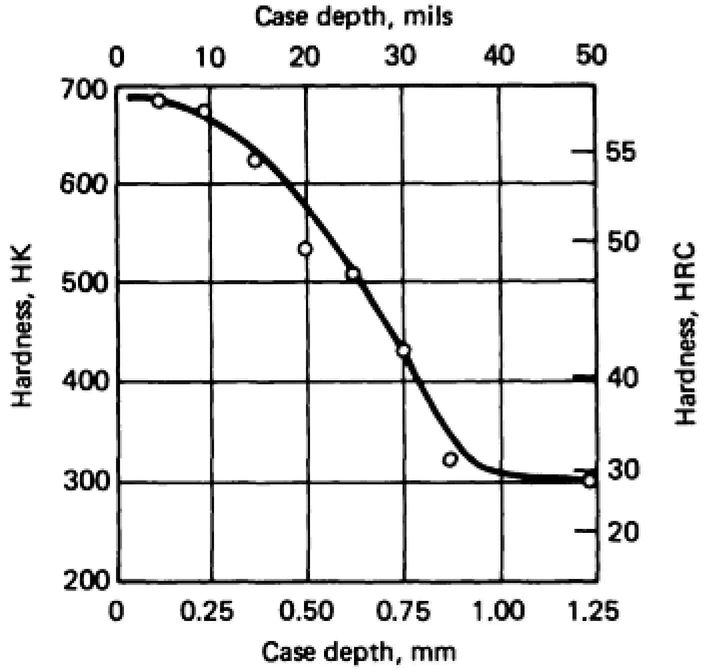

Fig. 14 Hardness profile of laser surface hardened cast iron camlobe. Source: Ref 18

Laser melting requires higher power densities than the levels used for laser transformation hardening. The workpiece is often made absorptive either by using coatings similar to those used for laser heating or by increasing surface roughness, for example, by sand blasting. Laser melting can harden alloys that cannot be hardened by laser transformation hardening. In ferritic malleable gray iron, melting enhances the diffusion of carbon, and the ensuing rapid quench produces a hardened region.

Processing conditions for laser melting are typically a power density from 10 to 3000 MW/m^2 (6.5 to 1935 $kW/in.^2$) and an interaction time from 0.01 to 1 s. Inert gas shielding is used to prevent oxidation of the surface.

Microstructural changes with laser melting are in the forms of grain refinement, solid solutions, and fine dispersions of precipitates. All of these can contribute to the hardening and strengthening of the surface. Laser-melted surfaces of cast irons appear dendritic, as shown in Fig. 15(a) for gray iron and in Fig. 15(b) for ductile iron. Below the melt zone is the heat-affected zone, which appears in lighter contrast in Fig. 15.

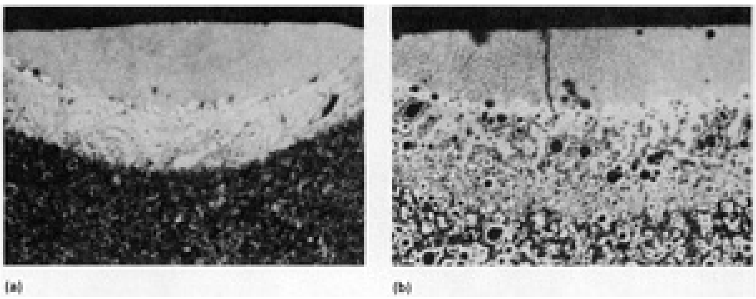

Fig. 15 Cross section of laser-melted cast iron surfaces. (a) Gray iron. (b) Ductile iron. Source: Ref 13

In the solidified melt in cast irons, a ledeburite (mixture of austenite and cementite) structure generally forms. Hardening is caused by graphite dissolution to form cementite and austenite transformation to martensite. Molian and Baldwin (Ref 14) described the formation of predominantly dendritic ledeburite with small amounts of plate-like, high-carbon martensite and retained austenite in the melt zone in gray and ductile irons.

Chen et al. (Ref 19) determined that microstructures in laser-melted ductile iron depended on the solidification rate. Dendritic retained austenite with a continuous interdendritic carbide, with a microhardness from 400 to 650 HV, formed at high solidification rates. A lamellar mixture of ferrite and cementite plates, with a microhardness from 1000 to 1250 HV, formed at low solidification rates.

Bamberger et al. (Ref 20) found that in laser-melted gray cast iron, full dissolution of the graphite occurred, leading to the formation of hot tears on the surface. On the other hand, in laser-melted nodular cast iron, partial dissolution of the graphite occurred, resulting in increased ductility and no hot tearing.

Bergmann (Ref 21) has summarized the wear properties of laser-melted cast irons. For laser-melted gray iron containing flake graphite in a pearlitic matrix, the dry pin-on-disk test demonstrated that the wear behavior improved by an order of magnitude and was better than a fully martensitic structure. In a test involving rolls that ran against one another with a fixed relative slip, it was found that the wear resistance of laser-melted ductile iron was superior to that of 0.6% C steel, case-hardened 16MnCr5 steel, nitrided or carburized 16MnCr5 steel, and a gas-tungsten arc welded melted surface.

Ju et al. (Ref 22) reported significant improvement in erosive wear behavior in laser-melted ductile and gray irons, as shown in Fig. 16. This improvement was due to the presence of mechanically metastable austenite that transforms to martensite when plastic deformation of the near-surface region occurs during wear.

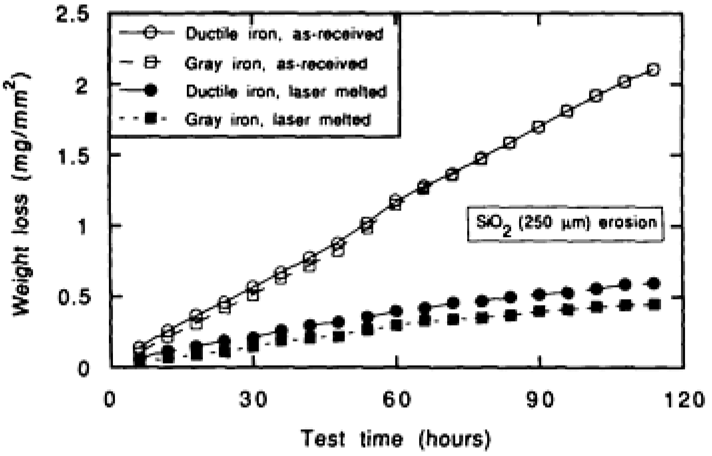

Fig. 16 Erosive wear behavior of as-received and laser-melted gray and ductile irons. Source: Ref 22

Tomlinson et al. (Ref 23) reported that laser melting reduced the amount of cavitation erosion of gray cast iron in distilled water by a factor of 0.3, and, in 3% saltwater, by a factor of 0.57.

Laser Alloying. A technique of localized alloy formation is laser surface melting with the simultaneous, controlled addition of alloying elements. These alloying elements diffuse rapidly into the melt pool, and the desired depth of alloying can be obtained in a short period of time. By this means, a desired alloy chemistry and microstructure can be generated on the sample surface; the degree of microstructural refinement will depend on the solidification rate. The surface of a low-cost alloy, such as cast iron, can be selectively alloyed to enhance properties, such as resistance to wear, in such a way that only the locally modified surface possesses properties typical of tribological alloys. This results in substantial cost savings, and reduces the dependence on strategic materials. Typical processing parameters for laser alloying are a power density from 10 to 3000 MW/m^2 (6.5 to 1935 kW/in.^{2}) and an interaction time from 0.01 to 1 s. An inert shielding gas is normally used.

One method of alloying is to apply appropriate mixtures of powders on the sample surface, either by spraying the powder mixture suspended in alcohol to form a loosely packed coating, or by coating a slurry suspended in organic binders. The use of metal powders in laser alloying is the least expensive, but, with appropriate process modifications, alloys in the form of rods, wires, ribbons, and sheets can also be added.

Cast irons, primarily gray irons, have been laser alloyed with chromium, silicon, carbon, nickel, nickel-aluminum, cobalt, and cobalt-chromium powders. Figure 17 shows the improved cavitation erosion resistance of a gray cast iron containing 2.9 to 3.2% C, 1.7 to 2.1% Si, 0.5 to 0.8% Mn, ≤0.1% P, and 0.06 to 0.11% S that was laser alloyed with chromium. The resulting coating, which was approximately 0.5 mm (0.02 in.) thick, contained 22% Cr and had a hardness value of 700 HV.

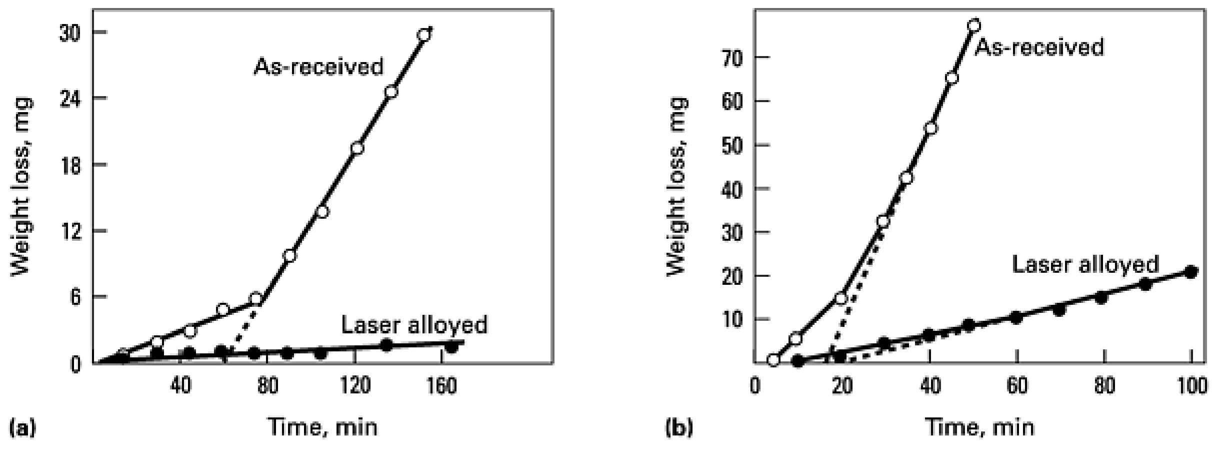

Fig. 17 Effect of laser alloying with chromium on the cavitation erosion resistance of gray cast iron in distilled water (a) and 3% sodium chloride solution (b). Source: Ref 24

Surface Hardening

Surface hardening is a generic term covering several processes applicable to a suitable ferrous alloy that produces a surface layer that is harder or more wear resistant than the core. The processes commonly used to surface harden cast irons which will be described in this section include flame hardening, induction hardening, and nitriding. Laser transformation hardening, which is a rapidly emerging technology for improving the performance of iron castings, was described in the previous section on "Laser Surface Processing." Other less commonly used methods for surface hardening of cast irons include boriding, nitrocarburizing, and the thermoreactive deposition/diffusion process (Toyota diffusion coating process). More detailed information on surface hardening can be found in Volume 4, *Heat Treating,* of the *ASM Handbook.*

Flame Hardening of Gray Iron

Flame hardening is the method of surface hardening most commonly applied to gray iron. After flame hardening, a gray iron casting consists of a hard, wear-resistant outer layer of martensite and a core of softer gray iron, which during treatment does not reach the A_1 transformation temperature (in fact, the unhardened metal immediately below the hardened case, which has been heated by the flame to some extent, may even be partially annealed during flame hardening if it is unalloyed).

Recommended Composition. Both unalloyed and alloyed gray irons can be successfully flame hardened. However, some compositions yield much better results than do others. One of the most important aspects of composition is the combined carbon content, which should be in the range of 0.50 to 0.70%, although irons with as little as 0.40% combined carbon can be flame hardened. In general, flame hardening is not recommended for irons that contain more than 0.80% combined carbon because such irons (mottled or white irons) may crack in surface hardening.

The stability of the microconstituents from which the carbon precipitates is a factor in determining the hardness of the flame-hardened iron. One user observed that the stability of microconstituents containing combined carbon is indicated by

the hardness of test specimens annealed at 845 °C (1550 °F). A test of four pearlitic irons from different sources, containing 3.30% C max, 1.40 to 1.60% Si, 0.80 to 1.10% Mn, and 0.15 to 0.20% Cr, gave the results:

Iron	Hardness, HB		Hardness[(a)], HRC
	As-cast	Annealed	
A	220	200	47-50
B	190	180	47-50
C	200	140	35-38

(a) After flame hardening as-cast iron

For maximum hardness, it is advisable to use an iron containing as small an amount of total carbon as is consistent with the production of sound castings free from any danger of cracking. The coarse graphite flakes typical of high-carbon irons should be avoided because they may be burned out during flame heating, thereby producing a porous and unattractive surface.

Because silicon promotes the formation of graphite and of a low combined carbon content, a relatively low silicon content is also advisable. Several users report that silicon content should not exceed 2% in any iron submitted to a flame-hardening operation, although alloy irons containing 2.4% Si can be hardened successfully. They also recommend that manganese content be held in the range of 0.80 to 1.00% to increase carbon solubility in austenite.

Gray iron to be flame hardened should be as free as possible from porosity and from foreign matter such as sand or slag because porosity and even small inclusions of foreign matter can produce a rough surface or result in cracking after hardening. Rough casting surfaces should be sand or shot blasted prior to heat treatment because skin or scale on the surface acts as a heat insulator and reduces the effectiveness of flame hardening.

Effects of Alloying Elements. In general, alloyed gray irons can be flame hardened with greater ease than can unalloyed irons, partly because alloyed gray irons have increased hardenability. Final hardness also may be increased by alloying additions. The maximum hardness obtainable by flame hardening an unalloyed gray iron containing approximately 3% total carbon, 1.7% Si, and 0.60 to 0.80% Mn ranges from 400 to 500 HB. This is because the Brinell hardness value for gray iron is an average of the hardness of the matrix and that of the relatively soft graphite flakes. Actually, the matrix hardness on which wear resistance depends approximates 600 HB. With the addition of 2.5% Ni and 0.5% Cr, an average surface hardness of 550 HB can be obtained. The same result has been achieved using 1.0 to 1.5% Ni and 0.25% Mo. Small additions of chromium are particularly valuable in preventing softening and ensuring the retention of a high content of combined carbon during austenitizing for hardening. Automotive camshafts containing 1% Cr, 0.50% Mo, and 0.8% Mn are easily flame hardened to 52 HRC to a required depth. These parts are not tempered or stress relieved.

Stress Relieving. Whenever practicable or economically feasible, flame-hardened castings should be stress relieved at 150 to 200 °C (300 to 400 °F) in a furnace, in hot oil, or by passing a flame over the hardened surface. Such a treatment will minimize distortion or cracking and will increase the toughness of the hardened layer.

Stress relieving at 150 °C (300 °F) for 7 h was found to remove 25 to 40% of the residual stresses in a flame-hardened casting, while reducing the hardness of the surface by only 2 to 5 points on the HRA scale. Although stress relieving is desirable, it can often be safely omitted.

Hardness. The surface of flame-hardened gray iron typically has a somewhat lower hardness than the metal immediately below the surface (Fig. 18). This decrease in hardness may be caused by the retention of relatively soft austenite at the surface. Surface hardness often can be raised by heating in the range from 195 to 250 °C (380 to 480 °F).

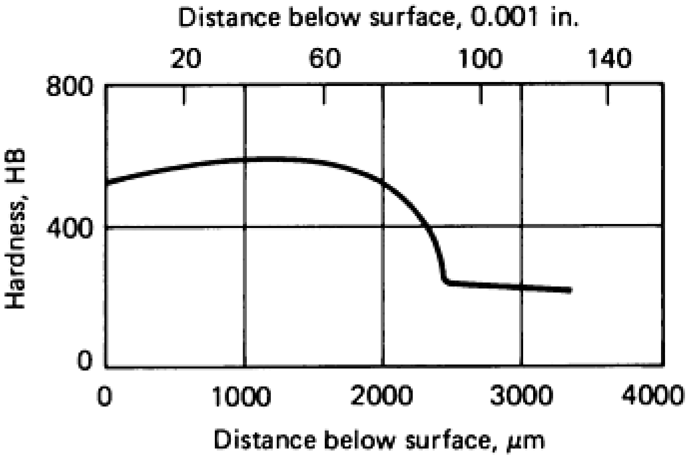

Fig. 18 Typical hardness gradient produced in gray iron by flame hardening

The depth and microstructure of the hardened layer depend on two other factors in addition to temperature: the amount of carbon and alloying elements in solution when the flame-hardened surface is quenched, and the efficiency of quenching. If softness is due to the presence of austenite in the microstructure, subjecting the part to -40 °C (-40 °F) for 1 h will transform the austenite and increase the hardness.

Fatigue strength is usually increased by surface hardening because the treatment induces compressive stresses at the surface. For example, flame or induction heating followed by water quenching induces high compressive stresses (>205 MPa, or 30 ksi) in the fillet areas of crankshafts; however, if self-quenching instead of water quenching is used, undesirable tensile stresses may result at the surface. The degree of improvement in fatigue strength by flame hardening cannot be produced by through hardening.

Quenching. The various methods of flame hardening influence the selection of the quenching medium. In the progressive method, only nonflammable media such as water, soluble-oil mixtures, and solutions of polyvinyl alcohol in water can be employed. Conventional oil cannot be used because of the fire hazard. In spot hardening or spinning methods, in which the flame head is withdrawn from the part before quenching, parts are quenched conventionally by immersion in hot oil.

When quenching is done with water, the water should be at about 30 °C (90 °F) for best results. Lower quenching rates, such as those obtained with 5 to 15% soluble-oil mixtures, compressed air, or compressed air and water at low pressure, are used to prevent cracking. Air quenching is especially suited to highly alloyed cast irons because of their susceptibility to cracking.

Induction Hardening of Gray Iron

Gray iron castings can be surface hardened by the induction method when the number of castings to be processed is large enough to warrant the relatively high equipment cost and the need for special induction coils. Considerable variation in the hardness of the cast irons may be expected because of a variation in the combined carbon content. A minimum combined carbon content of 0.40 to 0.50% C (as pearlite) is recommended for cast iron to be hardened by induction, with the short heating cycles that are characteristic of this process. Heating castings with lower combined carbon content to high hardening temperatures for relatively long periods of time may dissolve some free graphite, but such a procedure is likely to coarsen the grain structure at the surface and will result in undesirably large amounts of retained austenite in the

surface layers. The recommended minimum induction hardening temperature for gray iron is 870 to 925 °C (1600 to 1700 °F).

The surface hardness attained from the induction hardening of gray iron is influenced by the carbon equivalent (%C + 1/3% Si) when this hardness is measured by conventional Rockwell tests. The more graphite that is present in the microstructure, the lower the surface hardness will appear to be after hardening. Table 10 shows the surface hardness of induction-hardened gray iron castings of various carbon equivalents from 3.63 to 4.23. The microstructure of these castings, which were cast in the same manner and cooled at similar rates, contained more and larger graphite flakes as the carbon equivalent increased. This resulted in lower apparent surface hardness after hardening, yet the hardened matrix was consistently 57 to 61 HRC (converted from microhardness).

Table 10 Effect of carbon equivalent on surface hardness of induction-hardened gray irons

Composition, %[(a)]		Carbon equivalent[(b)]	Hardness HRC, converted from		
C	Si		As read	Rockwell 30-N	Microhardness
3.13	1.50	3.63	50	50	61
3.14	1.68	3.70	49	50	57
3.19	1.64	3.74	48	50	61
3.34	1.59	3.87	47	49	58
3.42	1.80	4.02	46	47	61
3.46	2.00	4.13	43	45	59
3.52	2.14	4.23	36	38	61

(a) Each iron also contained 0.50 to 0.90 Mn, 0.35 to 0.55 Ni, 0.08 to 0.15 Cr, and 0.15 to 0.30 Mo.

(b) Carbon equivalent = %C + $\frac{1}{3}$ % Si.

Distortion. Induction hardening causes less distortion than would a similar quenching treatment from a furnace. The maximum warpage in a 560 mm (22 in.) length of bar was found to be 0.03 mm (0.0015 in.) after induction hardening, compared with 0.17 to 0.25 mm (0.007 to 0.010 in.) for the same bars quenched from a furnace. For thin-walled cylinders, distortion is not a problem unless the thickness of the induction-hardened layer exceeds 20% of the wall thickness.

For selective hardening, in place or by scanning, to depths up to 3.8 mm (0.150 in.), water quenching can be used safely. However, the hardening of keyways, cross-drilled holes, or extremely thin walls may require the use of oil to prevent excessive distortion or cracking.

Surface Hardening of Ductile Iron

Ductile iron responds readily to surface hardening by flame, induction, or laser heating, or by nitriding. Because of the short heating cycle in these processes, the pearlitic types of ductile iron ASTM 80-60-03 and 100-70-03 are preferred. Irons without free ferrite in their microstructure respond almost instantly to flame or induction heating and require very little holding time at the austenitizing temperature in order to be fully hardened.

With a moderate amount of free ferrite, the response may be satisfactory, but an entirely ferritic matrix, typical of the grades with high ductility, requires several minutes at 870 °C (1600 °F) to be fully hardened by subsequent cooling. A matrix microstructure of fine pearlite, readily obtained by normalizing, has a rapid response to surface hardening and provides excellent core support for the hardened case.

With proper technique and the control of temperature between 845 and 900 °C (1550 and 1650 °F), the ranges of surface hardness for ductile iron with different matrices expected in commercial production are:

- Ductile iron, fully annealed (ferritic), water quenched behind the flame or induction coil, 35 to 45 HRC
- Ductile iron, predominantly ferritic (partly pearlitic), stress relieved prior to heating, self quenched, 40 to 45 HRC
- Ductile iron, predominantly ferritic (partly pearlitic), stress relieved prior to heating, water quenched, 50 to 55 HRC
- Ductile iron, mostly pearlitic, stress relieved before heating, water quenched, 58 to 62 HRC

Heating time and temperature, amount of dissolved carbon, section size, and rate of quench help to determine final hardness values. Often soluble-oil or polymer quench media are used to minimize quench cracking where the casting section changes.

Flame or induction-hardened ductile iron castings have been used for heavy-duty applications such as foils for cold working titanium, ring gears for paper-mill drives, crankshafts, and large sprockets for chain drives.

The response of ductile iron to induction hardening is dependent on the amount of pearlite in the matrix of as-cast, normalized, and normalized and tempered prior structures. In quenched and tempered iron, the secondary graphite nodules formed during tempering are close enough together to supply sufficient carbon to the matrix by re-solution during induction heating.

In the as-cast condition, a minimum of 50% pearlite is considered necessary for satisfactory hardening with induction heating cycles of 3.5 s and longer and hardening temperatures of 955 to 980 °C (1750 to 1800 °F). Structures containing less pearlite can be hardened by using higher temperatures, but at the risk of retaining austenite, forming ledeburite, and damaging the surface. With more than 50% pearlite, hardening temperatures may be reduced to within the range of 900 to 925 °C (1650 to 1700 °F).

In the Normalized Condition. For heating cycles of 3.5 s and longer, at temperatures of 955 to 980 °C (1750 to 1800 °F), 50% pearlite in a prior structure would be considered a minimum. Normalized and tempered irons exhibit a poor response with lower pearlite content because of the depletion of the matrix carbon. In the tempering operation, the carbon migrates from the pearlite matrix to the graphite nodules. In the heating cycle, carbon is reabsorbed in the matrix from the nodule; however, there is insufficient time for it to migrate throughout the ferritic areas. Another factor in the response of ductile iron is the graphite nodule count; the greater the number of nodules per unit area, the deeper the hardening for any given heat cycle. This effect is more evident as the percentage of ferrite increases (Fig. 19).

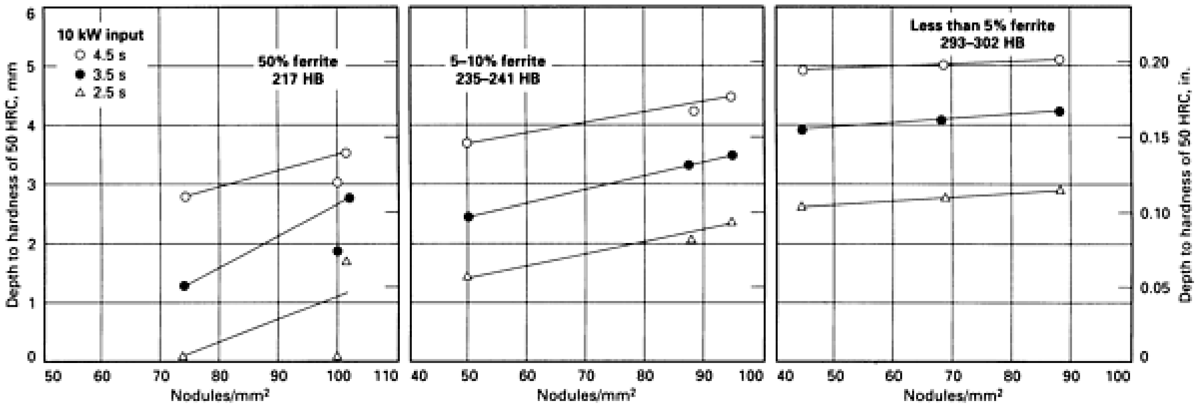

Fig. 19 Relationship between depth of induction hardening to 50 HRC and graphite nodule count in normalized and tempered ductile (nodular) iron

Quenched and Tempered. The response of quenched and tempered nodular iron to induction hardening is excellent over a wide range of microstructures containing up to 95% ferrite. As a prior treatment, quenching and tempering has the advantage of permitting a lower prior hardness; there is a risk of distortion and quench cracking, however.

Nitriding is a case-hardening process that involves the diffusion of nitrogen into the surface at a temperature of about 550 to 600 °C (1020 to 1110 °F). Usually the source of nitrogen is ammonia, and the process produces a surface layer about 0.1 mm (0.004 in.) deep with a surface hardness approaching 1100 HV. The surface layer is typically white and featureless in an etched microstructure, but nitride needles can be found just below it. Alloying elements can be used to increase case hardness, and 0.5 to 1% Al, Ni, and Mo have been reported to achieve useful results. Nitrided cases provide, in addition to very high hardness, increased wear resistance and antiscuffing properties, improved fatigue life, and improved corrosion resistance. Typical applications are for cylinder liners, bearing pins, and small shafts.

Nitriding can also be carried out in liquid salt baths based on cyanide salts. Such processes have lower temperatures of treatment, although case depth may be decreased. More recently, processes for nitriding in a plasma have been developed and applied with success to ductile iron, but the process may be more restricted because of the special equipment and cost likely to be involved.

Surface Hardening of Pearlitic Malleable Iron

Fully pearlitic malleable iron may be surface hardened by either induction heating and quenching or flame heating and quenching. Laser and electron beam techniques also have been used for hardening selected areas on the surface of pearlitic and ferritic malleable iron castings that are free from decarburization. Generally, hardness in the range from 55 to 60 HRC is attainable, with the depth of penetration being controlled by the rate of heating and by the temperature developed at the surface of the part being hardened. In induction hardening, this is accomplished by the close regulation of power output, operating frequency, heating time, and alloy content of the iron.

The maximum hardness obtainable in the matrix of a properly hardened part is 67 HRC; however, conventional hardness measurements show less than the true matrix hardness because of the temper carbon nodules that are averaged into the hardness. Generally, a casting with a matrix microhardness of 67 HRC will have about 62 HRC average hardness, as measured with the standard Rockwell tester.

Rocker arms and clutch hubs are examples of automotive production parts that are surface hardened by induction. Flame hardening requires close control for these applications in order to avoid distortion that would interfere with their operation.

Conversion Coatings

Chemical reactions at casting surfaces can produce iron-containing compounds that provide wear resistance or an attractive appearance or that serve as excellent bonding agents for subsequent organic coatings. Table 11 details common

conversion coatings and their useful properties (chromate and phosphate conversion coatings are discussed in greater detail in the articles "Chromate Conversion Coatings" and "Phosphate Coatings" in this Volume). Most of the successful processes are proprietary, and reproducibility of consistently good finishes is one of the important features.

Table 11 Chemical conversion coatings, structures, and characteristics

Type	Coating structure	Properties	Uses
Chromate	Nonporous film acts as moisture barrier	High corrosion resistance; inhibits corrosion if surface is broken; can be colored	Marine applications; can be decorative; nonporous bond layer for paint
Oxide	Ferric oxide formed from iron	Inhibits formation of ferrous oxide; highly absorbent; some wear resistance	Decorative blue-black coating; readily absorbs overlays of wax or oil
Phosphate	Iron zinc or manganese phosphates are crystalline structures formed on the surface by deposition from chemical solution	Chemically neutral and high adherence to iron surfaces; highly absorbent	Excellent for bonding paint to iron; prevents abnormal wear or seizing during break-in

Source: Ref 7

Phosphate coating is the treatment of cast iron with a dilute solution of phosphoric acid and other chemicals in which the surface of the metal, reacting chemically with the phosphoric acid medium, is converted to an integral, mildly protective layer of insoluble crystalline phosphate. The coating reduces corrosion, prevents surface seizure on initial wear contact, and provides an excellent base for organic paint bonding.

Gray, ductile, and malleable iron castings all lend themselves readily to phosphating. The ability of a cast iron to accept a phosphate coating is not affected by alloy content, but hinges primarily on two requirements: a clean surface, and a metal temperature approximately equal to that of the phosphating bath. Dry machined surfaces need no further cleaning; cast surfaces can be prepared by blasting or other cleaning methods to remove scale and sand.

Oxide Coatings (Ref 7). Conversion of the surface of an iron casting to a magnetic oxide, Fe_3O_4, gives a thin black finish. These films have a certain degree of wear resistance, provide a good bond for paint or lacquer, and have pleasing decorative features. The film layer, if oiled or waxed, provides satisfactory corrosion resistance against handling and storage and is useful with lubrication for sliding and rotating wear applications. The original method of forming a strongly adherent black oxide film is still useful today. The process involves use of steam around an iron part heated above 480 °C (900 °F) and yields a tight oxide coating. Steam generally is introduced to furnace atmospheres to completely replace air while the parts are heated to 590 °C (1100 °F). Twenty minutes at temperature in this atmosphere is sufficient for buildup of a thick, wear-resisting film.

Oxide film finishes can also be produced in a wide variety of proprietary basic-nitrate media. Reproducibility of consistent finishes in large-volume operations is one of their prime features. These provide thinner films that are more suitable for decorative purposes. Sodium carbonate and sodium and potassium nitrates constitute the bulk of the bath solutions. Often these are supplemented with additional agents, such as manganese, to give a mixed oxide film.

Chromate conversion coating is accomplished by immersion of iron in an aqueous solution of chromic acid or chromium salts. This solution can be used as a supplement to cadmium and zinc plating to prevent the formation of powder corrosion products (see Table 9) and it also provides an excellent bond for paints.

Porcelain Enameling

Porcelain enamels are inorganic vitreous coatings that are matured by heat. The inherently good heat transfer, thermal stability, and rigidity of iron at firing temperatures, coupled with the excellent adherence of vitreous ceramic frits as they fuse onto the cast surface, make the combination of porcelain on iron an excellent product. General corrosion resistance or resistance to specific chemicals can be obtained by selecting the proper porcelain enamel. The scratch resistance and hardness of the enamel coating, which allow the surface to resist abrasion, are almost equal in importance to the corrosion resistance.

Four processes are used to apply enamels: dry, wet, thermal spray (or plasma spray), and electrostatic precipitation. The latter two methods are seldom used on iron castings. Preparations for enameling start by blasting with sand, steel shot, or iron grit.

Dry coating methods use formulations that are mainly silica; these formulations generate a surface with the hardness and abrasion resistance of glass. Fluxes and opacifiers are mixed into the silica, and the mixture is then melted, quenched, and ground to make frit. (Frit is the term applied to the basic coating materials.) After application of a bonding ground coat, relatively heavy, smooth coatings (such as those on sinks and bathtubs) can be obtained by multiple firing. Each firing is followed by hot dusting with additional powdered frit, until the desired finish has been achieved.

Wet methods produce thinner coatings. The powdered frit is suspended in a solution of electrolytes and water or in an organic solvent and is applied by spraying or dipping over the ground coat. The sprayed or dipped coating must be dried prior to firing.

Ground coats that wet iron readily, adhere well, and are compatible with the cover coat are essential to the enameling process. Good ground coats promote adhesion between the enamel layer and the substrate, seal and smooth the irregularities of the surface, and prevent oxidation of the iron casting at firing temperatures. Top coats (cover coats) must provide the desired appearance and must be compatible with the ground coat. Formulation of frits requires the judgment and experience of a frit manufacturer to ensure that the coating provides successful results.

Cast iron for enameling usually has a composition that falls within the following limits:

Constituent	**Amount, %**
Total carbon	3.20-3.60
Silicon	2.30-3.00
Manganese	0.30-0.60
Sulfur	0.50-0.12
Phosphorus	0.40-0.80

Total carbon and silicon should vary in opposite directions within the ranges shown. If both are low, the iron tends to be brittle and to blister during porcelain enameling. If both are high, the iron is soft and warps easily when reheated for porcelain enameling. Manganese and sulfur should range in the same direction, so that all of the sulfur is converted to manganese sulfide. Within the normal range, phosphorus has a negligible effect on the strength of the cast iron at porcelain enameling firing temperatures.

The primary applications for porcelain enameled cast irons are in the manufacture of bathtubs, kitchen sinks, and lavatories. See the article "Porcelain Enameling" in this Volume for more detailed information.

Organic Coatings

Organic coatings have a wide variety of properties, but their primary uses require corrosion resistance combined with a pleasing colored appearance. An organic-base film is often resistant to certain environmental substances but not to others, and so must be chosen for a specific set of well-defined service conditions. For example, a vinyl paint might be used on a pump casing that must operate in contact with acidic industrial waters. However, if the same casing is expected to contact hydrocarbons such as gasoline or solvents, a styrene, epoxy, or phenolic coating would most likely provide superior protection.

Types of Organic Coatings. The term paint was once commonly used to designate all liquid organic coatings, but it is considered inadequate to describe modern liquid organic coatings, which in general are subdivided into enamels, lacquers, aqueous mixtures, suspensions, bituminous substances, and rubber-base products. Resins dispersed in a vehicle--for example, enamels or lacquers--cure to relatively hard gels by polymerization, oxidation, or solvent evaporation. A comparison of the chemical and environmental resistance of common resins is given in Table 12.

Table 12 Properties of organic coatings on iron castings

(a) E, excellent; G, good; F, fair; P, poor.

Enamels consist of milled pigments and other additives dispersed in resins and solvents and are converted from liquids to hard films by oxidation or polymerization. Lacquers are thermoplastic resins dissolved in organic solvents that dry rapidly by evaporation. In aqueous coatings, water is the principal vehicle or reducer. The advantages of water-base paints are nominal cost, nonflammability, true odorlessness, and nontoxicity. The disadvantages are difficulties in wettability, flow, and drying. Rubber-base coatings are noted for their mechanical properties and corrosion resistance rather than their decorative effects. Bituminous paints are black materials in which coal tar is dissolved in a solvent that evaporates. The major uses of bituminous paints are those that require extremely low permeability and high resistance to water. Unusual protection against chemical solutions, or special decorative effects, can be obtained by the use of asphaltic coatings or those produced by japanning, both of which are also considered bituminous coatings.

Fluorocarbon coatings produce an unusual combination of properties. They are tough, stain resistant, and nonsticking, and have a very low coefficient of friction. Fluorocarbon coatings resist all common industrial acids and temperatures to 300 °C (570 °F). Domestic cookware and chemical-processing equipment are two major applications of fluorocarbon coatings on iron castings. Fluorocarbon coatings are sprayed as emulsions of proprietary products onto a primed surface and then fused at temperatures of 385 to 425 °C (725 to 800 °F).

Methods of Application. Organic coatings are applied by spraying, dipping, flow coating, fluidized bed coating, electrostatic deposition, and electrophoresis (electrocoating).

Spraying is adaptable to both low-volume and high-volume workloads. It is done by propelling the coating material toward the workpiece by compressed air, hot spraying, hydraulic-airless, and airless-electrostatic methods. Overspraying is most troublesome with compressed air methods and least troublesome with electrostatic methods.

Dipping has been used for centuries; modern refinements include flow coating and electrophoresis. Not all shapes can be painted by dipping. Pockets can exclude paint from surfaces. The shape of the casting should allow easy draining after dipping. The coating should be selected to inhibit sagging or the formation of droplets on edges. The dipping process is easily automated and can be very efficient in use of materials. A thorough review of organic coatings and their applications, advantages, and limitations is available in Ref 25 and in the articles "Painting" and "Elastomeric Coatings and Linings" in this Volume.

Fused Dry-Resin Coatings

Dry-resin polymers can be applied (by fusion bonding) to iron castings for many of the same applications for which liquid organic coatings are used. Generally, the fused coatings are thick and can be applied very rapidly--often in minutes; in contrast, several hours are required for the drying and curing of a liquid organic coating.

The fusion bonding of polymers on iron castings can be readily accomplished by the application of dry solvent-free powder by fluidized bed coating or electrostatic deposition. The advantages of the process include the use of resins that are insoluble in ordinary solvents, the elimination of carrier solvents, and the ability to combine various plastics in the coating for maximum effectiveness. Sandblasted castings are excellent bases for this process. The plastic films can be easily machined, which contributes to flexibility in manufacturing. Two disadvantages are that thin films are not easily applied and that finding a suitable holding point on a part to be coated in a fluidized bed may be difficult. The six basic types of plastic fusion-bonded finishes, as well as a comparison of their characteristics, are given in Table 13.

Table 13 Relative effectiveness of fusion-bonding resin coatings

	Effectiveness[(a)]

(a) E, excellent; VG, very good; G, good; F, fair; P, poor.

(b) Ranges from excellent to poor depending on composition.

In a fluidized bed, castings heated to 175 to 310 °C (350 to 590 °F) are placed in a chamber containing resin powder suspended by upward-moving air. The dry resin floats around the casting, adhering to all the surfaces regardless of the complexity of the shape. Heating fuses the coating into a continuous film. This method produces a uniform coating that covers sharp corners, edges, and projections and that can be applied in a wide range of thicknesses (up to 1.5 mm, or 0.06 in.) in a single application.

In electrostatic deposition, the powdered resin is conveyed to a gun, in which it is given an electrostatic charge. The casting has the opposite charge. The charged powder is attracted to the surface, where it is deposited evenly. The electrostatic process is especially useful for applying thinner coatings because the residual charge on the workpiece is discharged by the powder, or leaks off, thus limiting the amount of powder that can be deposited. Preheating of the casting permits thicker coatings because the initial powder layer fuses as it is applied. Curing is done by reheating the

casting to fuse the resin coating. Primers may be needed for some types of polymers (such as butyrates and vinyls) in order to achieve adequate bonding.

Surface Engineering of Carbon and Alloy Steels

J.R. Davis, Davis & Associates

Introduction

CARBON AND ALLOY STEELS, the most widely used metallic material, account for more than 80 million tons, or approximately 98% of the annual steel production in the United States (Table 1). Steels are a popular material of choice because they can be manufactured relatively inexpensively in large quantities to very precise specifications. They also provide a wide range of mechanical properties, from moderate yield strength levels (200 to 300 MPa, or 30 to 40 ksi) with excellent ductility to yield strengths exceeding 1400 MPa (200 ksi) with fracture toughness levels as high as 110 MPa $\sqrt{m}$ (100 ksi $\sqrt{in}$).

(a) Thousands of net tons.

Following a brief review of the classification of steels, this article will review the following:

- Cleaning methods
- Finishing methods
- Conversion coatings
- Hot dip coating processes

- Electrogalvanizing
- Electroplating
- Metal cladding
- Organic coatings
- Zinc-rich coatings
- Porcelain enameling
- Thermal spraying
- Hardfacing
- Vapor deposited coatings
- Surface modification
- Surface hardening via heat treatment

Emphasis will be placed on the most commonly used methods for surface engineering of steels. No attempt is made at providing detailed information on any given process as this can be found in the cited articles found throughout this Volume. In terms of the coating, surface modification, and surface hardening processes described, the resulting property improvements (corrosion and/or wear resistance) will be stressed rather than the details of the process itself (equipment, plating bath compositions, process controls, etc.). Information on the surface engineering of stainless steels, tool steels, maraging steels, electrical steels, and ferrous powder metallurgy alloys can be found in the articles "Surface Engineering of Stainless Steels" and "Surface Engineering of Specialty Steels" which immediately follow in this Section of the Handbook.

Classification of Steels

Steels can be classified by a variety of different systems depending on:

- *The composition,* such as carbon, low-alloy, or stainless steels
- *The manufacturing methods,* such as open hearth, basic oxygen process, or electric furnace methods
- *The finishing method,* such as hot rolling or cold rolling
- *The product form,* such as bar, plate, sheet, strip, tubing, or structural shape
- *The deoxidation practice,* such as killed, semikilled, capped, or rimmed steel
- *The microstructure,* such as ferritic, pearlitic, and martensitic
- *The required strength level,* as specified in ASTM standards
- *The heat treatment,* such as annealing, quenching and tempering, and thermomechanical processing
- *Quality descriptors,* such as forging quality and commercial quality

Of the aforementioned classification systems, chemical composition is the most widely used and will be discussed below. More detailed information on the classification and designation of carbon and alloy steels can be found in Ref 1.

Carbon Steels

The American Iron and Steel Institute defines carbon steel as follows:

> Steel is considered to be carbon steel when no minimum content is specified or required for chromium, cobalt, columbium [niobium], molybdenum, nickel, titanium, tungsten, vanadium or zirconium, or any other element to be added to obtain a desired alloying effect; when the specified minimum for copper does not exceed 0.40 per cent; or when the maximum content specified for any of the following elements does not exceed the percentages noted; manganese 1.65, silicon 0.60, copper 0.60.

Carbon steel can be classified, according to various deoxidation practices, as rimmed, capped, semikilled, or killed steel. Deoxidation practice and the steelmaking process will have an effect on the characteristics and properties of the steel. However, variations in carbon have the greatest effect on mechanical properties, with increasing carbon content leading to

increased hardness and strength. As such, carbon steels are generally categorized according to their carbon content. Generally speaking, carbon steels contain up to 2% total alloying elements and can be subdivided into low-carbon steels, medium-carbon steels, and high-carbon steels.

As a group, carbon steels are by far the most frequently used steel. Table 1 indicates that more than 93% of the steel produced and shipped in the United States is carbon steel. Chemical compositions for selected carbon steels are provided in Table 2.

Table 2 Carbon steel compositions

Applicable only to structural shapes, plates, strip, sheets, and welded tubing

(a) When silicon ranges or limits are required, the following ranges and limits are commonly used; up to SAE 1025 inclusive, 0.10% max, 0.10-0.25%, or 0.15-0.35%. Over SAE 1025, 0.10-0.25% or 0.15-0.35%

Low-carbon steels contain up to 0.30% C. The largest category of this class of steel is flat-rolled products (sheet or strip) usually in the cold-rolled and annealed condition. The carbon content for these high-formability steels is very low, less than 0.10% C, with up to 0.4% Mn. Typical uses are in automobile body panels, tin plate, and wire products. For rolled steel structural plates and sections, the carbon content may be increased to approximately 0.30%, with higher manganese up to 1.5%. These latter materials may be used for stampings, forgings, seamless tubes, and boiler plate.

Medium-carbon steels are similar to low-carbon steels except that the carbon ranges from 0.30 to 0.60% and the manganese from 0.60 to 1.65%. Increasing the carbon content to approximately 0.5% with an accompanying increase in manganese allows medium-carbon steels to be used in the quenched and tempered condition. The uses of medium carbon-manganese steels include shafts, couplings, crankshafts, axles, gears, and forgings. Steels in the 0.40 to 0.60% C range are also used for rails, railway wheels, and rail axles.

High-carbon steels contain from 0.60 to 1.00% C with manganese contents ranging from 0.30 to 0.90%. High-carbon steels are used for spring materials and high-strength wires.

High-Strength Low-Alloy Steels

High-strength low-alloy (HSLA) steels are designed to provide better mechanical properties and/or greater resistance to atmospheric corrosion than conventional carbon steels. They are not considered to be alloy steels in the normal sense because they are designed to meet specific mechanical properties rather than a chemical composition (HSLA steels have yield strengths greater than 275 MPa, or 40 ksi). The chemical composition of a specific HSLA steel may vary for different product thicknesses to meet mechanical property requirements. The HSLA steels have low carbon contents (0.05 to ~0.25% C) in order to produce adequate formability and weldability, and they have manganese contents up to 2.0%. Small quantities of chromium, nickel, molybdenum, copper, nitrogen, vanadium, niobium, titanium, and zirconium are used in various combinations. The types of HSLA steels commonly used include:

- *Weathering steels,* designed to exhibit superior atmospheric corrosion resistance
- *Control-rolled steels,* hot rolled according to a predetermined rolling schedule designed to develop a highly deformed austenite structure that will transform to a very fine equiaxed ferrite structure on cooling
- *Pearlite-reduced steels,* strengthened by very fine-grain ferrite and precipitation hardening but with low carbon content and therefore little or no pearlite in the microstructure

- *Microalloyed steels,* with very small additions (generally <0.10% each) of such elements as niobium, vanadium, and/or titanium for refinement of grain size and/or precipitation hardening
- *Acicular ferrite steel,* very low carbon steels with sufficient hardenability to transform on cooling to a very fine high-strength acicular ferrite (low-carbon bainite) structure rather than the usual polygonal ferrite structure
- *Dual-phase steels,* processed to a microstructure of ferrite containing small, uniformly distributed regions of high-carbon martensite, resulting in a product with low yield strength and a high rate of work hardening, thus providing a high-strength steel of superior formability

Table 3 lists chemical compositions for various HSLA steels.

(a) If a single value is shown, it is a maximum unless otherwise stated.

(b) Values may vary, or minimum value may exist, depending on product size and mill form.

(c) Optional or when specified.

(d) May be purchased as type 1 (0.005-0.05 Nb), type 2 (0.01-0.15 V), type 3 (0.05 Nb, max, plus 0.02-0.15 V) or type 4 (0.015 N, max, plus V $\geq$4N).

(e) If chromium or silicon are each 0.50% min, the copper minimum does not apply.

(f) May be substituted for all or part of V.

(g) Niobium plus vanadium, 0.02 to 0.15%.

(h) Nitrogen with vanadium content of 0.015% (max) with a minimum vanadium-to-nitrogen ratio of 4:1.

(i) When silicon-killed steel is specified.

(j) For plate under 40 mm (1.5 in.), manganese contents are 0.70 to 1.35% or up to 1.60% if carbon equivalents do not exceed 0.47%. For plate over 40 mm (1 to 5 in.), ASTM A 841 specifies manganese contents of 1.00 to 1.60%.

Alloy Steels

Alloy steels constitute a category of ferrous materials that exhibit mechanical properties superior to plain carbon steels as the result of additions of such alloying elements as nickel, chromium, and molybdenum. Total alloy content can range from 2.07% up to levels just below that of stainless steels, which contain a minimum of approximately 11% Cr. For many alloy steels, the primary function of the alloying elements is to increase hardenability in order to optimize mechanical properties and toughness after heat treatment. In some cases, however, alloy additions are used to reduce environmental degradation under certain specified service conditions. Alloy steels can be classified according to:

- *Chemical composition*, such as nickel steels, nickel-chromium steels, molybdenum steels, chromium-molybdenum steels, and so on, as described in SAE-AISI designations and shown in Table 4

- *Heat treatment,* such as quenched and tempered, normalized and tempered, annealed, and so on

Table 4 SAE-AISI system of designations for carbon and alloy steels

Numerals and digits	Type of steel and nominal alloy content, %
Carbon steels	
10*xx*	Plain carbon (Mn 1.00 max)
11*xx*	Resulfurized
12*xx*	Resulfurized and rephosphorized
15*xx*	Plain carbon (max Mn range: 1.00-1.65)
Manganese steels	
13*xx*	Mn 1.75
Nickel steels	
23*xx*	Ni 3.50
25*xx*	Ni 5.00
Nickel-chromium steels	
31*xx*	Ni 1.25; Cr 0.65 and 0.80
32*xx*	Ni 1.75; Cr 1.07
33*xx*	Ni 3.50; Cr 1.50 and 1.57
34*xx*	Ni 3.00; Cr 0.77
Molybdenum steels	
40*xx*	Mo 0.20 and 0.25
44*xx*	Mo 0.40 and 0.52

Chromium-molybdenum steels	
41*xx*	Cr 0.50, 0.80, and 0.95; Mo 0.12, 0.20, 0.25, and 0.30
Nickel-chromium-molybdenum steels	
43*xx*	Ni 1.82; Cr 0.50 and 0.80; Mo 0.25
43BV*xx*	Ni 1.82; Cr 0.50; Mo 0.12 and 0.25; V 0.03 min
47*xx*	Ni 1.05; Cr 0.45; Mo 0.20 and 0.35
81*xx*	Ni 0.30; Cr 0.40; Mo 0.12
86*xx*	Ni 0.55; Cr 0.50; Mo 0.20
87*xx*	Ni 0.55; Cr 0.50; Mo 0.25
88*xx*	Ni 0.55; Cr 0.50; Mo 0.35
93*xx*	Ni 3.25; Cr 1.20; Mo 0.12
94*xx*	Ni 0.45; Cr 0.40; Mo 0.12
97*xx*	Ni 0.55; Cr 0.20; Mo 0.20
98*xx*	Ni 1.00; Cr 0.80; Mo 0.25
Nickel-molybdenum steels	
46*xx*	Ni 0.85 and 1.82; Mo 0.20 and 0.25
48*xx*	Ni 3.50; Mo 0.25
Chromium steels	
50*xx*	Cr 0.27, 0.40, 0.50, and 0.65
51*xx*	Cr 0.80, 0.87, 0.92, 0.95, 1.00, and 1.05
Chromium (bearing) steels	

50*xxx*	Cr 0.50	C 1.00 min
51*xxx*	Cr 1.02	
52*xxx*	Cr 1.45	
Chromium-vanadium steels		
61*xx*	Cr 0.60, 0.80, and 0.95; V 0.10 and 0.15 min	
Tungsten-chromium steel		
72*xx*	W 1.75; Cr 0.75	
Silicon-manganese steels		
92*xx*	Si 1.40 and 2.00; Mn 0.65, 0.82, and 0.85; Cr 0 and 0.65	
High-strength low-alloy steels		
9*xx*	Various SAE grades	
Boron steels		
*xx*B*xx*	B denotes boron steel	
Leaded steels		
*xx*L*xx*	L denotes leaded steel	

Note: The *xx* in the last two digits of these designations indicates that the carbon content (in hundredths of a percent) is to be inserted.

Because of the wide variety of chemical compositions possible and the fact that some steels are used in more than one heat-treated condition, some overlap exists among the alloy steel classifications, which include (1) low-carbon quenched and tempered (QT) steels, (2) medium-carbon ultrahigh-strength steels, (3) bearing steels, and (4) heat-resistant chromium-molybdenum steels.

Low-carbon quenched and tempered steels combine high yield strength (from 350 to 1035 MPa, or 50 to 150 ksi) and high tensile strength with good notch toughness, ductility, corrosion resistance, or weldability. The various steels have different combinations of these characteristics based on their intended applications. The chemical compositions of typical QT low-carbon steels are given in Table 5. Many of the steels are covered by ASTM specifications. However, a few steels, such as HY-80 and HY-100, are covered by military specifications. The steels listed are used primarily as plate. Some of these steels, as well as other similar steels, are produced as forgings or castings.

Table 5 Chemical compositions for typical alloy steels

(a) Single values represent the maximum allowable.

(b) Zirconium may be replaced by cerium. When cerium is added, the cerium/sulfur ratio should be approximately 1.5/1, based on heat analysis.

Medium-carbon ultrahigh-strength steels are structural steels with yield strengths that can exceed 1380 MPa (200 ksi). Table 5 lists typical compositions. Many of these steels are covered by SAE-AISI designations or are proprietary compositions. Product forms include billet, bar, rod, forgings, sheet, tubing, and welding wire.

Bearing steels used for ball and roller bearing applications are comprised of low-carbon (0.10 to 0.20% C) case-hardened steels and high-carbon (~1.0% C) through-hardened steels (Table 5). Many of these steels are covered by SAE-AISI designations.

Chromium-molybdenum heat-resistant steels contain 0.5 to 9% Cr and 0.5 to 1.0% Mo. The carbon content is usually below 0.20%. Table 5 lists typical compositions. The chromium provides improved oxidation and corrosion resistance, and the molybdenum increases strength at elevated temperatures. They are generally supplied in the normalized and tempered, quenched and tempered, or annealed condition. Chromium-molybdenum steels are widely used in the oil and gas industries and in fossil fuel and nuclear power plants. Product forms include forgings, tubing, pipe, castings, and plate.

Cleaning of Steels

Cleaning is the process of removing objectionable matter from the surfaces of manufactured products. Drawing and stamping lubricants, cutting fluids, heat treatment scale and oxides, and fingerprints are typical of soils that must be removed.

Important reasons for adequate cleaning of components and products are as follows:

- As an intermediate step to facilitate manufacturing operations, like inspection and assembly
- To prepare surfaces for subsequent operations such as coating
- As a final finish, to improve performance, appearance, and salability

The cleaning and surface preparation of manufactured components and products are accomplished by many different processes. Some of the more common processes include a variety of chemical cleaning methods such as the application of solvents, aqueous cleaners, and acids by soaking or spraying; steam and flame cleaning methods; vapor degreasing; and ultrasonic cleaning. In addition, some of the finishing processes discussed in the following section of this article, for example, dry or wet blasting, are also used for cleaning and surface preparation. Additional information on each of the cleaning procedures described below can be found in the various articles contained in the Section on "Surface Cleaning" in this Volume.

In selecting a cleaning process for steels, many factors must be considered, including: (a) identification and characterization of the soil to be removed; (b) identification of the substrate to be cleaned and the importance of the condition of the surface or structure to the ultimate use of the part; (c) degree of cleanness required, which depends on subsequent operations such as phosphating, plating and painting; (d) capabilities of the available facilities; (e) impact of the process on the environment; and (f) overall cost of the process.

Types of soil may be broadly classified into six groups: (a) pigmented drawing compounds, (b) unpigmented oil and grease, (c) chips and cutting fluids, (d) polishing and buffing compounds, (e) rust and scale, and (f) miscellaneous surface contaminants, such as lapping compounds and residue from magnetic particle inspection.

Dried or oxidized greases, oils, and drawing compounds are very difficult to remove, and thus every effort should be made to clean the parts as soon after processing as possible.

Removal of Pigmented Drawing Compounds. All pigmented drawing lubricants are difficult to remove from metal parts. Consequently, many plants review all aspects of press forming operations to avoid the use of pigmented compounds. Table 6 indicates cleaning processes typically selected for removing pigmented compounds from drawn and stamped parts.

Table 6 Selection guide for cleaning steel surfaces

Processes are listed in order of decreasing preference.

Type of production	In-process cleaning	Preparation for painting	Preparation for phosphating	Preparation for plating
Removal of pigmented drawing compounds[(a)]				
Occasional or	Hot emulsion hand slush,	Boiling alkaline,	Hot emulsion hand slush,	Hot alkaline soak, hot rinse (hand

intermittent	spray emulsion in single stage, vapor slush degrease[b]	blow off, hand wipe Vapor slush degrease, hand wipe Acid clean[c]	spray emulsion in single stage, hot rinse, hand wipe	wipe, if possible), electrolytic alkaline, cold water rinse
Continuous high production	Conveyorized spray emulsion washer	Alkaline soak, hot rinse, alkaline spray, hot rinse	Alkaline or acid(d) soak, hot rinse, alkaline or acid(d) spray, hot rinse	Hot emulsion or alkaline soak, hot rinse, electrolytic alkaline, hot rinse
Removal of unpigmented oils and greases				
Occasional or intermittent	Solvent wipe Emulsion dip or spray Vapor degrease Cold solvent dip Alkaline dip, rinse, dry (or dip in rust preventive)	Solvent wipe Vapor degrease or phosphoric acid clean[d]	Solvent wipe Emulsion dip or spray, rinse Vapor degrease	Solvent wipe Emulsion soak, barrel rinse, electrolytic alkaline rinse, hydrochloric acid dip, rinse
Continuous high production	Automatic vapor degrease Emulsion, tumble, spray, rinse, dry	Automatic vapor degrease	Emulsion power spray, rinse Vapor degrease Acid clean[c]	Automatic vapor degrease, electrolytic alkaline rinse, hydrochloric acid dip, rinse[e]
Removal of chips and cutting fluids				
Occasional or intermittent	Solvent wipe Alkaline dip and emulsion surfactant Stoddard solvent or trichlorethylene Steam	Solvent wipe Alkaline dip and emulsion surfactant Solvent or vapor	Solvent wipe Alkaline dip and emulsion surfactant[f] Solvent or vapor	Solvent wipe Alkaline dip, rinse, electrolytic alkaline[g], rinse, acid dip, rinse[h]
Continuous high production	Alkaline (dip or spray) and emulsion surfactant	Alkaline (dip or spray) and emulsion surfactant	Alkaline (dip or spray) and emulsion surfactant	Alkaline soak, rinse, electrolytic alkaline[g], rinse, acid dip and rinse[h]
Removal of polishing and buffing compounds				
Occasional or intermittent	Seldom required	Solvent wipe Surfactant alkaline (agitated soak), rinse Emulsion soak, rinse	Solvent wipe Surfactant alkaline (agitated soak), rinse Emulsion soak, rinse	Solvent wipe Surfactant alkaline (agitated soak), rinse electroclean[i]
Continuous high production	Seldom required	Surfactant alkaline spray, spray rinse Agitated soak or spray, rinse[j]	Surfactant alkaline spray, spray rinse Emulsion spray, rinse	Surfactant alkaline soak and spray, alkaline soak, spray and rinse, electrolytic alkaline[i], rinse, mild acid pickle, rinse

(a) For complete removal of pigment, parts should be cleaned immediately after the forming operation, and all rinses should be by spraying where practical.

(b) Used only when pigment residue can be tolerated in subsequent operations.

(c) Phosphoric acid cleaner-coaters are often sprayed on the parts to clean the surface and leave a thin phosphate coating.

(d) Phosphoric acid for cleaning and iron phosphating. Proprietary products for high- and low-temperature applications are available.

(e) Some plating processes may require additional cleaning dips.

(f) Neutral emulsion or solvent should be used before manganese phosphating.

(g) Reverse-current cleaning may be necessary to remove chips from parts having deep recesses.

(h) For cyanide plating, acid dip and water rinse are followed by alkaline and water rinses.

(i) Other preferences: stable or diphase emulsion spray or soak, rinse, alkaline spray or soak, rinse, electroclean; or solvent presoak, alkaline soak or spray, electroclean.

(j) Third preference: emulsion spray rinse

Removal of Unpigmented Oil and Grease. Common shop oils and greases, such as unpigmented drawing lubricants, rust-preventive oils, and quenching and lubricating oils, can be effectively removed by several different cleaners. Table 6 lists cleaning methods frequently used for removing oils and greases.

Removal of Chips and Cutting Fluids from Steel Parts. Cutting and grinding fluids used for machining may be classified into three groups, as follows:

- Plain or sulfurized mineral and fatty oils (or combinations of the two), chlorinated mineral oils, and sulfurized chlorinated mineral oils
- Conventional or heavy-duty soluble oils with sulfur or other compounds added and soluble grinding oils with wetting agents
- Chemical cutting fluids, which are water-soluble and generally act as cleaners. They contain soaps, amines, sodium salts of sulfonated fatty alcohols, alkyl aromatic sodium salts of sulfonates, or other types of the soluble addition agents

Usually, all three types of fluids are easily removed, and the chips fall away during cleaning, unless the chips or the part become magnetic. Plain boiling water is often suitable for removing these soils, and in some plants, mild detergents are added to the water to increase its effectiveness. Steam is widely used for in-process cleaning, especially for large components. Table 6 indicates cleaning processes typically used for removing cutting fluids to meet specific production requirements.

Removal of Polishing and Buffing Compounds. Table 6 lists preferred and alternate methods for removing polishing and buffing compounds from sheet metal parts. However, some modification may be required for complete removal of all classes of these soils.

Removal of Rust and Scale. The seven basic methods used for removing rust and scale from ferrous mill products, forgings, castings and fabricated steel parts are:

- Abrasive blasting (dry or wet)
- Tumbling (dry or wet)
- Brushing
- Acid pickling
- Salt bath descaling
- Alkaline descaling
- Acid cleaning

The most important considerations in selecting one of the above methods are:

- Thickness of rust or scale
- Composition of metal
- Condition of metal (product form or heat treatment)
- Allowable metal loss
- Surface finish tolerances
- Shape and size of workpieces
- Production requirements
- Available equipment
- Cost
- Freedom from hydrogen embrittlement

Combinations of two or more of the available processes are frequently used to advantage.

Cleaning Prior to Coating. Chemical cleaning is the most widely used method of providing a suitable surface for subsequent finishing by phosphating, electroplating, organic coating, or other coating processes. Chemical cleaning usually depends upon the use of solvents or a chemical action between the cleaning material and the contaminant. Table 7 compares the most common of the basic chemical cleaning methods. The types of chemical cleaners generally used for removing contaminants from metal surfaces fall into the broad categories of solvent cleaners, solvent emulsion cleaners, alkaline cleaners, and acid cleaners.

Table 7 Comparison of chemical cleaning methods

Factors	Emulsifiable solvent cleaning	Alkali cleaning, immersion or spray	Alkali electrocleaning	Acid pickling	Molten-salt descaling
Equipment	Same as for alkali cleaning without current	Still tanks or conveyorized spray washers of various sizes and capacities	Open steel tanks with dc current source, busbars, and control equipment	Appropriate corrosion-resistant tankage	Low-carbon steel tanks with high-temperature heat source
Cleaning medium	Mineral solvents mixed with suitable emulsifiers; used in water solution	Appropriate proprietary cleaners in water solution properly inhibited for sensitive metals	Same as for alkali cleaning without current	Various acids	Mixture of fused salts
Operating temperature	Depends on flashpoint of solvent. Usually room temperature to 60 °C (140 °F)	Room temperature to 100 °C (212 °F)	50-95 °C (120-200 °F)	Room temperature to 80 °C (180 °F)	205-510 °C (400-950 °F)

Health hazards	Safe when body contact is avoided. Venting may be required.	Safe when body contact is avoided. Venting may be required.	Safe when body contact is avoided. Venting may be required.	Safe with protective clothing, gloves, face shields, goggles, etc. Venting may be required.	Safe with protective clothing, gloves, face shields, goggles, etc.
Fire hazard	Temperature must not exceed flashpoint of solvent.	None	None	None	Slight
Type soil removed	Both organic and inorganic matter	Both organic and inorganic matter	Normally used for final cleaning prior to plating to remove slight contamination and to activate surface	Oxides, scale, rust, etc.	Scale, oxides, etc.
Effect on base metal	None	None when properly inhibited, but caustic alkali will attack aluminum and zinc.	None when properly inhibited	Very slight surface attack when properly controlled	Sometimes slight etch
Time required	1 to 15 min	1 to 30 min	$\frac{1}{2}$ to 3 min	1 to 30 min	Varies from seconds to minutes, depending on the application

Finishing of Steels

Of the many different processes used for finishing, some simply clean contaminants from surfaces. Others remove or form the surface material to produce the desired results. The finishing processes can be broadly classified into mechanical, thermal, and electrochemical methods, but some combine several methods. Each of these finishing categories will be briefly described below. The reader should also refer to the article "Classification and Selection of Finishing Processes" for additional information. Table 8 compares various finishing methods used for burr removal.

Table 8 Advantages and limitations of various finishing processes

Process	Advantages and typical applications	Possible limitations
Abrasive flow	Removes hard-to-reach burrs. Polishes surfaces	Blind features not deburred
Abrasive blasting	Good for hard metals	Produces matte finish. Dust control required. Burr must be accessible

Barrel tumbling	Low cost. Suitable for all materials	Edges must be exposed. Slow and not effective for interior surfaces and edges
Brushing and buffing	All accessible burrs and edges. Polishes surfaces	
Centrifugal barrel	Fast process. Suitable for all materials. Residual compressive stresses	
Electrochemical	Removes hard-to-reach burrs	Possible stray etching. Limited to conductive metals
Electropolishing	Good for thin burrs. Polishes surfaces	Possible pitting and streaking
Hand deburring	For hard-to-reach areas and small volume requirements.	Usually expensive and inconsistent. Burrs must be accessible
Spindle finishing	Fast process. For uniform shapes	Fixturing needed
Thermal energy	For thin burrs. Deburrs blind features	Covers part with oxide film. Burr area must be free of oil and water
Vibratory	Versatile, economical process. Many deburring and finishing applications	Not usually suitable for removing internal burrs in intersecting holes

Mechanical Finishing

The term "mechanical finishing" encompasses the technology of edge and surface conditioning of metal and nonmetal products for both cosmetic and functional purposes. Generation of smooth and specular surfaces to improve appearance of components is an essential part of the manufacturing cycle of most manufactured products, but functional finishing is still more important. Most mechanisms will run longer and more efficiently if component surfaces and edges are smooth. If an appropriate scratch pattern is generated, edges and surfaces may have much improved retention of lubricants, resulting in still smoother operation. Removal of stress raisers at sharp corners and generation of controlled radii on edges can substantially improve thermal and mechanical fatigue strength of highly stressed components. Removal of tensile stresses by improved surface integrity will reduce or eliminate their contribution to service failures. Moreover, generation of high compressive stresses, which can be achieved by several mechanical finishing processes, can significantly increase resistance to fatigue stresses and thus increase the service life of highly stressed parts. Improved edge and surface condition in passages through which gases or fluids flow reduces "drag" and thus increases flow rates.

Mechanical finishing is an essential part of the manufacturing cycle for most products. A high standard of mechanical finish will normally result in a better product that is also better looking. Proper attention to the technology of mechanical finishing will result in improved productivity as well as an improved product.

Mechanical finishing processes for processing steels may be classified as follows:

- Manual filing, scraping, and deburring
- Polishing, buffing, and brushing
- Abrasive and nonabrasive blasting
- Mass finishing
- Shot peening

- Honing and lapping
- Abrasive flow machining

Polishing, Buffing, and Brushing. Polishing is the mechanical finishing of a product using abrasives which are firmly adhered to a flexible backing, such as with an abrasive belt or with abrasives bonded to a flexible wheel or a flap wheel (while grinding is the use of abrasives firmly bonded to a rigid backing, as is the case with a grinding wheel). Polishing operations usually follow grinding and precede buffing.

Buffing refers to the finishing of a product by means of abrasive loosely adhering to a flexible backing, typically liquid or bar compounds applied to cloth wheels.

Brushing is the use of filament wheels for edge or surface conditioning of a product. Filaments are normally nonabrasive fibers or metal wires, but can be abrasive-laden filaments. Brushing may be done either wet or dry, and may employ compounds loosely applied.

Polishing processes are primarily abrasive processes, whereas in buffing and brushing a substantial part of the action may be plastic deformation of surfaces and edges.

Traditionally, polishing and buffing have been associated with decorative surface finishing operations and surface finishing prior to plating or painting. Modern automated polishing and buffing are more frequently used for improving functional edge and surface condition and are often used to improve product shape and tolerances (replacing some machining operations). Brushing is most often used for cleaning (removing scale, oxide films, rust, and old paint), although it also finds many applications in deburring and in edge and surface conditioning. More detailed information on polishing, buffing, and brushing can be found in the article "Finishing Methods Using Multipoint or Random Cutting Edges" in this Volume.

Blasting processes, both abrasive and nonabrasive, are based on the principle of propelling a series of particles (normally steel shot or grit for blasting steels) against a surface for the purpose of modifying the condition of that surface. In the vast majority of cases, the particles are propelled in a matrix of air or water to the work surface. The basic means of propelling the blasting material is with either air pressure or a centrifugal wheel. Equipment for blast cleaning and finishing is described in the article "Mechanical Cleaning Systems" in this Volume.

Blast finishing processes are used for removal of contaminants, effecting changes in surface condition, deburring, and peening.

Removal of Contaminants. Major applications in this group are removal of sand from castings and removal of scale from forgings. Blasting is also the standard means of removing all scale from steel products and of cleaning paint, rust, oil and other undesirable coatings from part surfaces.

Changes in Surface Condition. Blasting can be used to improve the mechanical bonding of most coatings--paints, galvanized coatings, elastomeric linings, and enamel coatings.

Deburring. Blasting may be used to break off small burrs on some products; if the material is ductile, blasting may blunt burrs and sharp edges. The blasting process is not suitable for generating radii on edges and corners.

Mass finishing normally involves loading of components to be finished into a container together with some abrasive medium, water, and compound. Action is applied to the container to cause the medium to rub against the surfaces, edges, and corners of the components, or to cause the components to rub against each other, or both. This action may deburr, generate edge and corner radii, clean the parts by removing rust and scale, and modify the surface stress. The basic mass finishing processes include:

- Barrel finishing
- Vibratory finishing
- Centrifugal disk finishing
- Centrifugal barrel finishing

- Spindle finishing

Each of these processes is described in the article "Mass Finishing Methods" in this Volume. Table 9 compares the advantages and limitations of mass finishing processes.

Table 9 Advantage and limitations of major mass finishing processes

Mass finishing process	Advantages	Limitations
Rotary barrel	Low initial, operating, and maintenance costs. Batch automation capability	Slow process. High operator skill needed. Large floor space required. No in-process inspection. Wet working area. Little-to-no work in part recesses
Vibratory tub	Faster than barrel. Can handle small to very large and very long parts. Open for in-process inspection. Full automation capability. Batch or continuous operation	Noisy. Slower than high-energy processes (centrifugal barrel and disk). External material handling generally needed
Vibratory bowl	Faster than barrel. Handles very small to large parts. Open for in-process inspection. Integral separation. Less noisy than vibratory tub. Generally lower initial cost and better media-parts mixing than vibratory tub. Economical for general-purpose work, heavy deburring, and continuous processing. Good automation capabilities. Batch or continuous operation	Cannot handle very long parts
Centrifugal barrel	Fast processing. Can handle precision and fragile parts. Produces smooth finishes. Batch automation capability. Versatile-can change from fine finishing to heavy stock removal. Improves fatigue strength. Low floor space needs	No in-process inspection. Complex to automate
Centrifugal disk	Fast processing. Open for in-process inspection. Batch automation capability. Versatile	Limited part sizes. External material handling
Spindle	Fast processing. No impingement of workpieces. Produces smooth finishes. Automation capability with robot reload	Parts must be fixtured. Limited part sizes and geometries (typically used for cylindrical parts). Less versatile than other processes

Shot peening is the cold working of a metal surface with a stream of spherical shot particles applied to the surface at high velocity under carefully controlled conditions. Shot peening is most effective in reducing fatigue failures in parts subject to cyclic loading. Failures originate in surface areas under repeated tensile loading, and cracks will propagate from a surface defect or other stress riser. Shot peening prevents these failures by creating compressive stress layers in the surfaces of parts. As a part is loaded, its critical surface area will not develop tensile stresses until the shot-peen-induced compressive stresses are first overcome, thus permitting an increase in the allowable stress level and hence in the service life of the part. The effect of shot peening in improving the surface integrity of the part is also important. No matter how carefully a part is manufactured, it will exhibit some surface imperfections. These flaws may be localized areas of tensile stresses or phase transformations from machining or grinding, as well as pits, scratches, and other surface defects. As peening cold works the part surface, it blends these surface imperfections and effectively eliminates them as stress concentration points. Table 10 shows the effect of shot peening on the fatigue strength of machined 4340 alloy steel.

Table 10 Effect of shot peening on fatigue strength of 4340 steel

Machining operation	Endurance limit in bending, 10^7 cycles		Gentle grinding, %
	MPa	ksi	
Gentle surface ground	703	102	100
Gentle surface ground and shot peened	772	112	110
Abusive surface ground	430	62	61
Abusive surface ground and shot peened	630	92	90
Electropolished	620	90	88
Electropolished and shot peened	660	96	94

Shot peening has long been used to improve the fatigue characteristics of leaf and coil springs (Fig. 1). Increases in fatigue life up to 800% are often obtained. The process is also used extensively on gears, driveshafts, crankshafts, torsion bars, axles, ball studs, high-strength fasteners, railroad wheels, and oil well drilling equipment. Often it is applied only at a critical area, such as a fillet radius.

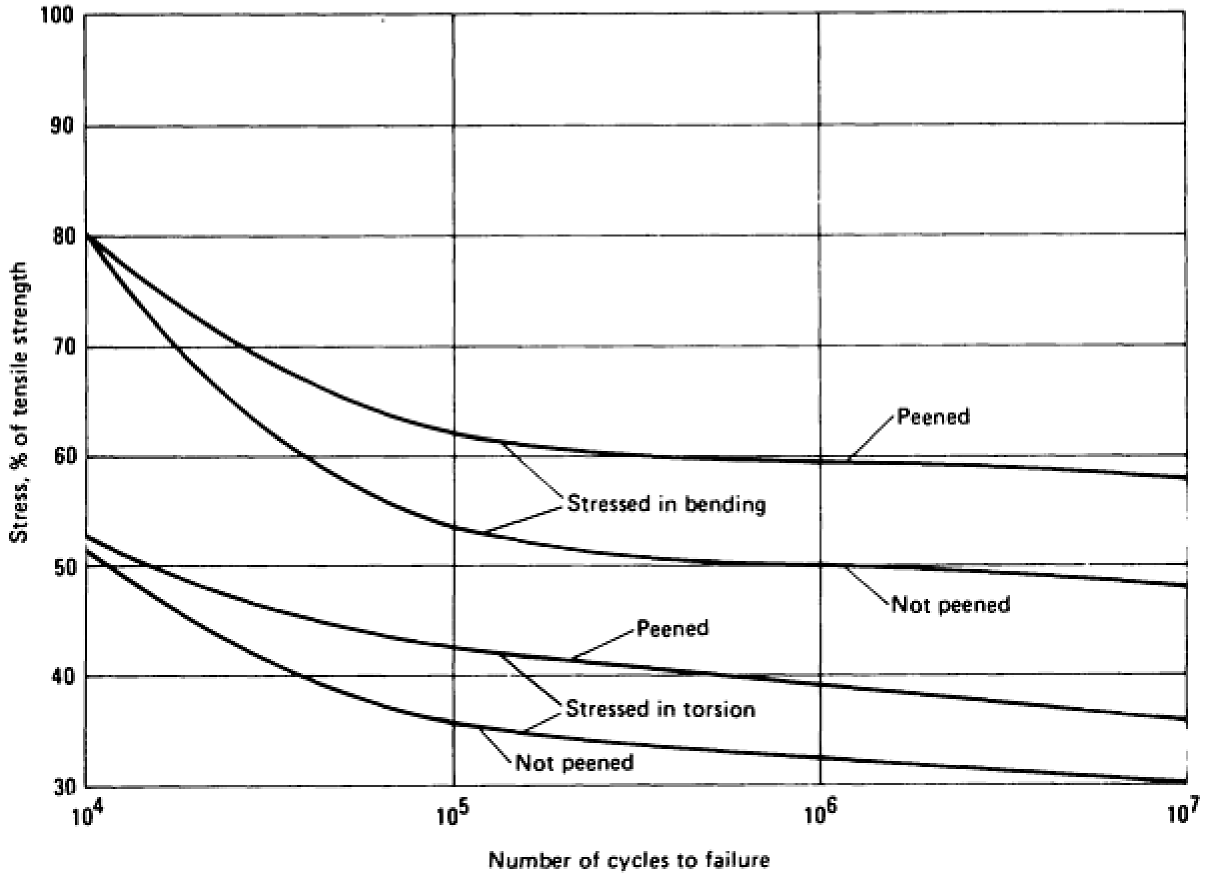

Fig. 1 Fatique curves for peened and unpeened and steel spring wires

Parts requiring shot peening should be clean, dry, and free of any scale. Any material on top of the base material may absorb the energy of the controlled peening process. Degreasing, descaling, or blast cleaning operations are often performed prior to shot peening to ensure proper and beneficial results. Additional information on this process can be found in the article "Shot Peening" in this Volume.

Honing is a controlled, low-speed sizing and surface-finishing process in which stock is removed by the shearing action to the bonded abrasive grains of a honing stone, or stick. Honing machines simultaneously apply several sticks (although one can be used) mounted on the periphery of a cylindrical body to the work surface. The usual purpose of honing is to produce uniform high accuracy and fine finish, and in the most common applications only a few thousandths of an inch of stock is removed although heavy stock removal up to 6.35 mm (0.250 in.) can also be cost effective.

The most frequent application of honing is for finishing inside cylindrical surfaces, but numerous outside surfaces also are honed. Gear teeth, valve components, and races for ball bearings and roller bearings are typical applications of external honing. Microhoning, also known as superfinishing or microfinishing, is closely related to honing. Microhoning uses finer grit (or grain) sizes (320 to 1200) than honing (60 to 600 grit). The primary distinction between honing and microhoning is that the tool rotates in honing, while in microhoning it is always the workpiece that rotates. Microhoning is a special honing operation in which the bonded abrasive stone is subjected to very light pressure and a short, high-frequency stroke.

Honing is generally used to produce surface finishes in the range of 0.80 to 0.20 μm (32 to 8 μin.) R_a (roughness average), while microhoning can be cost effective in producing surface finishes of the order of 0.10 to 0.050 μm (4 to 2 μin.) R_a. Each method can produce even finer finishes, but productivity, as a result, suffers. Figure 2 compares typical ranges of surface finishes obtained by honing and microhoning to other common production finishing processes. More detailed information on honing can be found in the article "Honing" in *Machining,* Volume 16 of the *ASM Handbook.*

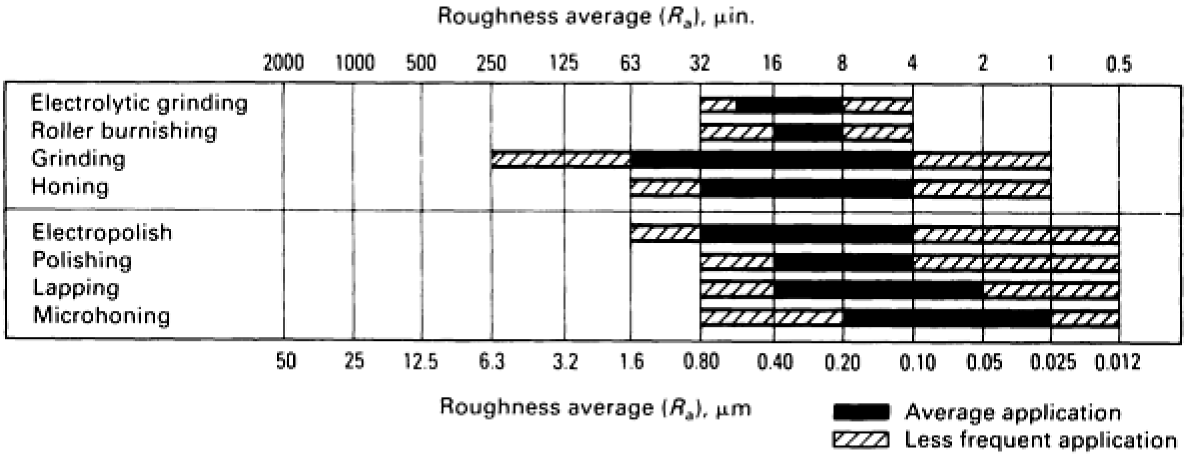

Fig. 2 Typical ranges of surface finish from common production processes. Higher or lower values may be obtained under various conditions.

Lapping is a low-velocity abrading process that removes controlled, very small amounts of material. It is accomplished with loose abrasive grains (usually retained in a viscous or liquid media, called the vehicle) between a tooling plate or wheel, called the lap, and the work surface to be finished. A typical setup for lapping flat steel products is shown in Fig. 3.

Fig. 3 A 1220 mm (48 in.) planetary top plate drive dual-face lapping machine loaded with a variety of components having various configurations and thicknesses to demonstrate the processing capabilities of the equipment. Shown clockwise, starting with the bottom-most carriers, are hardened high-carbon steel shear blades; 102 by 102 mm (4 by 4 in.) photomask blanks used to project microcircuits onto electronic substrates; stainless steel sender bars, which will be etched into optical position indicators; valve plates machined from cutoff hot-rolled bar stock for use in hydraulic motors; and a hardened alloy steel rotary slitter blade.

Lapping is generally a final finishing operation that results in four major refinements in the workpiece: (1) extreme accuracy of dimension, (2) correction of minor imperfections of shape, (3) refinement of surface finish, and (4) close fit between mating surfaces. The life of moving parts that are subject to wear can be greatly increased by eliminating the hills and valleys on workpiece surfaces and creating a maximum percentage of bearing area. Besides developing a workpiece that meets the surface finish requirements and is correct for geometrical and dimensional accuracy, there is no distortion, as lapping procedures do not require the use of magnetic chucks or other holding or clamping devices.

In normal lapping operations, less heat is generated than in most other finishing operations, thus minimizing the possibility of rehardened and decarburized areas on hardened or heat-treated parts. When both sides of a flat piece are lapped in the same operation (Fig. 3), extreme accuracy in flatness and parallelism can be accomplished; and by removing the same amount of stock from both sides of the part simultaneously, any inherent stresses in the piece are equally relieved. Typical applications for lapping include piston rings, crankshafts, ball bearings and bearing assemblies, and gears. More detailed information on lapping can be found in the article "Lapping" in *Machining,* Volume 16 of the *ASM Handbook.*

Abrasive-flow machining (AFM) is a process in which a semisolid abrasive media is forced, or extruded, through a workpiece passage. The media consist of a pliable polymer carrier and a concentration of abrasive grains such as silicon carbide. The viscosity of the carrier and the type, concentration, and size of the abrasive grains can be varied to achieve specific results.

By proper control of parameters and abrasive flow, the AFM process can perform a wide range of precision machining and finishing operations. These operations include deburring, edge radiusing, honing, polishing, and the removal of recast layers from workpiece surfaces. Important features of the process include selectivity, the capability of finishing inaccessible areas, and versatility.

Polishing with AFM can improve surface finishes of 0.75 to 7.5 μm (30 to 300 μin.) to one tenth or less of the original finishes. Material removal by the abrasion results in a dimensional change of about 25 to 35% more than the total roughness of the surface. For example, in reducing a surface finish of 2.5 μm (100 μin.) produced by electrical discharge machining to a finish of 0.25 μm (10 μin.) requires the removal of about 0.03 mm (0.001 in.) of stock. In most cases, stock removal can be held uniform throughout a passage with ±20%.

The finishing of dies (extruding, compacting, cold heading, upsetting, and others) is a major application of the AFM process. Advantages include reduced costs and longer die life. Costs are reduced by eliminating or minimizing the need for time-consuming hand polishing of the dies. Longer die life results from the directional finish produced by AFM and the improved uniformity and quality of the finished surfaces. Other components commonly finished by the AFM process include gears, bearing races and cages, and splined parts. More detailed information on AFM can be found in the article "Abrasive Flow Machining" in *Machining,* Volume 16 of the *ASM Handbook.*

Thermal and Electrochemical Finishing

Thermal Deburring. Burrs and flash, both internal and external, are rapidly burned away using the thermal energy method (TEM). Parts to be processed are loaded in baskets or special fixtures and placed in a water-cooled furnace chamber. A fuel mixture of natural gas and oxygen is then injected into the chamber under pressure. The initial fire or heat is supplied by an ignition system in the form of a spark from an ignitor. The spark causes the combustible gas mixture to ignite, and all the fuel gas is consumed in approximately 2 ms to form a 3300 °C (6000 °F) heat wave.

The heat wave hits everything within the chamber. It hits the water-cooled walls of the chamber, the parent metal of the part or parts, and the burrs within blind holes, external edges, and intersecting holds (small or large) that cannot be reached by hand. The main body of the part becomes warm (usually under 150 °C, or 300 °F), while the flash or burrs (having less mass per surface area) heat up instantly and burst into flames. Heat created by the burning of fuel gas thus triggers the start of a second fire of the burr material itself. Because there is an abundance of oxygen in the initial fuel mixture, burrs will continue to burn until the heat is dispersed throughout the main body of the part.

Applications for the TEM include deburring of various steel castings and machined gears. For the gears, burrs are removed from the teeth and from tapped holes at the rate of 120 gears per hour. More detailed information on thermal deburring can be found in the article "Thermal Energy Method" in *Machining,* Volume 16 of the *ASM Handbook.*

Electropolishing is an electrochemical process for removing metal. Etching, deburring, smoothing, coloring, and machining are typical electropolishing processes. The removal of metal is done anodically in an acid or alkaline solution.

During the process, products of anodic metal dissolution react with the electrolyte to form a film at the metal surface. Two types of films have been observed: (a) a viscous liquid that is nearly saturated, or is supersaturated, with the dissolution products; and (b) anodically discharged gas, usually oxygen. Both types of films exist simultaneously in most commercial electropolishing solutions. The gas appears to be a blanket on the outside of the viscous film. Which type of film predominates depends on (a) the kind of metal, (b) the nature of the electrolyte, and (c) the surface condition prior to electropolishing (i.e., surface contamination, grain size, inclusions).

The most widely used electropolishing solutions for steels contain one or more of the concentrated inorganic acids--sulfuric, phosphoric, and chromic. Table 11 lists conditions for electropolishing alloy steels in acid electrolytes. Some of the steel products that undergo electropolishing are low-alloy (4130, 4140, and similar steels) automotive piston rings, crankpins, cotton-picker spindles, hand tools, gears, television chassis, and paper knives.

Table 11 Conditions for electropolishing steels in acid electrolytes

Type of metal (and product)	Purpose of treatment	Bath volume		Installed power		Current density		Polishing cycle, min	Daily production			Operators
										Area		
		L	gal	A	V	A/dm^2	A/ft^2		No. of parts	m^2	ft^2	
Sulfuric-phosphoric acid electrolytes												
Carbon steels (job-shop work)	Brighten; deburr	1500	400	1500	12	25-40	250-400	Varies	Varies	. . .	. . .	1
4140 steel	Prepare for chromium plate	3200	850	4000	12	15	150	10	7000-10,000	45-75	500-800	3
Sulfuric-phosphoric-chromic acid electrolytes												
Carbon steel	Smooth; deburr	1500	400	. . .	. . .	30	300	2	5000	90	1000	1
4130 steel (tools)	Bright finish	950	250	1500	9	17.5	175	4	2000-5000	. . .	. . .	2

Steels are electropolished for one or more of the following purposes:

- Improve appearance and reflectivity
- Improve resistance to corrosion
- Prepare metals for plating, anodizing, or conversion coating
- Remove edge burrs produced by mechanical cutting tools
- Remove the stressed and disturbed layer of surface metal caused by the cutting, smearing, and tearing action of mechanical stock removal or of abrasive finishing

- Inspect for surface imperfections in cast, forged, or wrought metal
- Remove excess material as desired for milling metal parts

Effect on Fatigue Strength. Removal of not more than 25 μm (1 mil) on the diameter of steel fatigue specimens by electropolishing can lower the endurance limit from 10 million cycles without failure to failure at 100,000 to 120,000 cycles at 520 MPa (75 ksi) (Ref 5). The decrease in diameter is not responsible for the loss. Grinding and hand finishing to the same undersize has no adverse effect.

Static stress-strain values on electropolished specimens showed little or no scatter, and when the electropolished surface was rubbed with used 000 emery paper, the original value for fatigue limit was obtained. The mild treatment indicates that any detrimental effect of an electropolished surface results from removal of a compressively stressed skin. It has been observed that wet blasting raised fatigue strength of electropolished specimens to the level attained by polishing mechanically.

The lower fatigue strength of electropolished specimens appears to be because of removal of, or inability to produce, compressive stress in metal surfaces. Thus, electropolishing is comparable in effect to a stress-relieving anneal. For example, mechanical polishing of a chromium-vanadium steel produced a compressive stress of 350 to 520 MPa (50 to 75 ksi) at a depth of 0.02 to 0.05 mm (0.008 to 0.002 in.) below the surface. The stress was relieved by heating at 500 °C (930 °F) for 2 h, which resulted in lowering the fatigue limit from approximately 580 to 560 MPa (85 to 80 ksi). Similar treatment of a low-carbon steel lowered fatigue limit from approximately 730 to 630 MPa (105 to 90 ksi). Electropolishing lowered fatigue limit comparably.

Fatigue strength is not always lower after electropolishing. In an alternating torsion test, a nickel-chromium-molybdenum steel heat treated to 1450 MPa (210 ksi) had 34% higher fatigue strength after electropolishing a ground surface. The same steel heat treated to a lower tensile strength showed lower fatigue strength after electropolishing.

Because fatigue data for electropolished specimens show considerably less scatter than for mechanically polished specimens, electropolishing tends to show true fatigue value characteristic of a particular metal and metallurgical condition. Thus, any irregularly stressed surface can be removed by electropolishing, and a uniform compressive stress can then be applied by controlled working, such as shot peening (Table 10), wet blasting, or mild abrasive polishing.

Removal by electropolishing of 100 μm (4 mils) of metal from the surface of mechanically polished low-alloy steel containing 0.44% C, 0.61% Mn, 2.48% Ni, 0.82% Cr, and 0.48% Mo that was heat treated to a tensile strength of 1100 MPa (160 ksi) changed the residual surface compressive stress of approximately 170 to 200 MPa (25 to 30 ksi) to a tensile stress of 0 to 34 MPa (0 to 5 ksi). The fatigue limit was lowered about 28 MPa (4 ksi). The stress gradient was approximately 140 to 200 MPa (20 to 30 ksi) in 0.100 mm (0.004 in.) in the mechanically polished surfaces. The residual surface stress in mechanically polished specimens differed by approximately 200 to 240 MPa (30 to 35 ksi) from that of electropolished specimens with comparable surface roughness; fatigue limits differed by approximately 580 to 550 MPa (85 to 80 ksi). Variability of fatigue strength after certain mechanical operations and after electropolishing is shown in Table 12.

Table 12 Typical surface compression stress and fatigue strength of various carbon steels finished mechanically or by electropolishing

Finishing method	Fatigue strength, % of value for mechanical polishing	Depth of cold work		Surface compressive stress	
		mm	in.	MPa	ksi
Mechanical polishing	100	<0.050	<0.002	620	90
Electropolishing	70-90	None	None	None	None

Lathe turning	65-90	0.50	0.02	. . .	. . .
Milling	. . .	0.18	0.007	. . .	. . .
Grinding	80-140	≤.25	≤.01	760	110
Surface rolling	115-190	1.00	0.04	900	130
Shot peening	85-155	0.50	0.02	1030	150

Conversion Coatings

Phosphate or chromate conversion coatings are used to enhance the corrosion resistance of steels. By themselves, they provide slightly better corrosion resistance than bare steel; more often, they are used in conjunction with another coating system. Conversion coatings are applied after hot-dip galvanizing and provide good corrosion protection when topcoated with an organic coating system. More detailed information on conversion coatings can be found in the articles "Phosphate Coatings" and "Chromate Conversion Coatings" in this Volume.

Phosphate Coating

Phosphate coating is the treatment of bare or galvanized steel with a dilute solution of phosphoric acid and other chemicals in which the surface of the metal, reacting chemically with the phosphoric acid medium, is converted to an integral, mildly protective layer of insoluble crystalline phosphate. Phosphate conversion coatings are applied to steel substrates to enhance corrosion resistance, increase paint adhesion, or both.

Phosphate coatings range in thickness from less than 3 to 50 μm (0.1 to 2 mils). Coating weight (grams per square meter of coated area), rather than coating thickness, has been adopted as the basis for expressing the amount of coating deposited.

Types of Phosphate Coatings. The three principal types of phosphate coatings in general use include:

- *Iron phosphate*--lightweight, amorphous phosphate coatings that do not contain significant amounts of divalent metal ions from solution. Coating weights range from 0.16 to 0.80 g/m^2 (15 to 70 mg/ft^2). Although iron phosphate coatings are applied to steel to provide receptive surfaces for bonding of fabrics, woods, and other materials, they are used chiefly as base coatings for subsequent painting.
- *Zinc phosphate*--medium-weight, crystalline phosphate coatings that contain divalent metal ions from the solution and/or the metal surface. Coating weights range from 1.4 to 4.0 g/m^2 (130 to 370 mg/ft^2). Zinc phosphate coatings can be used for any of the following applications of phosphating: (a) as a base for paint or oil; (b) as an aid to cold forming, tube drawing, or wiredrawing; (c) for increasing wear

resistance; or (d) for rustproofing.

- *Heavy phosphate* (manganese phosphates)--heavy coatings that contain divalent metal ions from solution and from the metal surface. Coating weights range from 7.5 to 30 g/m^2 (700 to 2800 mg/ft^2). Manganese phosphate coatings are applied to ferrous parts (bearings, gears, and internal-combustion engine parts, for example) for break-in and for prevention of galling. These coatings are usually dark gray. However, because almost all manganese phosphate coatings are used as an oil base and because the oil intensifies the coloring, manganese phosphate coatings are usually black in appearance.

The characteristics of these three phosphate coating types are summarized in Table 13.

Table 13 Characteristics of phosphate coatings

Characteristics	Type of coating		
	Iron phosphate	**Zinc phosphate**	**Heavy phosphate**
Coating weight	0.16-0.80 g/m^2 (0.0005-0.0026 oz/ft^2)	1.4-4.0 g/m^2 (0.0045-0.013 oz/ft^2)	7.5-30 g/m^2 (0.025-0.1 oz/ft^2)
Types	Cleaner/coater Standard Organic phosphate	Standard Nickel-modified Low-zinc Calcium-modified Manganese-modified	Manganese phosphate Zinc phosphate Ferrous phosphate
Common accelerators	Nitrite/nitrate Chlorate Molybdate	Nitrite/nitrate Chlorate Nitrobenzene sulfonic acid	None Chlorate Nitrate Nitroguanidine
Operating temperatures	Room -70 °C (160 °F)	Room -70 °C (160 °F)	60-100 °C (140-212 °F)
Free acid, points	-2.0 to 2.0	0.5-3.0	3.6-9.0
Total acid, points	5-10	10-25	20-40+
Prephosphate conditioners	None	Titanium phosphate None	Manganese phosphate Titanium phosphate None
Primary use	Paint base for low-corrosion environments	Paint base for high-corrosion environments	Unpainted applications
Limitations	Low painted corrosion resistance; low	Poor unpainted corrosion resistance	Expensive, long

Materials needed for tanks	Low-carbon steel	Low-carbon steel, stainless steel, or plastic-lined steel	Stainless steel or low-carbon steel

Process Details. The application of a phosphate coating as a base for subsequent painting normally comprises five successive operations: (a) cleaning, (b) rinsing, (c) phosphating (by immersion or spraying), (d) rinsing, and (e) chromic acid rinsing. Some of these operations may be omitted or combined, such as cleaning and coating in one operation. Additional operations may be required, depending on the surface condition of the parts to be phosphated or on the function of the phosphate coating. Parts exemplifying these exceptions are:

- Heavily scaled parts, which may require pickling before cleaning
- Parts with extremely heavy coatings of oil or drawing compounds, which may require rough cleaning before the normal cleaning operation
- Parts that are tempered in a controlled atmosphere before being phosphated, which may not require cleaning and rinsing before phosphating
- Parts that are phosphated and later oiled for antifriction purposes, which may have the chromic acid rinse omitted, because corrosion resistance is not required. Some rust-preventive oils negate the need for a chromic rinse while still providing excellent corrosion resistance
- Automotive parts when electrodeposition of a primer is involved. A deionized water rinse is required after the chromic acid rinse

Chromate Conversion Coatings

Chromate conversion coatings are formed by a chemical or an electrochemical treatment of metals or metallic coatings in solutions containing hexavalent chromium (Cr^{6+}) and, usually, other components. The process results in the formation of an amorphous protective coating composed of the substrate, complex chromium compounds, and other components of the processing bath.

Chromate conversion coatings are applied primarily to enhance bare or painted corrosion resistance, to improve the adhesion of paint or other organic finishes, and to provide the metallic surface with a decorative finish. Chromate conversion coatings are most frequently applied by immersion or spraying, but other methods of application, such as brushing, roll coating, dip and squeegee, electrostatic spraying, or anodic deposition, are used in special cases.

Processing Sequence. Chromate coatings are applied by contacting the processed surfaces with a sequence of processing solutions. The processing baths are arranged in a series of tanks, and the surfaces to be processed are transferred through the sequence of stages by using manual, semiautomatic, or automatic control. The chromate coatings are usually applied to metal parts or to a continuous metal strip running at speeds to 5 m/s (1000 ft/min).

The basic processing sequence consists of the following six steps: cleaning, rinsing, conversion coating, rinsing, post-treatment rinsing or decorative color rinsing, and drying. In many applications, this sequence is expanded to accommodate pickling deoxidizing, dyeing, brightening, and other rinsing stages, or the sequence can be shortened when cleaning or post-treatment rinsing is not necessary. Some typical processing sequences are given in Table 14.

Table 14 Typical process sequences for chromating of continuous galvanized strip

Step	Electrogalvanized strip	Step	Hot-dip galvanized strip
1	Electrogalvanizing	1	Hot-dip galvanizing
2	Rinsing: warm water, multiple stages, neutralizing (optional)	2	Surface conditioning: heat treatments

3	Conversion coating: chromate	3	Conversion coating: chromate
4	Rinsing: cold or warm water	4	Drying: warm air
5	Post-treatment: chromate (optional)	5	Oiling (optional)
6	Drying: warm air		
7	Oiling or painting (optional)		

Chromating Galvanized Steels. Although zinc-coated steels provide better atmospheric-corrosion resistance than bare cold-rolled steel, the natural resistance of zinc surfaces to atmospheric corrosion remains low. Most articles coated with zinc by electroplating or hot-dipping are further protected. Chromating is widely used to provide corrosion protection and a decorative finish in bare applications; it can also be used as a pretreatment before painting. The chromate coatings are formed on zinc surfaces from acid solutions containing Cr^{6+}, usually other mineral acids, and accelerators. Chromate coatings on zinc can be categorized as clear, iridescent, and colored.

The largest area for the application of clear coatings is the passivation of hot-dip galvanized steel. Most unpainted zinc and zinc-aluminum coated steel sheet products used for roofs and walls of industrial and farm buildings are chromated on hot-dip galvanizing lines. These chemical treatments are applied in the coating weight range of 0.01 to 0.02 g Cr/m^2 (1 to 2 mg Cr/ft^2), with the upper limit usually defined by the color acceptable to the coated sheet users. On the strip line, coatings are applied by immersing or spraying the freshly prepared galvanized strip in chromating solutions for 1 to 3 s immediately before a set of squeegee rolls, which remove the excess solution from the strip. Broad ranges of chromium concentration and temperatures of 40 to 70 °C (100 to 160 °F) are used to achieve the desired coating weights. The corrosion protection provided by the chromate coatings increases with their color. Typical salt spray corrosion data are given in Table 15.

Table 15 Typical salt spray data for chromate coatings on zinc-coated steel

Substrate	Type of chromate coating	Time to corrosion stain, h
Electroplated zinc	Untreated	<4
	Clear	24-48
	Iridescent	100-200
	Olive drab	100-400
	Electrolytic	1000
Hot-dip zinc	Untreated	<4

Chromate coatings can be deposited electrolytically from baths containing CrO_4^{2-}, PO_4^{3-}, F^-, and other anions. The resulting coatings, which are gray to black in appearance, have superior corrosion resistance and hardness when compared to the conversion coatings (Table 15).

Chromating Bare Steel. Both chemical and electrochemical methods for chromating steel have been used. The chemical method requires high temperatures and prolonged contact times. No-rinse chromate treatments are used on continuous strip lines for paint base applications. They are applied using chemical compositions and wet film thicknesses to give coating weights in the 0.16 to 0.38 g/m^2 (15 to 35 mg/ft^2) range and provide excellent paint base properties. Electrolytically produced chromium/chromium oxide coatings, better known as tin-free steel, are extensively used in the metal-packaging industry.

Hot-Dip Coating Processes

Hot-dip coating processes are used to apply coatings of zinc, aluminum, lead, tin, and some alloys of these metals to carbon steels. The hot-dip process consists of immersing the steel in a molten bath of the coating metal. Zinc coating (galvanizing) protects steel galvanically because the zinc is anodic to the steel base metal and therefore corrodes preferentially in most environments. Hot-dip galvanizing affords adequate atmospheric-corrosion protection to steel. Aluminum hot-dip coatings (aluminizing) provide carbon steels with resistance to both corrosion and heat. In many environments, aluminum protects steel galvanically in much the same way as zinc.

Zinc-aluminum and aluminum-zinc alloys are also applied to steel by hot dipping. Heating aluminized steel results in the formation of an iron-aluminum intermetallic compound that resists oxidation at temperatures up to about 800 °C (1500 °F). Aluminized steel is often used where heat resistance is required--for example, in automotive exhaust systems.

Hot-dip lead coatings are sometimes used on steel that will be exposed to sulfuric acid fumes or other aggressive chemical environments. Terne plate, a lead-tin alloy coating, gives more protection than pure lead coatings and is solderable.

Hot Dip Galvanizing

Hot dip galvanizing is a process in which an adherent, protective coating of zinc and iron-zinc alloys is developed on the surfaces of iron and steel products by immersing them in a bath of molten zinc. Most zinc coated steel is processed by hot dip galvanizing. In general, steels with the following maximum alloying/impurity levels are best suited to galvanizing: 0.05% Si, 0.05% P, 0.25% C, and 1.3% Mn.

Batch Galvanizing. One method of hot dip galvanizing is the batch process, which is used for prefabricated steel items. This method involves cleaning the steel articles, applying a flux to the surfaces, and immersing them in a molten bath of zinc for varying time periods to develop a thick alloyed zinc coating.

The advantage to galvanizing after fabrication is that the zinc completely seals edges, overlaps, rivets, and welds; establishes liquid tightness; and prevents corrosion from starting. Iron and steel in all shapes and sizes can be coated with zinc by batch galvanizing. The process is simple, extremely versatile, and has been used to provide protection to articles ranging from small items, such as bolts, nuts, and miscellaneous hardware, to large items like structural beams for bridges or buildings. The virtually unrestricted size range of parts that can be galvanized and the ability to bolt or weld prefabricated sections after galvanizing enables almost any structure to be built from galvanized steel. Shape is not a restriction to batch galvanizing. Tubes, open vessels, drums, tanks, and complicated shapes such as large heat exchangers are readily galvanized on the inside and outside in one operation.

The thickness of the coating is controlled by the composition of the steel substrate and the immersion time. Part withdrawal rate and any postgalvanizing treatments also influence the coating thickness. Process details (zinc bath temperature, steel surface preparation, degree of wiping, shaking, or centrifuging, and rate of cooling) are described in the article "Batch Hot Dip Galvanized Coatings" in this Volume.

The zinc coating on batch galvanized parts is generally specified in ounces or grams per unit of surface area, measured in either square feet or square meters on a single surface or on one side of the part. With proper coating techniques, the coating weight can usually be controlled between 610 and 1220 g/m^2 (2 and 4 oz/ft^2), equivalent to a coating thickness of approximately 43 to 86 μm (1.7 to 3.4 mils) per side (Ref 6).

Continuous Galvanizing. Steel sheet and wire are coated by a continuous hot dip process; that is, they enter the coating bath in an unending strip. In theory, all continuous hot dip processes are similar in that the steel sheet or wire is subjected to successive cleaning, coating, and postcoating steps.

Typical cleaning steps may include alkaline cleaning or acid pickling (both of which may be electrolytic), oxidation (usually gaseous for sheet, but often in molten lead for wire), and reduction (gaseous). If a gaseous reduction is the final cleaning step, the steel must enter the molten coating bath directly without being exposed to air. When the final cleaning step is an acid pickle (this is usually the case for wire), the steel is then immersed in a liquid flux, which dissolves any remaining oxides, before entering the molten bath. Similarly, gaseous reduction can also be considered a flux treatment. All-gaseous cleaning is used on about 60% of the steel-coating lines. The remaining 40% is approximately half liquid cleaning/flux and half liquid cleaning/gaseous cleaning. Most wire-coating lines use the liquid/flux technique. More detailed information on surface cleaning and fluxing can be found in the article "Surface Preparation for Continuously Applied Coatings" in this Volume.

The clean steel is then immersed in the molten coating bath long enough to allow the coating metal to wet and react with the steel surface. As the coated sheet or wire emerges from the molten bath, it pulls coating metal up from the surface which can then be smoothed or wiped to the desired thickness by a variety of methods. Most sheet-coating lines use a gas-wiping technique in which a jet of steam, air, or gas (such as nitrogen) is directed against the emerging sheet.

The coated steel can be given any number of subsequent mechanical, thermal, or chemical post-treatments designed to impart specific properties. Typically, a coated sheet might be oiled or coated with a chromate solution to inhibit staining or superficial corrosion during storage and transit (see the previous discussion of chromate conversion coating in this article). Waxing would serve the same purpose on wire and would facilitate handling during subsequent processing.

Hot-dipped galvanized coatings are applied by highly mechanized mass production methods at speeds of over 90 m/min (300 ft/min). Several designs of galvanizing lines have been developed for commercial use by the steel suppliers. Most steel suppliers can produce galvanized coils (sheets) in widths of 250 to 1830 mm (10 to 72 in.) and thicknesses of 0.43 to 4.2 mm (17 to 165 mils). Typical applications for mill coated sheets are roofing and siding panels, guardrails, appliance cabinets, automotive body parts, and ductwork.

Coating weights applied by continuous galvanizing vary from 150 to 840 g/m^2 (0.5 to 2.75 oz/ft^2) (Ref 7). The zinc coating may be on one side of the sheet only, of equal weight on both sides of the sheet, or differentially applied (one side has a thicker coating than the other side). Process details are given in the article "Continuous Hot Dip Coatings" in this Volume.

Nature of the Hot Dip Galvanized Coating. Figure 4 shows a photomicrograph of a typical hot dip galvanized coating consisting of a series of layers. These layers are also identified in Table 16. Starting from the base steel at the bottom of the section, each successive layer contains a higher proportion of zinc until the outer layer, which is relatively pure zinc, is reached. Therefore, there is no real line of demarcation between the iron and the zinc; instead, there is a gradual transition through the series of iron-zinc intermetallics, which provide a powerful bond between the base metal and the coating.

Table 16 Properties of alloy layers of hot dip galvanized steels

Layer	Alloy	Iron, %	Melting point		Crystal structure	Diamond pyramid microhardness	Alloy characteristics
			°C	°F			
Eta (η)	Zinc	0.03	419	787	Hexagonal	70-72	Soft, ductile
Zeta (ζ)	$FeZn_{13}$	5.7-6.3	530	986	Monoclinic	175-185	Hard, brittle
Delta (δ)	$FeZn_7$	7.0-11.0	530-670	986-1238	Hexagonal	240-300	Ductile

Gamma (Γ)	Fe_3Zn_{10}	20.0-27.0	670-780	1238-1436	Cubic	. . .	Thin, hard, brittle
Steel base metal	Iron	. . .	1510	2750	Cubic	150-175	. . .

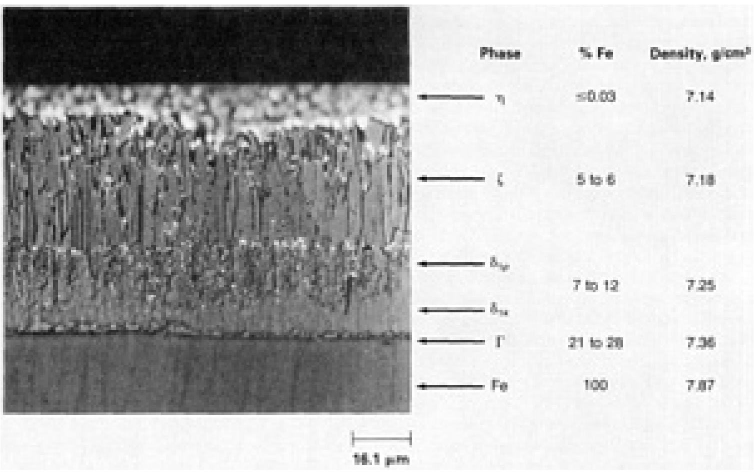

Fig. 4 Typical hot dip galvanized coating. Note the gradual transition from layer to layer, which results in a strong bond between base metal and coating.

Hardness and Abrasion Resistance. The layers that compose the galvanized coating, being discrete zinc-iron alloys, vary in hardness. The free zinc layer (η) is relatively soft, but the alloy layers are very hard, harder even than ordinary structural steels. Typical values for the microhardness and other properties of the various alloy layers are given in Table 16.

The alloy layers are from four to six times more resistant to abrasion than pure zinc. Galvanized coatings exhibit better abrasion resistance compared to paints with the same coating thickness and can be effectively used where excessive abrasive wear is expected, for example, floor gratings, stairs, conveyors, and storage bins.

Adhesion and Impact Resistance. Unlike other coatings, which are mechanically or chemically bonded to the steel, the galvanized coating is metallurgically bonded to and integral with the steel, making conventional measures of bond strength inappropriate for this coating. As a result of the metallurgical bond, the galvanized coating is very adherent.

The structure of the galvanized coating, particularly the relative thicknesses of the δ and ζ layers (Table 16), is primarily influenced by the steel chemistry and, to a lesser extent, by the galvanizing temperature and the duration of immersion. Coating structure has the greatest effect on the impact resistance of the coating. A high relative proportion of ζ phase in the iron-zinc alloy may result in localized flaking if the coating is subjected to heavy impact or excessive twisting or bending. Semikilled steels with silicon contents of 0.05 to 0.12% are the most susceptible to coating brittleness and less adherent coatings.

Corrosion Protection Mechanism. Galvanized coatings protect steel in corrosion service in two ways: barrier protection and cathodic protection. Barrier protection is provided by the galvanized coating and is further enhanced by the formation of a thin, tightly adherent layer of zinc corrosion products on the coating surface. Upon initial weathering of a freshly galvanized surface, ZnO is formed, and it is converted to $ZnOH_2$ in the presence of moisture. Further reaction with CO_2 in the air results in the formation of basic $ZnCO_3$, which is relatively insoluble and impedes further corrosion. The gray patina normally associated with weathered galvanized coatings is the result of this thin layer of basic $ZnCO_3$.

Cathodic protection is provided to the steel by the fact that zinc is anodic to steel in most environments. Minor discontinuities or small areas of exposed steel resulting from drilled holes or cut edges are protected from corrosion by the sacrificial protection afforded by zinc. The corrosion products that result from this action provide further protection.

Atmospheric Exposure. Zinc, steel, and hot dip galvanized coatings have been the subject of long-term atmospheric studies conducted throughout the world (Ref 8, 9). From these studies, the behavior of these materials in a specific atmospheric environment can be reasonably estimated. An exact determination of corrosion behavior is complicated by several factors: the frequency and duration of exposure to moisture (rain, sleet, snow, and dew), the type and concentration of corrosive pollutants, the prevailing wind direction and velocity, and exposure to sea spray or windborne abrasives. All atmospheres contain some type of corrosive agent, and the concentration of these agents, as well as the frequency and duration of moisture contact, determines the corrosion rate of galvanized coatings.

Figure 5 shows the results of outdoor atmospheric-exposure tests designed to measure the protective life of galvanized coatings in various atmospheric environments. The sites were selected as representative of various broad environmental classifications: heavy industrial, moderate industrial (urban), suburban, rural, and marine. Within these broad classifications, the following factors are most significant in influencing the rate of corrosion of the galvanized coating.

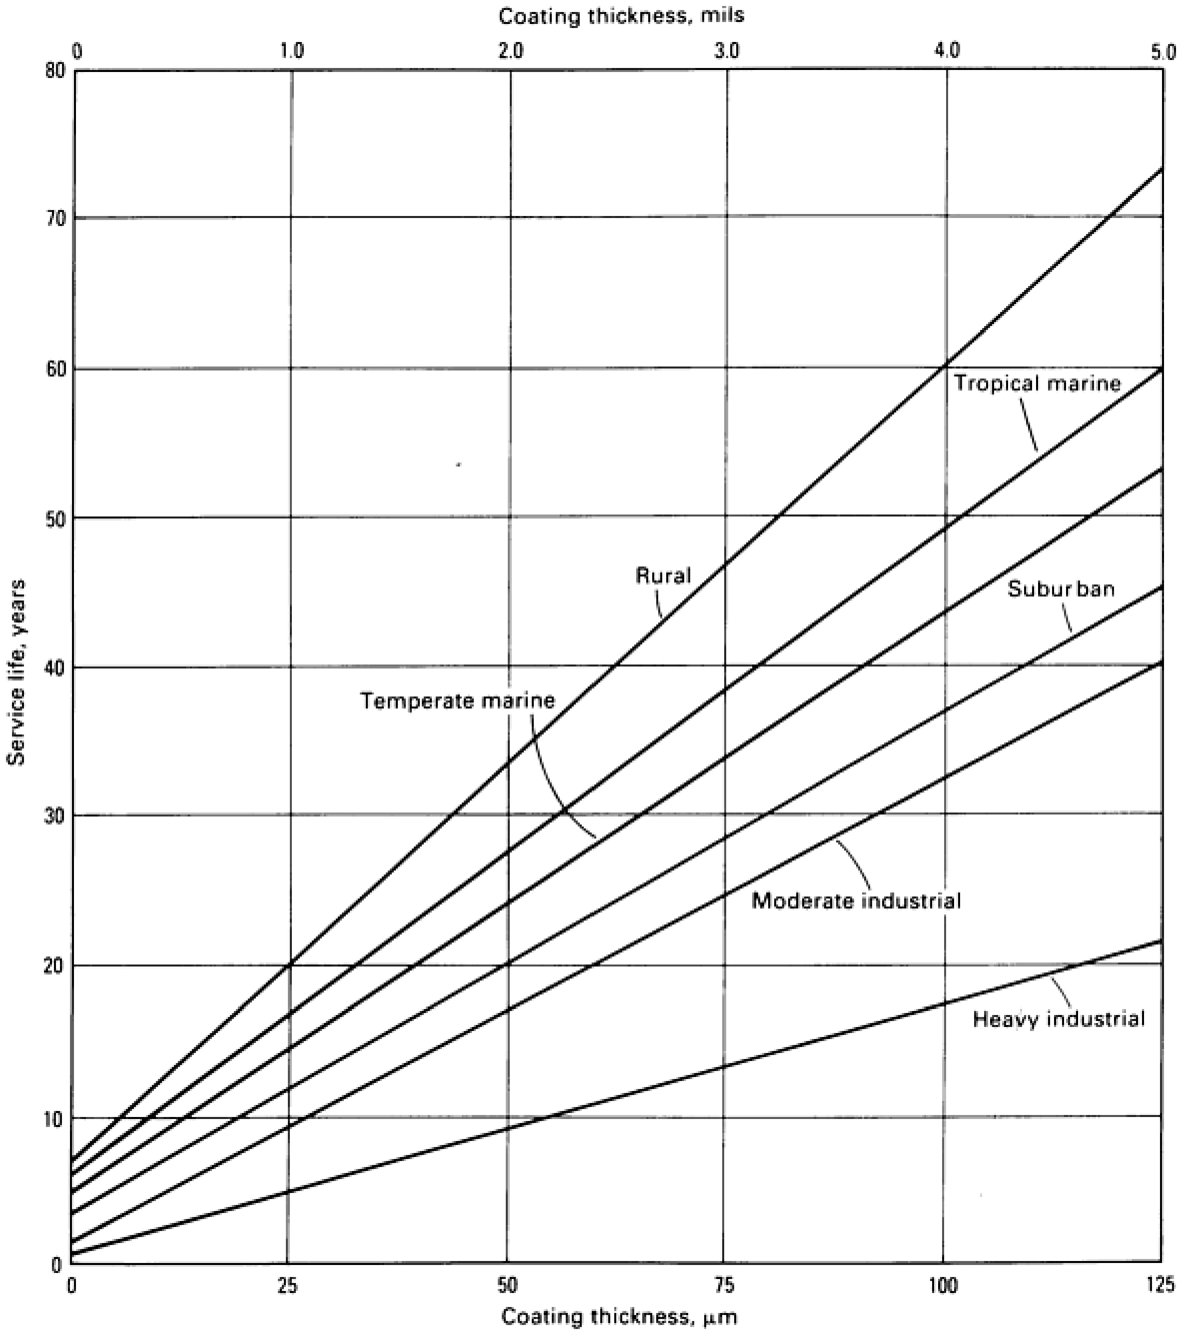

Fig. 5 Service life versus coating thickness for hot dip galvanized steel in various atmospheres. Source: Ref 8

Industrial and Urban Environments. Corrosive conditions are most pronounced in areas with highly developed industrial complexes that release sulfurous gases and corrosive fumes and mists to the atmosphere. These corrodents react with the normally impervious basic $ZnCO_3$ film to produce $ZnSO_4$ and other soluble zinc salts that, in the presence of moisture, are washed from the surface. This exposes fresh zinc to the atmosphere, and another corrosion cycle begins.

Rural and Suburban. The corrosion rate of zinc in these areas is relatively slow compared to that in industrial settings. Once the original weathering occurs, there is little in the atmosphere to convert the basic zinc salts to water-soluble compounds.

Marine Atmospheres. The corrosion rate of zinc and galvanized steel in marine atmospheres is influenced by several factors. Zinc forms a soluble corrosion product, zinc chloride ($ZnCl_2$), in marine atmospheres; therefore, the corrosion rate is influenced by salt spray, sea breezes, topography, and proximity to the coastline. For example, one investigation found that the corrosion rate for zinc exposed 25 m (80 ft) from the ocean was three times that for zinc exposed 250 m (800 ft) from the ocean (Ref 9).

The corrosion product formed in a given type of atmosphere (industrial, marine, and so on) determines the corrosion rate of zinc in that atmosphere. Results from exposures in a variety of atmospheres show that zinc is 20 to 30 times more resistant to corrosion than is steel (Table 17).

Seawater and Salt Spray Performance. Table 18 gives the approximate corrosion rates of zinc in various waters, and Fig. 6 illustrates the expected service life of galvanized coatings in areas exposed to salt spray influences. Sea salts are mainly NaCl, with small amounts of calcium, magnesium, and manganese salts. Typical pH is about 8. Compared to other metals and alloys, galvanized coatings provide considerably more protection to steel than many other metals and alloys, even though the anticipated coating life is shorter in seawater and salt spray exposures than a number of other environments.

Table 18 Corrosion of zinc in various waters

Water type	Approximate material loss	
	µm/yr	mils/yr
Seawater		
Global oceans, average	15-25	0.6-1.0
North Sea	12	0.5
Baltic Sea and Gulf of Bothnia	10	0.4
Freshwater		
Hard	2.5-5	0.1-0.2
Soft river water	20	0.8
Soft tap water	5-10	0.2-0.4

Distilled water	50-200	2.0-8.0

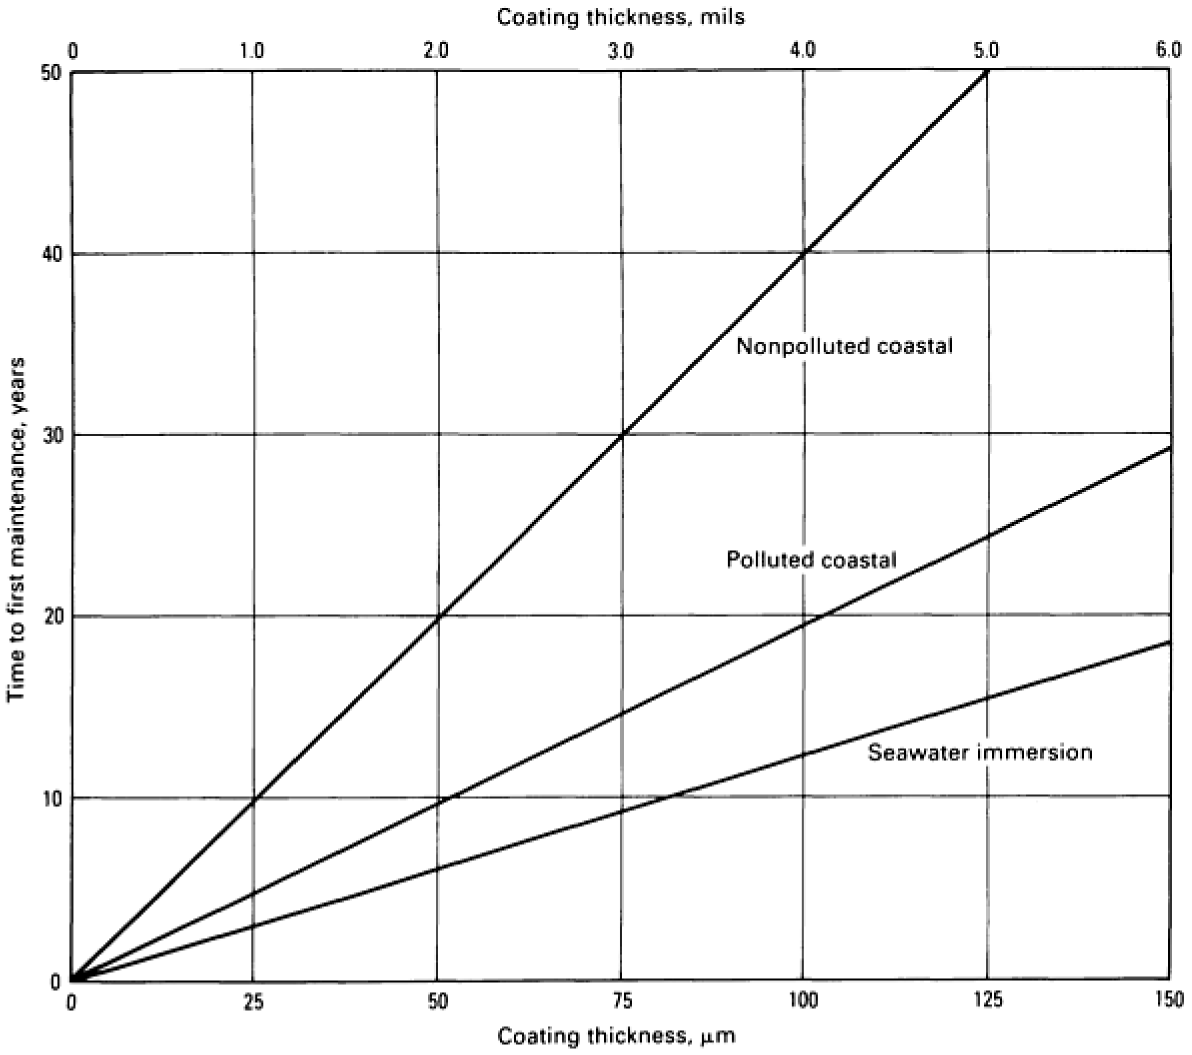

Fig. 6 Time to first maintenance versus coating thickness for hot dip galvanized coatings in seawater immersion and sea spray exposures. Source: Ref 11

Freshwater Performance. The corrosion protection mechanism of zinc in freshwater is similar to that in atmospheric exposures. The corrosion rate depends on the ability of the coating to develop a protective layer of adherent basic zinc salts. This layer denies access to the coating by oxygen and slows the rate of attack. The ability of the water to form scale depends on a number of variables, such as the pH of the water, hardness, total alkalinity, and total dissolved solids. Table 19 demonstrates the effects of various water chemistries on the relative corrosion rates of zinc.

Table 19 Corrosion of zinc in different types of water

Water type	Attacking substances	Passivating substances	Properties of corrosion products		Relative corrosion rate
			Solubility	Adhesion	

Hard water	Oxygen, CO_2	Calcium, magnesium	Very low	Very good	Very low
Seawater	Oxygen, CO_2, Cl^-	Calcium, magnesium	Low	Very good	Moderate
Soft with free air supply	Oxygen, CO_2	. . .	High	Good	High
Soft or distilled with poor air supply	Oxygen	. . .	Very high	Very poor	Very high

Source: Ref 10

Water Temperature. The corrosion rate of zinc in water, and therefore that of the galvanized coating, increases with temperature to between 65 and 70 °C (150 and 160 °F), at which point the rate begins to decrease (Fig. 7). At temperatures near 70 °C (160 °F), a reversal in potential may occur where zinc coatings become cathodic to iron. Low oxygen and high bicarbonate contents favor reversal, but the presence of oxygen, sulfates, and chlorates tends to maintain the natural anodic state of the zinc.

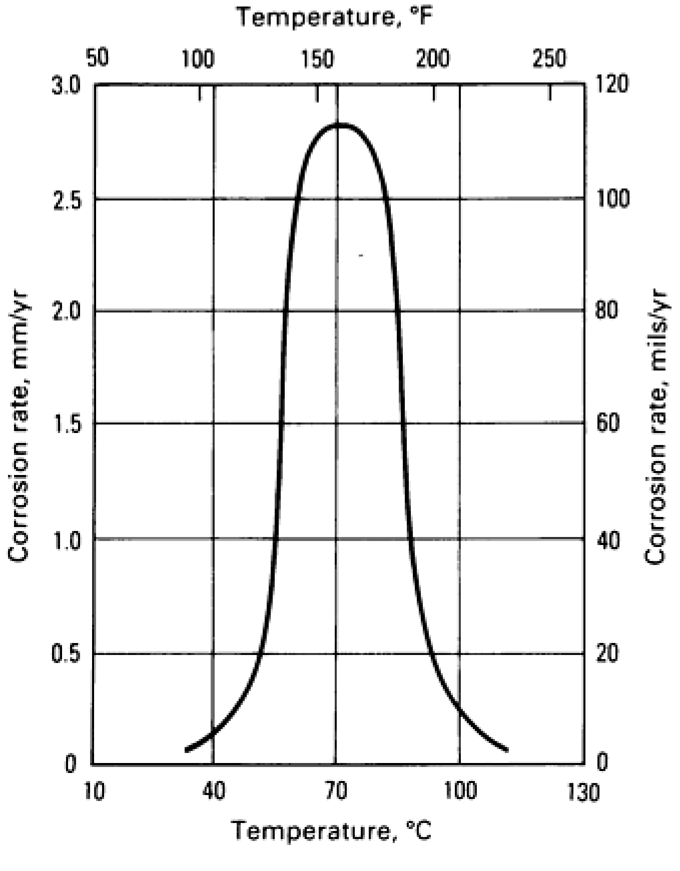

Fig. 7 Influence of water temperature on the corrosion rate of zinc in distilled, aerated water. Source: Ref 12

Water pH. Zinc is an amphoteric metal with the capacity to passivate by means of protective layers. The corrosion rate of zinc decreases with increasing pH and reaches a minimum at 12.0 to 12.5. Most waters are in the pH range of 6 to 8. The scale-forming ability of the water and the concentration of dissolved ions in the water are more important influences on the corrosion rate than pH in this practical exposure range.

Performance in Soils. The corrosion rate and performance of galvanized steels in soils are a function of the type of soil in which the steel is located. Soils can vary considerably in composition and can contain bound and unbound salts, organic compounds, products of weathering, bacteria and other microorganisms, dissolved gases (such as hydrogen, oxygen, and methane), acids, and alkalies. Soils vary in permeability, depending on the soil structure. Although the concentration of oxygen is lower in soils than in air, the CO_2 concentration is higher. Variation among soils is high, and corrosion conditions are complicated.

In general, soils in coarse, open textures are often aerated, and the performance of galvanized steel would be expected to be similar to that in air. In soils with fine textures and high water-holding capacities, such as clay and silt-bearing soils, corrosion rates are likely to be higher. Soil resistivity is recognized as a reliable method of predicting the corrosivity of soils. High-resistivity (poor conducting) soil would be less corrosive than low-resistivity (good conducting) soil. Dry soils are poor conductors and are the least corrosive to zinc.

Painting Galvanized Steel. Galvanized coatings, when used without further treatment, offer the most economical corrosion protection for steel in many environments. The galvanized coating makes an excellent base on which to develop a paint system. Painting of galvanized steel is desirable for aesthetics, as camouflage, as warning or identification markings, to prevent bimetallic corrosion, or when the anticipated environment is particularly severe.

In corrosive atmospheres, a duplex system of galvanized steel top coated with paint has several advantages that make it an excellent system for corrosion prevention:

- The life of the galvanized coating is extended by the paint coating
- The sacrificial and barrier properties of the zinc coating are used if a break occurs in the paint film
- Undercutting of damaged paint coatings, a major cause of failure of paints on steel, does not occur with a zinc substrate
- Surface preparation of a weathered zinc surface for maintenance painting is easier than that for rusted steel

The galvanized coating prevents rusting of steel by acting as a barrier against the environment and by sacrificially corroding to provide cathodic protection. Painting the galvanized coating extends the service life of the underlying zinc because the barrier property of the paint delays the reaction of zinc with the environment. If a crack or other void occurs in the paint and exposes the galvanized coating, the zinc corrosion products formed tend to fill and seal the void; this delays further reaction.

When painted steel is exposed to the environment, rust forms at the steel/paint interface. Because rust occupies a volume several times that of the steel, the expansion resulting from rusting leads to rupture of the steel/paint bond. Further, rust is porous; it accumulates moisture and other reactants, and this increases the rate of attack on the steel. The result is undercutting, flaking, and blistering of the paint film, leading to failure of the paint coating (Fig. 8). Zinc corrosion products occupy a volume only slightly greater (20 to 25%) than zinc; this reduces the expansive forces and conditions that lead to paint failure.

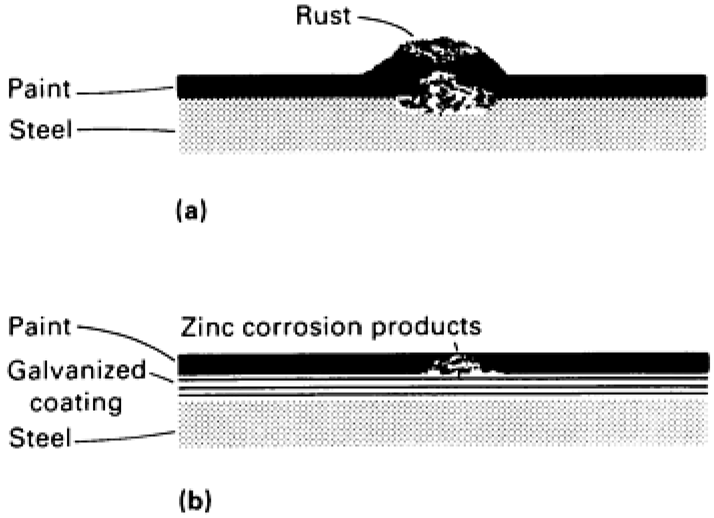

Fig. 8 Illustration of the mechanism of corrosion for painted steel (a) and painted galvanized steel (b). (a) A void in the paint results in rusting of the steel, which undercuts the paint coating and results in further coating degradation. (b) A void in the coating of a painted galvanized steel is sealed with zinc corrosion products; this avoids the undercutting seen in (a) and prevents further deterioration of the painted coating.

A coating system consisting of painted galvanized steel provides a protective service life up to 1.5× that predicted by adding the expected life times of the paint and the galvanized coating in a severe atmosphere (Ref 13). This is demonstrated in Table 20. The synergistic improvement is even greater for mild environments (Ref 14, 15).

Table 20 Synergistic protective effect of galvanized steel/paint systems in atmospheric exposure

Type of Atmosphere	Galvanized steel			Paint			Galvanized plus paint

Source: Ref 14

(a) Service life is defined as time to about 5% red rust.

Paint adhesion is the primary concern in painting galvanized steel. The surface of the zinc is nonporous and does not allow mechanical adhesion of the paint. Surface contaminants, such as oils, waxes, or postgalvanizing treatments, also effect adhesion. A fresh zinc surface is reactive to certain paint ingredients, such as fatty acids; this can produce zinc soaps and disrupt the zinc-paint bond.

Galvanized coatings can be successfully painted immediately after galvanizing or after extended weathering. The deliberate use of weathering is not recommended, because weathering may not be uniform, the time required is long (6 to 17 months), hygroscopic impurities can form that may be difficult to remove, and there is exposure to atmospheric pollutants.

Chemical etchants, such as acids or copper sulfate, should not be used for surface preparation. The action of these chemicals is difficult to control, the resulting surface may be nonuniform, and the galvanized coating could be damaged if allowed to remain in extended contact with the chemicals. Long-term adhesion will suffer with this type of treatment, although initial adhesion may be obtained.

Mechanical roughening of the zinc surface through the use of a light blast can provide a good surface for painting. However, careful control of the blast pressure and flow rate must be exercised to avoid excessive removal of the galvanized coating.

Initial adhesion of the paint can be achieved through the use of a pretreatment primer to provide an adequate base for further coating. Long-term adhesion is obtained by the selection of a top coat that is compatible with the primer and galvanized steel. Additional information on various paints can be found in the sections "Organic Coatings" and "Painting With Zinc-Rich Paints" in this article.

Hot Dip Aluminum Coatings

Although zinc is well established as a coating material, aluminum is gaining in popularity. Aluminum-coated steel products are used successfully in corrosive and oxidizing environments in which the temperature ranges from that of outdoor exposure to 1150 °C (2100 °F). Aluminum coatings protect steel from attack by forming a very resistant barrier between the corrosive atmosphere and the steel. The aluminum oxide that forms on the aluminum surface is highly resistant to a wide range of environments.

The process of applying a hot-dipped aluminum coating to steel substrates is also referred to as aluminizing. As in hot dip galvanizing, aluminizing can be carried out by batch or continuous processes. Additional information on batch and continuous hot dip aluminum coating processes can be found in Ref 16 and 17.

The batch aluminizing process consists of cleaning, heating, fluxing, and coating. Organic soils can be removed from the parts to be coated by alkaline cleaning and water rinsing. Steel parts are then descaled by abrasive blasting or acid pickling, followed by rinsing and drying.

Fluxing dissolves any oxide film left on the part surface after cleaning and is carried out in either molten-salt baths or aqueous solutions prior to hot dipping. The salt bath is usually maintained at approximately 600 °C (1100 °F) and the parts are immersed in the bath from 30 s to several minutes. Immediately after fluxing, the parts are immersed in the molten-aluminum bath at 700 °C (1300 °F).

Temperature control of the molten aluminum is important in order to control the coating thickness. Temperatures that are too high increase the thickness of the intermetallic layer and decrease the thickness of the pure aluminum coating. Immersion time must also be closely controlled. Coating thickness is also affected by substrate composition and aluminum coating bath composition.

Parts that can be aluminum hot dipped include fasteners, poppet valves, and blades and nozzle vanes for gas turbines. Parts with small threads are not considered practical, nor are parts that may nest during the coating process.

Continuous Aluminizing. The aluminum dip coating of continuous steel strip, sheet, or tubing is produced on continuous in-line equipment similar to that used for galvanizing. The process consists of surface preparation, heat treatment, and immersion coating with aluminum. Surface preparation may take place in an oxidizing furnace or in a nonoxidizing preheater; if an oxidizing furnace is used, the surface oxides are reduced in a suitable atmosphere. The immersion time, the temperature of the steel before and after immersion, and the temperature of the molten aluminum must be controlled to prevent the formation of an excess of iron-aluminum interfacial alloy. More detailed information on processing of continuous hot-dipped aluminum coatings can be found in the articles "Surface Preparation for Continuously Applied Coatings" and "Continuous Hot Dip Coatings" in this Volume.

Microstructure of Aluminum Coatings. Two types of aluminum coatings are commercially significant. Type 2 uses commercially pure aluminum for the coating, and Type 1 uses an aluminum alloy containing 5 to 11% Si. The microstructure of the Type 2 coating shows a layer of aluminum, often with scattered iron-aluminum intermetallic particles, bonded to the steel substrate by an iron-aluminum intermetallic layer (Fig. 9). This intermetallic layer forms a distinctive serrated boundary with the steel and is generally identified as Fe_2Al_5, although some investigations have found additional iron-aluminum compounds (Ref 18).

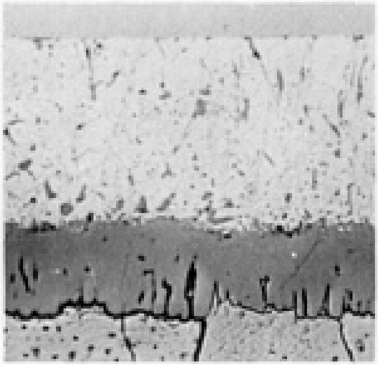

Fig. 9 Microstructure of type 2 aluminum coating on steel. This coating forms a layer of essentially pure aluminum (top) with scattered gray particles of aluminum-iron; the light gray center layer is aluminum-iron, and the bottom layer is the base steel. 1000×

When silicon is added to form a Type 1 coating, a different microstructure results. The intermetallic layer becomes narrower and smoother (Fig. 10), resulting in increased coating ductility relative to the Type 2 coating. With increasing silicon additions, the coating bath temperature can also be lowered, and the growth of the intermetallic layer is further inhibited.

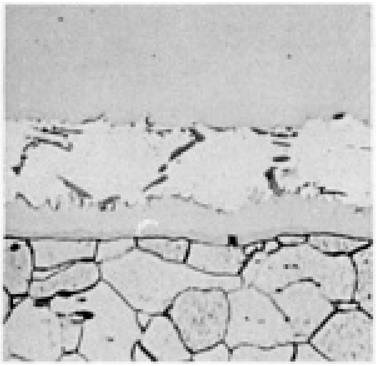

Fig. 10 Microstructure of type 1 aluminum coating on steel. From top: a nickel filler, aluminum-silicon alloy, aluminum-silicon-iron alloy, and steel base metal. 1000×

Beryllium, copper, and some other elements have also been found to retard the growth of the intermetallic layer. Additions of these and other elements to the steel itself can also retard the growth of the alloy layer. The way in which these elements reduce the growth is not understood, although silicon appears to act after being incorporated into the intermetallic layer itself (Ref 19).

Atmospheric Corrosion Resistance. Numerous tests have shown that Type 1 and Type 2 aluminum coatings provide excellent atmospheric corrosion protection for steel. The major difference between the two coatings is the darkening and pinpoint rust formation that occur very early on Type 1 coatings. Weight loss measurements show that overall corrosion losses are nearly identical for both coatings (Ref 20). However, because of this appearance factor, the major use for Type 1 coatings is for high-temperature resistance, especially in automotive exhaust components. Typical atmospheric corrosion data for Type 2 aluminum-coated steel are given in Table 21. Galvanized steel data are included for comparison purposes. On the basis of this and similar investigations, a Type 2 aluminum coating will provide substantially longer life than a galvanized coating of equivalent thickness.

Table 21 Coating thickness losses for galvanized steel and type 2 aluminized steel in atmospheric exposure

Years exposed	Middletown, OH				Kure Beach, NC			
	G90[(a)]		Type 2		G90		Type 2	
	μm	mils	μm	mils	μm	mils	μm	mils
1	2.6	0.1	0.5	0.02	7.0	0.28	1.4	0.04
2	5.2	0.2	0.7	0.028	8.6	0.34	2.4	0.09

10	24.4	0.96	2.9	0.11	23.5	0.93	6.0	0.24

Source: Ref 20

(a) G90 galvanized steel has a coating weight of 0.90 oz/ft^2 (270 g/m^2).

In 1961, the American Society for Testing and Materials (ASTM) exposed aluminum-coated wire (all hot dip coated wire is made with a Type 1 coating) and galvanized wire at marine, industrial, and rural atmosphere test sites. Results from unfabricated wire show that (Ref 21):

- Aluminum coatings are rust free 1.3 to 2.2 times longer than zinc coatings of the same thickness (43 μm) in industrial and marine atmospheres
- Zinc coatings are rust free longer at the rural test site, an unexpected result that is possibly explained by the nonuniformity of the aluminum coating. Fabricated wire products made from precoated wire showed virtually no difference between aluminum and zinc coatings

Corrosion Mechanism. Because contact with oxygen results in the formation of a protective aluminum oxide layer, other components of the atmosphere must be responsible for the corrosion of the aluminum coating. Careful analysis of the corrosion products formed on aluminum coatings in industrial and marine atmospheres has shown that the predominant product is an amorphous, hydrated aluminum sulfate. This suggests that SO_2 is an important factor in atmospheric corrosion. This sulfate compound also appears to be more protective than the sulfates found on zinc coatings, which is consistent with observed corrosion behavior.

Aqueous Corrosion Resistance. Aluminum-coated steel has not generally been used in situations requiring aqueous corrosion resistance. There are no counterparts to galvanized water tanks, galvanized pipe, or galvanized pails. However, since 1979 the Type 2 aluminum coating has been used in the manufacture of corrugated steel pipe.

Corrosion in Natural Waters. Numerical data on the corrosion resistance of aluminum coatings are few because of the lack of use. Behavior is usually inferred from aluminum alloy data, but this could be inappropriate because of differences in structure and composition. Nonetheless, studies on aluminum alloys have shown that the air-formed aluminum oxide is destroyed after immersion (Ref 22). Corrosion resistance then depends on the oxide being re-formed from dissolved oxygen quicker than the aluminum is attacked by other ions, such as chlorides (Cl^-), nitrates (NO_3^-), or sulfates (SO_4^{2-}). With the protective aluminum oxide layer in place, the normal mode of failure is pitting, not general dissolution.

In general, soft waters are the least aggressive toward aluminum. The oxide is regarded as stable from pH 5 to 9. However, specific ions can change this range of stability. There is also some evidence that pitting may increase as the pH varies from neutral, but increasing the flow rate, especially at the more extreme pH values, can alleviate pitting. Small concentrations of copper and some other heavy metals can also lead to accelerated pitting. Pitting and corrosion have been observed in less than 3 years on aluminum-coated roofing panels exposed to stagnant water (Ref 23). On the other hand, when under a constant flow of relatively soft neutral pH water, corrugated steel pipe made from Type 2 aluminum-coated steel gives excellent service (Ref 24).

Corrosion in Seawater. Unlike aluminum alloys, aluminum-coated steel is not used in seawater. Corrosion rates are too high to provide economical use except as part of a more complex protection system. Typical thickness loss after 1 year of immersion in seawater has been reported to be 198 μm (7.8 mils) for Type 1 and 38 μm (1.5 mils) for Type 2 aluminum-coated sheets (Ref 20).

Corrosion in Soils. As with aqueous environments, aluminum-coated steel does not have a history of use in soils. Behavior would be expected to depend on pH, resistivity, and especially the chemistry of the soil. The mode of failure should be pitting.

Elevated-Temperature Exposure. Successful application of aluminum-coated steel for resistance to oxidation and corrosion at elevated temperatures depends on the physical and mechanical properties of the alloy chemical bond between the aluminum and the steel. It is important that the hot strength of the steel be suitable for the stress and temperatures

encountered. Low-carbon HSLA steels alloyed with titanium or niobium offer improved high-temperature creep resistance when used as substrates for aluminum coatings.

Aluminum coatings that contain from 5 to 11% Si minimize the thickness of the iron-aluminum alloy bond and improve formability. Undiffused, such coatings retain excellent heat reflectivity at temperatures to 480 °C (900 °F).

Above 480 °C (900 °F), further alloying occurs between the aluminum coating and steel base. Because the rate of alloying is dependent on time and temperature, all coating converts to aluminum-iron-silicon alloy with sufficient time at temperature. The refractory alloy formed is extremely heat-resistant and resistant to spalling up to 680 °C (1250 °F). Spalling at service temperatures above 680 °C (1250 °F) can be overcome by the use of heat-resistant aluminized steel that contains sufficient titanium to stabilize carbon and nitrogen as well as maintain excess titanium in solution (Ref 25).

Table 22 lists applications for steels that have been prepared by batch hot dipping in aluminum and then heat-treated to diffuse the aluminum into the steel. This treatment eliminates spalling and provides an impervious protective coating during high-temperature service.

Table 22 Applications of diffused aluminum hot dip coatings for resistance to oxidation and corrosion at 455 to 980 °C (850 to 1800 °F)

Product and base metal	Type of service
Heat treating equipment	
Burner pipes, 5Cr-0.5Mo	Oxidation, 870 °C (1600 °F)
Fixtures, low-carbon and medium-alloy steels	Carburizing, carbonitriding
Flue stacks, low-carbon steel	Oxidation, sulfur corrosion
Furnace insulation supports, low-carbon and medium-alloy steels	Oxidation, 540-650 °C (1000-1200 °F)
Pyrometer protection tubes, 310 and 316 stainless steel, low-carbon steel	Oxidation, 980 °C (1800 °F)
Heat exchanger components	
Boiler soot blowers, 1Cr-0.5Mo	Oxidation, sulfur attack
Boiler tubing, 2Cr-05.Mo	Oxidation, 540-595 °C (1000-1100 °F)
Cylinder barrel, air-cooled engine, Nitralloy	Oxidation to 480 °C (900 °F)
Preheater tubing, 1Cr-0.5Mo	Oxidation, 650 °C (1200 °F)
Tubing, low-carbon steel, 1.5Cr-0.5Mo	Hydrogen sulfide gases
Fasteners	

Steel fasteners for chemical piping and boilers	Oxidation to 480 °C (900 °F)
High-temperature fasteners	Oxidation to 760 °C (1400 °F)
Studs, 4140, for chemical and oil refineries	Oxidation and ease of removal after service at 480 °C (900 °F)
Miscellaneous equipment	
Chemical reactor tubing, low-carbon steel	Carbonization, iron contamination
Chimney caps, low-carbon steel	Oxidation and corrosion
Recuperator tubing, 2.5Cr-0.5Mo	Oxidation and sulfidation
Refinery tubing, 304 stainless steel, 2.25Cr-1Mo	Oxidation and sulfidation
Sulfuric acid converters, 5Cr-0.5Mo	Sulfur dioxide corrosion, 705 °C (1300 °F)

The use of aluminum-coated plain carbon steel for complicated heat-treating fixtures subjected to temperatures lower than 870 °C (1600 °F) may decrease overall fixture cost in comparison to fixtures made of the highly alloyed austenitic steels normally used for this application. Figure 11 shows the effects of coating thickness and operating temperature on oxidation resistance for coated and uncoated heat-treating fixtures made of 1020 steel.

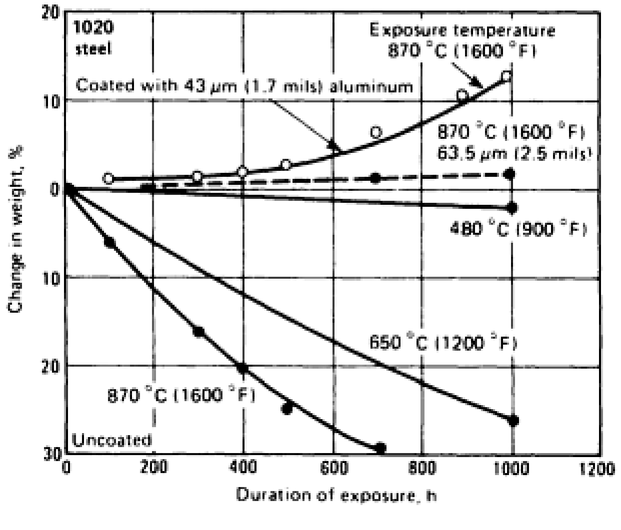

Fig. 11 Effects of coating thickness and exposure temperature on oxidation of coated and uncoated steel. Oxidation at 480 to 870 °C (900 to 1600 °F). Steel 6.4 mm ($\frac{1}{4}$ in.) thick was completely oxidized after 700 h at 870 °C (1600 °F).

Compared to solid stainless steel, aluminum-coated carbon steel offers greater resistance to attack by hydrogen sulfide. One set of test data indicated that, at 595 °C (1110 °F), aluminized carbon steels offer more than 100 times the resistance

of 18-8 stainless steel to pure hydrogen sulfide. Other data have shown them to be 25 times more resistant than straight chromium steel.

Hot Dip Aluminum-Zinc Coatings

Many attempts have been made to improve the corrosion resistance of both galvanized and aluminum coatings through alloying. Although combinations of these two elements with each other were known to provide an attractive degree of corrosion resistance, hot dip coatings did not become feasible until the discovery that silicon inhibits the rapid alloying reaction with steel (Ref 26). The 55Al-Zn coating was first available commercially in 1972. This composition was selected from a systematic investigation of aluminum-zinc alloys, with up to 70% Al providing the best combination of galvanic protection and low corrosion rate. Current use varies from metal roofing, for which it is the major coated steel used, to automotive components, appliances, and, most recently, corrugated steel pipe.

Aluminum-zinc alloy coatings of steel sheet and wire are applied on continuous hot dip coating lines with in-line gas cleaning and heat treating of the steel substrate. With a nominal composition of 55% Al, 43.4% Zn, and 1.6% Si, the coating provides the durability and high temperature resistance of aluminum coatings with the sacrificial protection characteristics of zinc coatings. Silicon is added to the coating bath to control growth of an intermetallic layer. Steel sheet and wire products coated with 55% aluminum-zinc alloy are especially useful in applications requiring superior atmospheric corrosion resistance, cut edge protection, and/or high-temperature oxidation resistance. Processing details for aluminum-zinc coatings are given in Ref 16.

Microstructure of 55Al-Zn Coating. The 55Al-Zn coating has a two-phase structure of cored aluminum-rich dendrites and a zinc-rich interdendritic constituent (Fig. 12). This overlay is bonded to the steel substrate by a thin intermetallic layer whose composition is 48% Al, 24% Fe, 14% Zn, and 11% Si. X-ray diffraction suggests a structure similar to $Al_{13}Fe_4$. In addition, silicon particles are often found in the interdendritic region. By volume, the coating is approximately 80% Al + Si and 20% Zn. The effect of cooling rate during solidification is manifested in the spacing between the dendritic arms. Faster cooling (used commercially) results in finer spacing, which improves corrosion resistance.

Fig. 12 Microstructure of an aluminum-zinc coated sheet

Protection by Aluminum-Zinc Alloy Coatings. The 55Al-Zn coating provides both barrier and galvanic protection. Because the zinc-rich constituent is intimately distributed throughout the coating, it will be in contact with exposed steel at any break in the coating and at cut edges. Although less galvanic protection is available than with pure galvanized coatings, the alloy coating lasts longer because the overall corrosion rate is controlled by the aluminum-rich phase, which corrodes much more slowly than zinc.

Atmospheric Corrosion Resistance. Samples of 55Al-Zn-coated steel have been tested in atmospheric exposure for over 20 years. Figure 13 shows thickness loss with time for the first 13 years of exposure in four different atmospheres. Compared to galvanized panels exposed at the same time, the 55Al-Zn coating provides two to six times the corrosion resistance (based on equal coating thicknesses). Although these results were based on pilot line samples, subsequent testing of commercial 55Al-Zn sheet steel for 10 years shows a slightly greater advantage over galvanized steel (Ref 28).

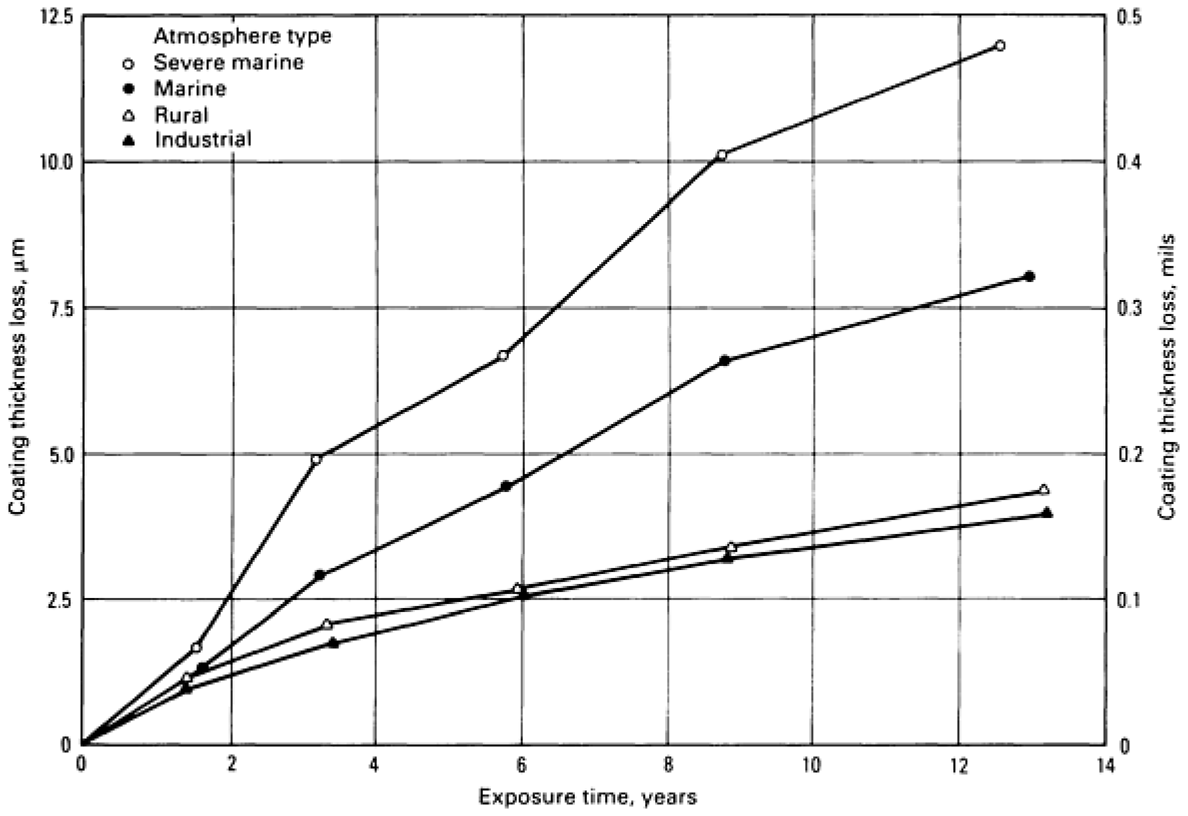

Fig. 13 Coating thickness loss of 55Al-Zn-coated steel in four atmospheres. Source: Ref 27

Corrosion Mechanism. The zinc-rich constituent of the coating has been observed to corrode preferentially. As these regions are removed, their space is taken by corrosion products that become mechanically locked into the interdendritic spaces. These corrosion products are mostly amorphous aluminum or hydrated aluminum-zinc sulfates--similar to the corrosion products found on the coating surface of aluminum and 55Al-Zn coatings. These sulfates are adherent and may help explain the improved durability of the aluminum-zinc coating. Support for this mechanism is also obtained from aqueous corrosion studies in which the corrosion potential is observed to change that of a galvanized coating upon immersion to a value approaching that of aluminum after subsequent corrosion (Ref 29).

Aqueous Corrosion Resistance. The 55Al-Zn coating is finding increased use in applications demanding resistance to aqueous corrosion, especially where wet/dry cycles are obtained.

Corrosion in Natural Waters. As with other coatings, the corrosion of 55Al-Zn coating would be expected to vary with the specific properties of the water. It is not known how water hardness will affect corrosion, but in distilled water (very soft) and distilled water containing 85 mg/L of Cl^- ion, the 55Al-Zn coating is much more resistant than a galvanized coating (Table 23). In similar tests, 55Al-Zn and galvanized panels were immersed for 90 days in distilled water containing 45 ppm of SO_4^{2-} and 10 ppm of Cl^- at pH values from 3 to 11 (Ref 31). The pH was maintained through sulfuric acid (H_2SO_4) or sodium hydroxide (NaOH) additions. As Table 24 demonstrates, the 55Al-Zn retains more coating than the galvanized at all pH values, especially within the 5 to 9 range most characteristic of natural waters.

Table 23 Average coating thickness loss of galvanized and 55Al-Zn-coated steel after 56 days of immersion

Material	Thickness loss	
	Distilled water	85 mg/L NaCl

	µm	mils	µm	mils
Galvanized	1.06	0.042	1.26	0.049
55Al-Zn	0.015	0.0005	0.133	0.005

Source: Ref 30

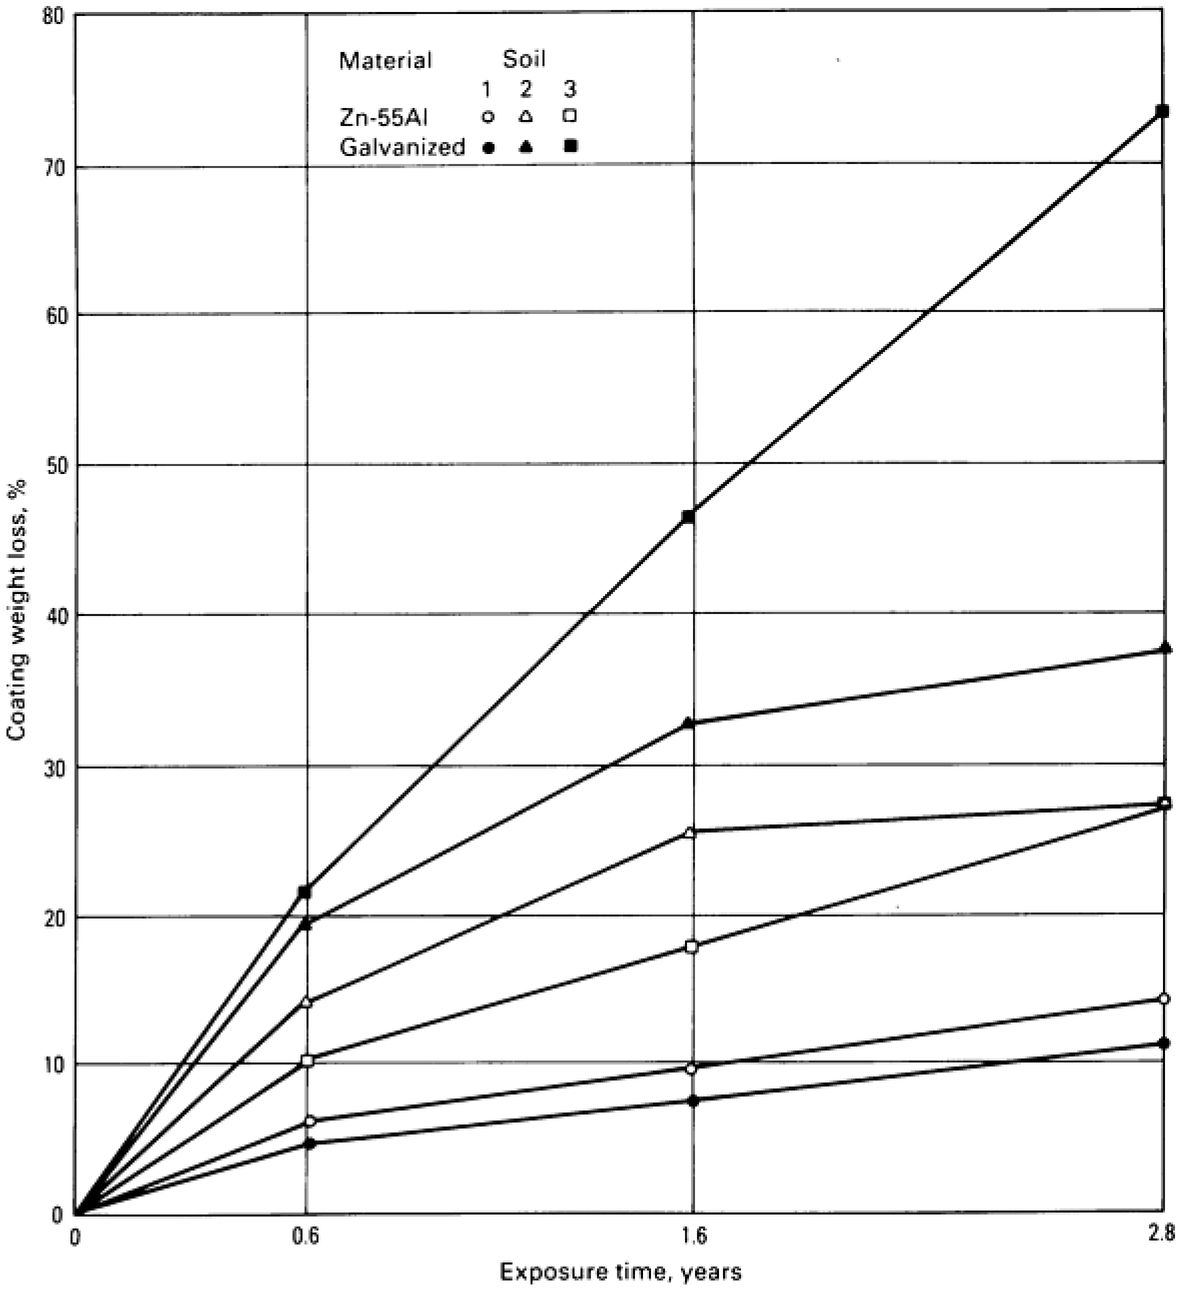
Table 24 Coating weight losses of galvanized and 55Al-Zn-coated steels after a 90-day immersion in water of various pHs

pH	Coating weight loss, %	
	Galvanized	55Al-Zn
3	32	31
5	45	2
7	41	4
9	40	8
11	33	26

The longest service history of exposure to natural water for the 55Al-Zn coating is obtained from corrugated steel pipe installed between October, 1973, and October, 1974 (Ref 32). Water chemistry, pH, and resistivity varied widely from site to site and sometimes changed considerably with time. Erosion and abrasion caused additional wear factors.

Overall, 55Al-Zn applied at a coating weight of 180 g/m^2 (0.6 oz/ft^2) provides greater durability than a 600 g/m^2 (2 oz/ft^2) galvanized coating. Continued monitoring of these sites suggests an average of 10 years of additional life for the 55Al-Zn coating in the pipe inverts, the point of severest corrosion and wear.

Corrosion in Soils. There are few performance data for the 55Al-Zn coating in soil. The corrugated steel pipe exposures described previously provide the longest history of soil exposure, but because most culverts fail from the inside, exterior soil corrosion was not monitored closely in these tests. Some data are available from laboratory tests in which 16-gage coated steel panels were buried in test soils and monitored for coating loss (Ref 32). Figure 14 shows coating loss and the soil characteristics. These data suggest that the 55Al-Zn coating should provide corrosion resistance in soil similar to that of a galvanized coating.



Soil number	Description	pH	Resistivity, Ω· cm
1	Native shale, clay: wet to dry	4	76,000
2	Native shale with chloride and sulfate salts: wet and dry	5	35,000
3	Native shale, clay, and bentonite with chloride and sulfate salts: wet	6	1,700

Hot Dip Lead Alloy (Terne) Coatings

Long terne steel sheet is carbon steel sheet that has been coated by bath or continuous hot dip processes with terne metal (lead with 3 to 15% Sn). This coated sheet is duller in appearance than conventional tin-coated sheet; this accounts for the name terne, which means dull or tarnished in French. The smooth, dull coating gives the sheet corrosion resistance, formability, excellent solderability, and paintability. The term long terne is used to describe terne-coated sheet, whereas short terne is used for terne-coated plate.

Applications. Because of its unusual properties, long terne sheet has been adapted to a wide variety of applications. Its principal use is in automotive gasoline tanks. Its excellent solderability and special corrosion resistance make the product well-suited for this application. Other typical applications include:

- Automotive parts such as air conditioners, air filters, cylinder head covers, distributor tubes, oil filters, oil pans, radiator parts, and valve rocker arm covers
- Caskets
- Electronic chassis and parts for radios, tape recorders, and television sets
- File drawer tracks
- Fire doors and frames
- Furnace and heating equipment parts
- Railroad switch lamps
- Small fuel tanks for lawn mowers, power saws, tractors, and outboard motors

Forming. Long terne sheet is often produced in accordance with ASTM A 308. For applications requiring good formability, the coating is applied over commercial quality, drawing quality, or drawing quality special killed low-carbon steel sheet. The terne coating acts as a lubricant and facilitates forming, and the strong bond of the terne metal allows it to be formed along with the base metal. When higher strength is required, the coating can be applied over low-carbon steel sheet of structural (physical) quality, although this will result in some loss in ductility. The mechanical properties of long terne sheet are essentially the same as those of hot dip galvanized or aluminized steel sheet.

Corrosion Characteristics. Lead has excellent corrosion resistance, and terne metal is principally lead, with 3 to 15% tin added to react with the steel to form a tight intermetallic bond. However, because lead does not offer galvanic protection to the steel basis metal, care must be exercised to avoid scratches and pores in the coating. Small openings can be sealed by corrosion products of iron, lead, and oxygen, but larger ones can corrode in an environment unfavorable to the steel base metal.

Joining. Long terne sheet can be readily soldered with noncorrosive fluxes using normal procedures because the sheet is already presoldered. This makes it a good choice for applications in which ease of solderability is important, such as television and radio chassis and gasoline tanks. It also can be readily welded by either resistance seam welding or spot welding; however, when the coating is subjected to high temperatures, significant concentrations of lead fumes can be released. Therefore, the U.S. Occupational Safety and Health Administration and similar state agencies have issued standards that must be followed when welding, cutting, or brazing metals containing lead or metals coated with lead or lead alloys.

Painting and Handling Considerations. Long terne sheet has excellent paint adherence, which allows it to be painted using conventional systems; however, it is not usually painted. When painting is done, no prior special surface treatment or primer is necessary, except for the removal of ordinary dirt, oil, and grease. Oiled sheet, however, should be thoroughly cleaned to remove the oil. Alternatively, a wash primer treatment or a paint that will tolerate a slight residue of manufacturing oil can be used.

Long terne sheet normally is furnished dry and requires no special handling. It should be stored indoors in a warm, dry place. Unprotected outdoor storage of coils or bundles can result in white or gray staining of the terne coating. Also, if pores are present in the terne coating, rust staining can occur.

Nickel terne coated steel includes an electrolytic flash coating of nickel (1 to 1.5 g/m^2) underneath a conventional lead-tin coating for enhanced corrosion resistance. Applications are similar to the conventional long terne coatings described above.

Composite Coatings. A variation of long terne coated steel employs a subsequent prepainted organic coating on each surface for some fuel tanks. The outer surface has a zinc-rich organic coating to provide added exterior corrosion protection, while the inner surface has an aluminum-rich organic coating to augment the lead-tin coatings resistance to gasoline, and low concentrations of methanol- and ethanol-containing fuels.

Electrogalvanizing

The development of continuous electrogalvanizing lines added another dimension to zinc-coated steel, that is, very thin, formable coatings ideally suited to deep drawing or painting. Zinc is electrodeposited on a variety of mill products by the steel industry: sheet, wire, and, in some cases, pipe. Electrogalvanizing at the mill produces a thin, uniform coat of pure zinc with excellent adherence. The coating is smooth, readily prepared for painting by phosphatizing, and free of the spangle that is characteristic of some other zinc coatings.

Electrogalvanized steel is produced by electrodepositing an adhering zinc film on the surface of sheet steel or wire. These coatings are not as thick as those produced by hot dip galvanizing and are mainly used as a base for paint. Processing details applicable to electrogalvanizing can be found in the article "Continuous Electrodeposited Coatings" in this Volume.

The coating produced on strip coils or sheets has a coating weight in the range of less than about 18 to 60 g/m^2 (0.06 to 0.2 oz/ft^2), or 1.3 to 4.3 μm (0.05 to 0.17 mil) thick on each side. A small amount carries considerably less--approximately 7.6 g/m^2 (0.025 oz/ft^2), or 0.5 μm (0.21 mil) on each side.

Zinc is usually electrodeposited on steel wire in the range of 90 to 915 g/m^2 (0.3 to 3 oz/ft^2). The diameter of plated wire (including wire that is cold drawn after plating) usually ranges from 0.23 to 4.9 mm (0.009 to 0.192 in.). Steel carbon contents range from 0.08 to 0.85%. Tensile strengths range from 345 to 2070 MPa (50 to 300 ksi). Heat-treated and coated wire can be cold drawn to approximately 95% reduction in area, depending on chemical composition, heat treatment, and diameter.

Nature of the Electrogalvanized Coating. The pure zinc coating deposited is highly ductile. Because of its excellent adhesion, electrogalvanized steel strip and wire have good working properties, and the coating remains intact after severe deformation.

Electrodeposited zinc coatings are simpler in structure than hot dip galvanized coatings. They are composed of pure zinc and have a homogeneous structure. Surfaces have a smooth texture whose appearance can be varied by additives and special treatments in the plating bath. They can be used where a fine finish is needed.

Electrogalvanizing provides adequate protection for many types of mild exposures. These coatings are frequently treated with chromate conversion solutions to improve appearance, reduce staining, and retard the formation of white corrosion products under high-humidity conditions.

Advantages and Limitations. In electrogalvanizing, steel strip or wire is continuously fed through suitable entry equipment, a series of washes and rinses, and a plating bath. Either an acid sulfate zinc or cyanide zinc bath is used as the plating bath. Both produce even, adhering zinc deposits. Although brighteners are not used for electrogalvanizing, grain refiners are usually added to help produce a fine, tightknit zinc surface on the steel.

Zinc electrodeposits are considered to have the best adhesion of any metallic coating. Good adhesion depends on very close physical conformity of the coating with the base metal. Therefore, particular care must be taken during initial cleaning. Electrodeposition affords a continuous process for applying zinc coatings to parts that cannot be hot dipped. They are especially useful where a high processing temperature could damage a part.

Applications. Electrogalvanized sheets are produced in various tempers suitable for simple bending or forming, for curving, and for rolling into cylinders without fluting. Spot welding is easily accomplished if care is taken.

Electrogalvanized steel is easily prepared to receive decorative finishes. Much of it is produced with a phosphate treatment or an organic coating. The phosphate treatment provides an adequate surface for a good bond with organic finishing materials. Organic coating applied over electrozinc thus treated maintains good adhesion in adverse conditions, such as sudden changes in temperature and high humidity. Phosphated electrogalvanized steel is used for parts subject to atmospheric corrosion or salt spray and for parts that will be lacquered or painted. Phosphate treatment increases corrosion resistance markedly, particularly in atmospheres with a high sulfur content.

Electrogalvanized sheet is used for manufacturing water cooler housings, exterior panels of ranges, freezers, dryers, washers, air conditioners, and other major appliances. It is used for deep-drawn parts for kitchen cabinets, refrigerators, and allied products instead of plain cold rolled sheet because zinc holds better in the dies and reduces breakage significantly. Bakery goods and other merchandizing display cases, stud systems for steel building construction, acoustical ceiling members, and television antennas are also made of electrogalvanized steel.

Sheets for automotive applications can be electrogalvanized on one side only. The galvanized side protects against corrosion, and the bare side can take the baked enamel finish required by the outer automobile surface.

Electrogalvanized wire is especially useful in applications in which the wire must be bent, twisted, or wrapped around its own diameter. When formed, the coating does not crack, peel, or flake. Many chain link fences are made from zinc-electrocoated wire because it is not rough and therefore is safe to handle. The wire is used for conveyor belts, twisted wire brushes, chains, baskets, kitchen utensils, staples, cages, bobby pins, clotheslines, and telephone and transmission wire.

Electroplating

Electroplated coatings are applied to steel for corrosion resistance, appearance, solderability, or other special requirements. A wide variety of materials are electroplated on steel, including nickel, chromium, zinc, cadmium, and tin. Multilayer coatings can also be applied by electroplating; an example is the copper-nickel-chromium plating system used for bright automotive trim. This section will review some of the more widely used electroplating processes for steels. More detailed information on each of the processes described below can be found in the articles contained in the Section entitled "Plating and Electroplating" in this Volume.

Surface Preparation for Electroplating

Preparation for plating is one of the most critical of all cleaning operations, because maximum adhesion of the plated coating to the substrate is the major requirement for quality work. Maximum adhesion depends on both the elimination of surface contaminants in order to induce a metallurgical bond whenever possible and the generation of a completely active surface to initiate plating on all areas. In addition to pickling or other descaling operations, adequate cleaning requires multistage cycles, usually comprised of the following steps: (a) precleaning with a solvent to remove most of the soil; (b) intermediate cleaning with alkaline cleaners; (c) electrocleaning to remove the last traces of solids and other contaminants that are especially adherent; (d) acid treatment and surface conditioning to remove light oxide films formed during previous cleaning processes and to microetch the surface; and (e) electrolytic (anodic) desmutting to remove any smut formed during acid pickling of heat treated high-carbon steel parts. Low-carbon steels do not require this desmutting step. Anodic electrocleaning also offers oxidation or conditioning of scale. The oxidized or softened scale is easily removed in subsequent acid pickling. The types of cleaning usually employed in the above steps are:

- *Precleaning:* cold solvent, vapor degreasing, emulsifiable solvent, solvent emulsion spray, or alkaline spray with or without solvent emulsion
- *Intermediate alkaline cleaning:* soak cleaning with 30 to 90 g/L (4 to 12 oz/gal) of cleaner at 80 °C (180 °F) to boiling, spray cleaning with 4 to 15 g/L (0.5 to 2 oz/gal) at 65 to 80 °C (150 to 180 °F), and barrel cleaning with 7.5 to 45 g/L (1 to 6 oz/gal) at temperatures below 80 °C (180 °F)
- *Electrocleaning:* cathodic, anodic, or periodic-reverse
- *Acid treatment:* practice is highly specific for the metal being processed
- *Anodic desmutting:* necessary to remove carbon smut

The ASTM recommended practice for cleaning steels with carbon contents less than 0.35% C is ASTM B 183 (Ref 33); ASTM B 242 covers surface preparation of steels with carbon contents of $\geq$0.35% C (Ref 34). Additional information on cleaning carbon and alloy steels prior to electroplating can also be found in the article "Classification and Selection of Cleaning Processes" in this Volume.

Nickel Plating

Electrodeposits of nickel exhibit a wide variety of properties, depending on composition of the plating bath and operating conditions. They may be classified according to application or appearance as general-purpose, black, and bright. More detailed information on plating bath chemistries and processing parameters can be found in the article "Nickel Plating"in this Volume.

Plating Baths. General-purpose nickel deposits, produced by Watts, sulfamate and fluoborate baths, are essentially sulfur-free. They are used primarily to protect steels against corrosive attack in rural, marine, and industrial atmospheres.

Black nickel deposits are used primarily for decorative effect and to provide nonreflecting surfaces. Black nickel deposits are produced by sulfate or chloride baths containing zinc (Zn^{2+}) and thiocyanate (CNS^{-}) ions.

Bright nickel plating baths are modifications of the Watts nickel solution and contain organic or combined organic and inorganic brightening agents; these additions serve to produce a high degree of brightness, leveling reflectivity, and hardness. A wide variety of additives are used, usually in highly specific combinations. Their function is to produce as brilliant and ductile a deposit as possible over a wide range of current densities and operating conditions. Some of these additives are consumed very slowly during electrolysis; others are consumed more rapidly.

Applications and Properties. Nickel plating is widely used for decorative purposes. Bright nickel plate--especially in combination with a lower layer of sulfur-free, semibright nickel and a much thinner upper layer of chromium--is very widely used over steel to provide a bright and corrosion-resistant finish with a nontarnishing and wear-resistant surface. Typical applications are decorative trim for automotive and consumer products. For best corrosion resistance, the chromium deposit should be microdiscontinuous (microcracked or microporous).

Nickel deposits are also used for nondecorative purposes to improve or modify surface properties such as corrosion resistance, hardness, wear, and magnetic characteristics. For example, in the automotive industry, nickel coatings, generally greater than 125 μm (5 mils) thick, are deposited on pistons, cylinder walls, ball studs, transmission thrust washers, and different pinion cross-shafts to improve wear resistance. The most widely used solution for plating nickel for wear applications is the Watts solution. Its main components are nickel sulfate, nickel chloride, and boric acid. Organic addition agents in the plating solution can increase the hardness and wear resistance mainly by decreasing the grain size. Nickel usually is deposited with a tensile internal stress. Some sulfur compounds can cause the stress to become compressive, but also make the deposit more brittle, especially under elevated-temperature conditions. The nickel sulfamate plating solution produces low-stress deposits. It is possible to codeposit such metals as tungsten and molybdenum with nickel, even though they cannot be plated alone in aqueous solutions. Inclusion of hard particles or those of solid lubricants can also improve the wear or friction properties of electroplated nickel.

Improved wear resistance resulting from the incorporation of SiC particles is shown in Fig. 15. In the test on which the data of Fig. 15 are based, a plated block was pressed against a lubricated steel ring. Further improvement that was due to phosphide precipitates in heat-treated Ni-P-SiC coatings is also seen in this figure.

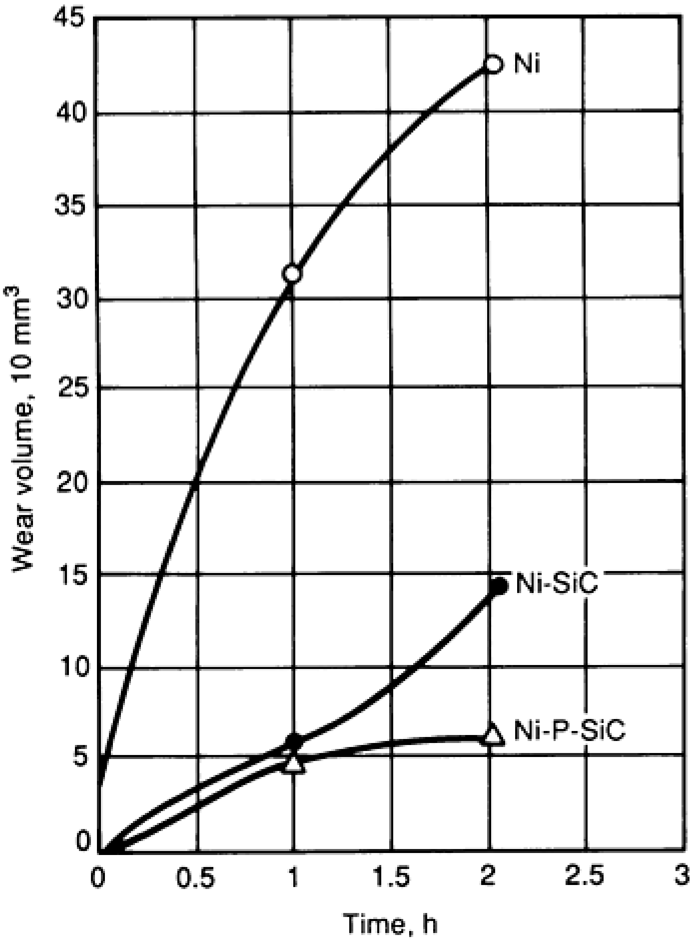

Fig. 15 Effects of codeposited SiC particles and phosphide precipitates on wear of electrodeposited nickel heat treated for 1 h at 400 °C (750 °F). Source: Ref 35

The hardness of nickel deposits can vary from about 150 to 500 on the Vickers scale. The hardness depends on the plating conditions, that is, current density, solution pH and temperature, and composition. Pulse plating can increase the hardness.

The coefficient of friction and wear rates of electroplated nickel are generally greater than those of chromium or electroless nickel deposits (Fig. 16).

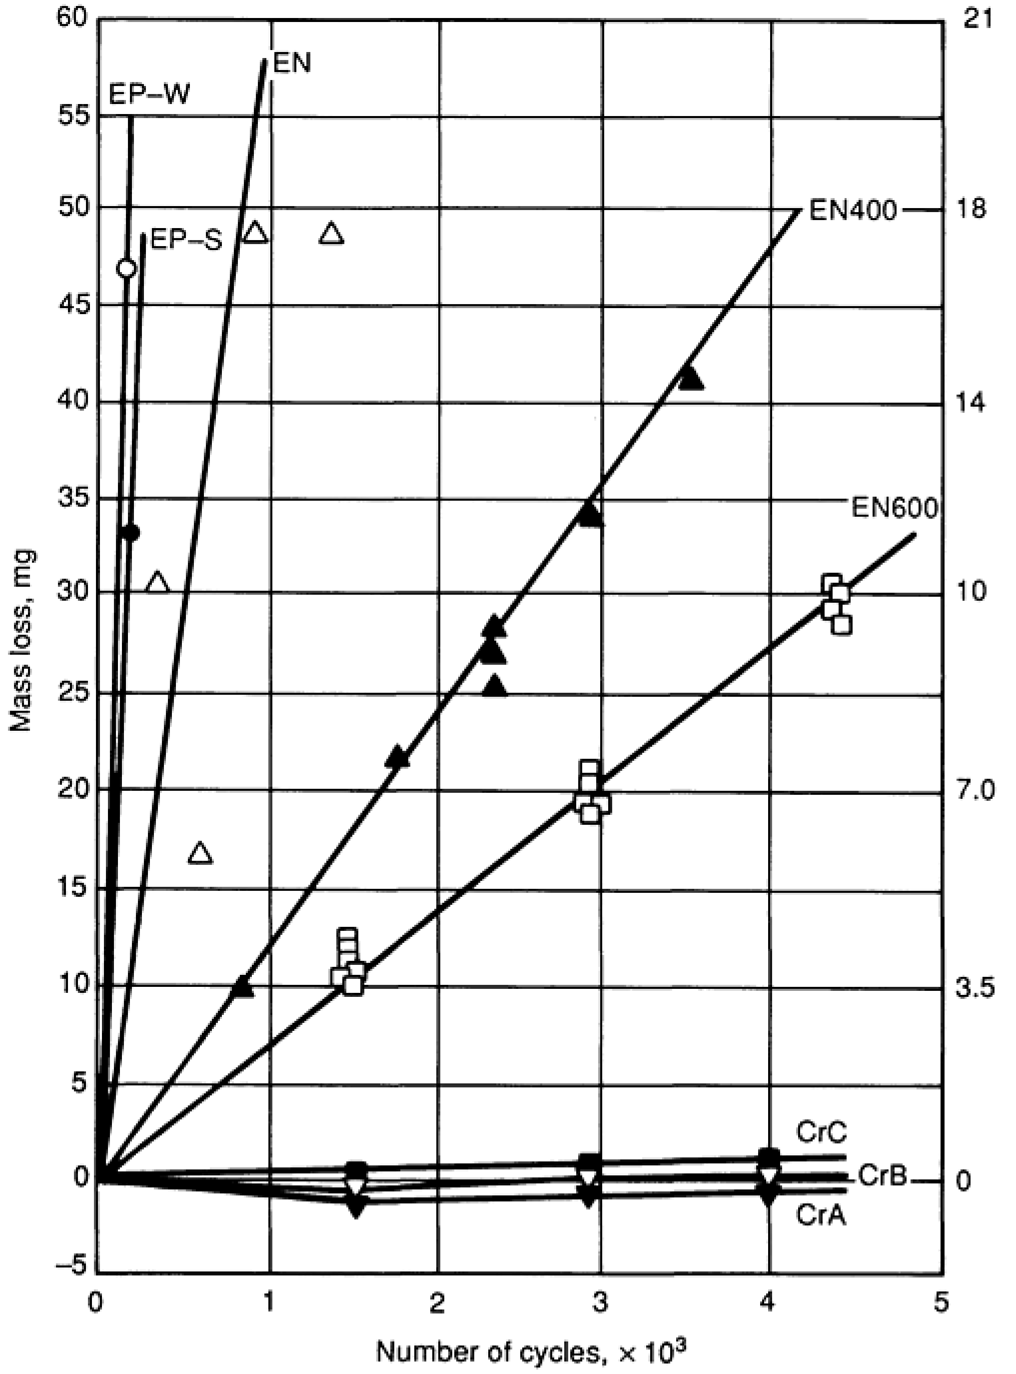

Fig. 16 Effect of number of cycles on wear loss of plated pin versus steel blocks in a Falex test for three chromium deposits (CrA, CrB, and CrC), heat treated electroless nickel deposits (EN400 and EN600), a non-heat-treated electroless nickel deposit (EN), and two electroplated nickel deposits from a sulfamate solution (EP-S) and a Watts solution (EP-W). Source: Ref 36

Depending on the substrate and the end use of the plated product, nickel may be applied directly to the substrate or over another metal coating such as copper and/or chromium. Because of their importance in the automotive industry, nickel-chromium (with or without a copper underlayer) coatings have been subjected to many changes and exhaustive testing over a long span of years. Figure 17 shows a history of the development and use of nickel-chromium coatings. Significant developments in this history were the determination that the basic corrosion resistance of these systems is controlled by the thickness and composition of the nickel layer, the invention of the leveling copper and nickel plating processes, the

development of semibright and bright nickel plating, the emergence of crack-free and microcracked chromium, and the evolution of duplex and triplex (multilayer) nickel-chromium systems.

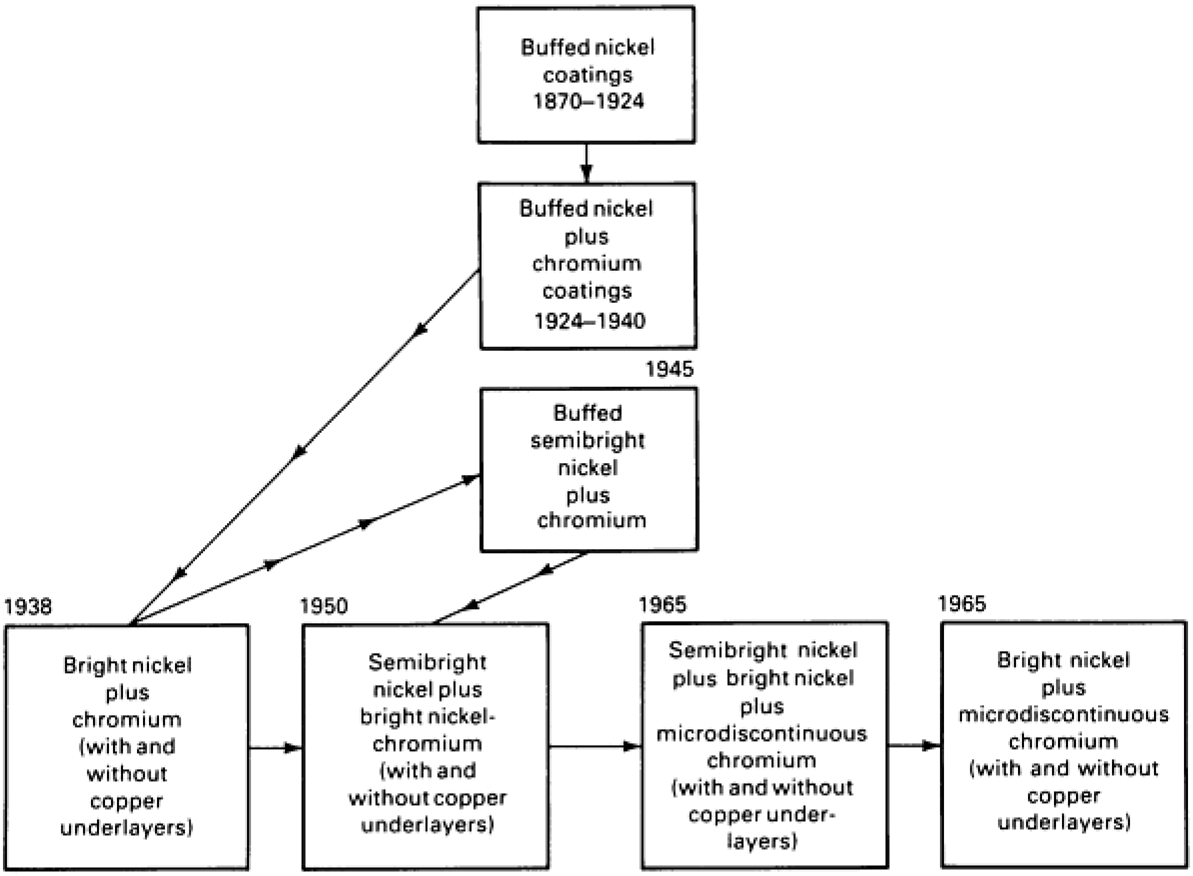

Fig. 17 History of the development of nickel and nickel-chromium coatings showing time of introduction and periods of use. Source: Ref 37

In nickel-chromium systems, the chromium layer is very thin--of the order of only 0.25 μm (0.01 mil). However, the corrosion resistance of chromium plate depends not so much on its thickness as on its physical state. Crack-free, or nonporous, chromium is excellent, but does not remain crack-free in service. A small number of cracks are detrimental, but the presence of many fine microcracks may be beneficial (Ref 38). Microcracked chromium deposits cause the galvanic-corrosion action to be spread over a very wide area and therefore do not suffer from localized corrosion. Microcracked chromium, in combination with duplex or triplex nickel, is the most durable of these coatings. The results of marine exposure for 36 months on variations of these coatings on steel are shown in Fig. 18. Recommended minimum thicknesses and typical applications of bright nickel-chromium coatings are listed in Table 25.

Table 25 Recommended minimum thicknesses and typical applications for electrodeposited bright nickel-chromium coatings on steel, iron, or zinc die-cast substrates

Service conditions	Classification[(a)]		Minimum thickness				Typical applications

Electroless Nickel Plating

Electroless nickel plating is used to deposit nickel without the use of an electric current. The coating is deposited by an autocatalytic chemical reduction of nickel ions by hydrophosphite, aminoborane, or borohydride compounds. Details of the process can be found in the article "Electroless Nickel Plating" in this Volume. When sodium hypophosphite is the reducing agent, the deposit generally contains between 3 and 11% P. The boron contents of electroless nickel range from 0.2 to 4 wt% and from 4 to 7 wt% when the reducing agents are an aminoborane and sodium borohydride, respectively.

Electroless nickel is an engineering coating, normally used because of excellent corrosion and wear resistance. Because of these properties, electroless nickel coatings have found many applications, including those in petroleum, chemicals, printing, mining, aerospace, nuclear, and automotive industries.

Electroless nickel can be heat treated to hardnesses comparable to those of electrodeposited chromium. The maximum hardness can be attained in 1 h at about 400 °C (750 °F) or 10 h at 260 °C (500 °F). The hardness of as-plated nickel-phosphorus alloys varies from 500 to 650 on the Vickers scale. As-plated nickel-boron deposits are generally harder than the nickel-phosphorus ones. The ability of electroless nickel deposits to maintain their hardness under elevated-temperature service conditions increases with increasing phosphorus or boron content, but decreases rapidly above 385 °C (725 °F). Nickel-boron coatings tend to better withstand wear at elevated temperatures and are therefore more widely used under these conditions.

Wear rates of electroless nickel are summarized in Fig. 16. As this figure indicates, the wear loss of heat treated electroless deposits is lower than either electroplated nickel or non-heat-treated electroless deposits.

Coefficients of friction of electroless nickel in the as-deposited condition (EN) and heat treated at 400 °C (750 °F) (EN400) and at 600 °C (1110 °F) (EN600) are compared in Table 26 to the three chromium alloys depicted in Fig. 16. Additional information on the friction and wear characteristics of electroless nickel deposits can be found in Ref 36.

Table 26 Coefficients of friction of chromium versus electroless nickel

Coating	Coefficients of friction	
	Counterface diamond	Counterface plain carbon steel
CrA	0.040	0.88
CrB	0.035	0.82
CrC	0.030	0.81

Chromium Plating

Plating Baths. Most chromium plating is done from hexavalent chromic acid (CrO_3) baths, but trivalent systems are gaining in popularity. Hexavalent chromium plating baths consist of chromic acid and small amounts of a sulfate catalyst (SO_4^{2-}). Recently, mixed catalyst baths containing fluoride compounds in addition to chromic acid and sulfate have been employed. Proprietary self-regulating baths control the concentration of the catalyst automatically. Bath formulations and process controls are discussed in the articles "Industrial (Hard) Chromium Plating" and "Decorative Chromium Plating" in this Volume.

Applications and Properties. As implied above, chromium plating is divided into decorative and hard coatings. Decorative coatings are applied over a base deposit of nickel or copper plus nickel to provide color and tarnish resistance. Coating thicknesses are usually less than 1 μm (0.04 mil). Decorative chromium coatings are most often found on automobiles, furniture, and kitchen appliances.

Hard chromium coatings are generally deposited directly on the base material without a nickel undercoat in thicknesses ranging from 1 to 500 μm (0.04 to 20 mils). Hard coatings provide resistance to wear, heat, abrasion, and/or corrosion. Typical applications for hard coatings include hydraulic pistons and cylinders, piston rings, wearing parts in business machines, aircraft engine parts, yarn and thread guides for textiles, plastics molds, and various parts of nuclear reactors where galling is a particular concern.

Microcracks are present in most electroplated hard chromium deposits. Figure 19 shows a typical microcrack structure. The density of the microcracks in chromium deposits varies from 0 to more than 1200 cracks/cm (3000 cracks/in.), depending on bath chemistry, current density, and temperature. The number of microcracks increases with the concentration of the catalyst in the plating bath. The depth of a microcrack is less than about 8 μm (0.3 mil) on a deposit that is 130 μm (5 mils) thick with crack counts of about 800 cracks/cm (2000 cracks/in.).

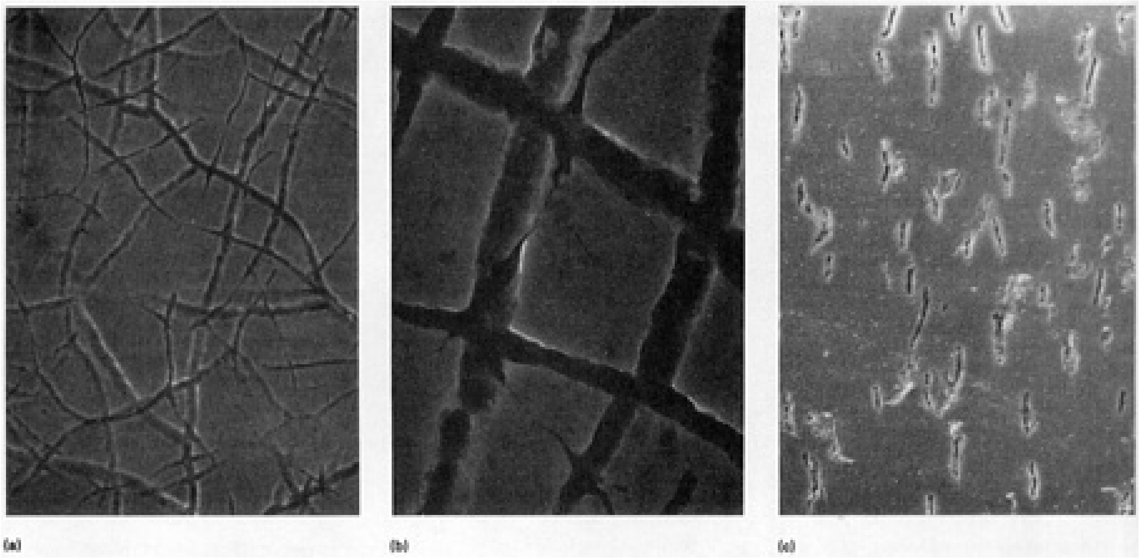

Fig. 19 Photomicrographs of chromium deposits (plated in a high-efficiency etch-free bath) after etching. (a) and (b) Deposit plated at 78 A/dm^2 (5 A/in.^{2}) and at 55 °C (130 °F). (a) 540×. (b) 2300×. (c) Cross section of a chromium deposit plated at 93 A/dm^2 (6 A/in.^{2}) and at 58 °C (135 °F). The specimen was polished before etching. 880×. Both deposits contain 800 microcracks/cm (2000 microcracks/in.).

Electroplated hard chromium is chemically resistant to most compounds and offers excellent corrosion protection in various environments. Electroplated chromium for atmospheric corrosion applications should be between 20 and 25 μm (0.8 and 1 mil) thick. For corrosion resistance in chemical exposures, electroplated chromium should be 50 to 75 μm (2 to 3 mils) thick. A detailed review on the corrosion resistance of electroplated chromium can be found in Ref 40.

The hardness of hard chromium varies from about 900 to 1100 on the Knoop and Vickers hardness scales. These values are considerably higher than the hardness of bulk chromium. Deposits from trivalent solutions are softer than those that are plated from hexavalent chromium solutions. However, after heat treating at about 700 °C (1290 °F), a hardness comparable to that of hard chromium can be achieved (Ref 41).

Chromium deposits are characterized by high internal tensile stresses that can reach 1000 MPa (145 ksi). These stresses can reduce the fatigue properties of coated components. Hydrogen is also codeposited with chromium and can diffuse into components, causing hydrogen embrittlement. Heat treatments are typically required to relieve the stresses and hydrogen effects, but can reduce the hardness.

The coefficients of friction of hard chromium against hard materials are generally the lowest of any electrochemically deposited coatings. The actual values vary considerably, depending on the test method, the mating surfaces of the materials, and the degree of lubrication. Some values of static and sliding coefficients of friction are listed in Table 27. In general, hard chromium has a lower wear rate than either electroplated or electroless nickel, which are the two competing materials. Wear rates are compared in Fig. 16.

Table 27 Coefficients of friction for hard chromium electrodeposits

Couple	Static coefficient	Sliding coefficient
Chromium-plated steel versus itself	0.14	0.12
Chromium-plated steel versus steel	0.15	0.13

Steel versus steel	0.30	0.20

Zinc Plating (Ref 43)

Plating Baths. Zinc is deposited from three different baths: the conventional cyanide bath, the acid chloride bath, and the alkaline noncyanide (or zincate) bath. Compositions and processing conditions for these plating baths are described in the article "Zinc Plating" in this Volume. Cyanide baths offer the ease of control and normally trouble-free plating. However, the cost and toxicity associated with cyanide baths have prompted platers to install low-cyanide solutions or cyanide-free baths.

Chloride zinc baths have been available since the late 1960s. The original baths were chelated or based on complexing agents such as ammonium chloride. Today, state-of-the-art chloride baths use potassium or ammonium chloride. The advantages of the chloride systems include brilliant deposits, high cathode efficiency, low electric power consumption, and a nontoxic, easily treated electrolyte. The disadvantages are poor throwing power, a higher initial equipment investment, and higher brightener costs compared to the alkaline processes.

Alkaline noncyanide electrolytes consist of zinc and sodium hydroxide. In the absence of cyanide, proprietary sequestering agents are sometimes used to yield grain refinement. Alkaline noncyanide electrolytes are simple and low cost. The solutions and rinse waters are easily treated, and metal hydroxide sludges are reduced owing to low zinc content in the bath. These baths, however, offer the lowest cathode efficiency, and the deposits may be yellowish in color. Blistering is common at higher thicknesses and may be related to the greater hydrogen occlusion.

Applications and Properties. Zinc is plated over steel on a wide variety of parts where sacrificial corrosion resistance is required. The conventional zinc coating is dull gray in color with a matte finish, but whiter and more lustrous deposits can be produced by the use of proprietary addition agents. Zinc plate is almost always passivated with a chromate coating for added corrosion protection. The effects of chromate conversion coatings on the corrosion resistance of electrodeposited zinc are listed in Table 28. Coating thickness ranges from 5 to 25 μm (0.2 to 1 mil), depending on the particular application.

Table 28 Recommended minimum thicknesses and typical applications for zinc and cadmium coatings electrodeposited on iron and steel

Service conditions	Coating thickness		Chromate finish	Time to white corrosion in salt spray, h	Typical applications

Source: Ref 39

(a) Thickness specified is after chromate conversion coating, if used.

(b) There are some applications for cadmium coatings in this environment; however, these are normally satisfied by hot-dipped or sprayed coatings.

The formation of white corrosion products in marine environments makes zinc less desirable than cadmium; but because it is less toxic and less expensive and its electrolytes are more easily waste treated, zinc has replaced cadmium in many applications. Zinc coatings are also superior to cadmium coatings in industrial environments. Common applications for zinc plating include fasteners, wire goods, tools, and sheet metal parts.

Cadmium Plating (Ref 43)

Plating Baths. Cadmium is primarily plated from a cyanide electrolyte. Acid cadmium baths are also used to a limited extent, and are fluoborate, sulfate, or chloride in nature. The acid-type baths are more desirable if hydrogen embrittlement is a problem, and their waste treatment is simplified. However, the cyanide baths are easier to control than the acid baths. Typical cadmium plating compositions are described in the article "Cadmium Plating" in this Volume.

Applications and Properties. Cadmium provides galvanic protection when deposited on steel. The government is by far the largest specifier of cadmium, for military applications. As shown in Table 28, deposit thicknesses range from 5 to 25 μm (0.2 to 1 mil), depending on the degree of exposure to corrosion, and wear. As with zinc electroplates, chromate conversion coatings improve the corrosion resistance of cadmium electrodeposits. Cadmium is generally preferred for the protection of steel in marine environments whereas zinc is preferred in industrial environments. The coefficient of friction of cadmium is less than that of zinc; therefore, cadmium is preferred for fastening hardware and connectors that have to be taken on and off repeatedly. Typical applications include springs, lock washers, fasteners, electronic and electrical parts, washing machine parts, and military hardware. Because it is toxic, cadmium plating should never be used on parts that will come in contact with food or beverages.

Avoiding Hydrogen Embrittlement. Cadmium deposited from a cyanide solution is more likely to produce hydrogen embrittlement than any other commonly plated metal. Heat treated high-strength steels, particularly those plated and used at 35 HRC and above, are susceptible to hydrogen embrittlement.

Although the thickness of the plated deposit appears to have no direct bearing on hydrogen embrittlement, it is always more difficult to release the hydrogen (by baking) from heavy deposits. By adhering to the following procedures, hydrogen embrittlement can be minimized:

- Use mechanical cleaning methods, such as brushing, blasting, and tumbling
- Wherever possible, avoid the use of strong acid pickling solutions and extended exposure to acid pickling

- If pickling is essential to the preparation of medium-strength and high-strength steel parts, bake the parts at 175 to 205 °C (350 to 400 °F) for 3 h after pickling and before plating
- In plating, use the higher current densities to produce a more porous deposit; 7 A/dm^2 (70 A/ft^2) in a cyanide bath without brighteners has been satisfactory for steel at 46 HRC
- After plating, bake parts at 175 to 205 °C (350 to 400 °F) for 3 to 24 h. The shorter baking periods are generally adequate for parts with a tensile strength below about 1520 MPa (220 ksi); longer baking periods are recommended for steel of tensile strength above about 1520 MPa (220 ksi) or lower strength parts if sharp notches or threads exist. Parts greater than 25 mm (1 in.) thickness should also be baked for 24 h. The elapsed time between plating and baking must never exceed 8 h, and baking should be carried out as soon as possible, preferably within 4 h
- Plate parts to a thickness of about 5 μm (0.2 mil), bake for 3 h at 195 °C (385 °F), activate in cyanide, and then complete the plating to required final thickness

Tinplate

The term *tinplate* refers to a low-carbon steel strip product coated on both sides with a thin layer of tin. Electrolytic tinplate can be produced with either equal or unequal amounts of tin on the two surfaces of the steel base metal. Nominal coating thicknesses for equally coated tinplate range from 0.38 to 1.5 μm (15 to 60 μin.) on each surface. The thicker coating on tinplate with unequal coatings (differential tinplate) rarely exceed 2.0 μm (80 μin.). Tinplate is produced in thicknesses from 0.15 to 0.60 mm (0.006 to 0.024 in.). For almost 200 years, tinplate has been the primary material used to make containers (tin cans) for the long-term storage of food. More than 90% of the tinplate manufactured worldwide is used to make food cans, and nearly all food cans are made of tinplate.

Modern tinplate is much more sophisticated than a simple coating of tin on steel. To achieve the demanding deep-drawing properties necessary for the production of can bodies for two-piece can manufacture, the steel base for tinplate is often continuously cast using the most current technology. Inclusions or other defects in the steel may otherwise cause breakage in the can-body drawing operation. Because the economics of canmaking depend on high-speed operation using a continuous coiled strip, such breakage cannot be tolerated due to the lost production time; therefore, the steel must be as clean as possible.

In preparing the base steel, the metal is processed to strip form, the final step being a cold reduction that brings the strip to a thickness that is typically from 0.15 to 0.50 mm (6 to 20 mils). Next, the strip is annealed and then temper rolled to obtain the desired mechanical properties. At the final stage of temper rolling, textured rolls can be used to produce a special surface finish for particular applications. A cold reduction in place of temper rolling yields a product that is termed double reduced.

The coiled steel is now ready for the tinplate line. It is first welded to the end of the previous coil to form a continuous strip for processing. The strip passes through cleaning and pickling sections to prepare it for plating, then immediately through the plating cells, where up to 11.2 g/m^2 (1 g/ft^2) of tin is deposited. Tin may be plated from either alkaline electrolytes (stannate) or acid electrolytes (sulfate, fluoborate). Plating bath compositions and operating conditions are described in the article "Tin Plating" in this Volume.

The production steps that typically follow plating create additional layers in the tinplate structure that significantly affect corrosion properties. Upon exiting the plating cells, the tinplate has a matte surface that is usually reflowed by momentarily melting the tin coating in a resistance or induction heating unit. In doing so, a thin layer of tin-iron intermetallic compound is formed at the tin/steel interface. Next, an extremely thin passivation film based on chromium oxide is created by immersion or spraying of chromic acid (H_2CrO_4) on the tinplate surface or by passing the tinplate through a solution of $Na_2Cr_2O_7$, with or without the simultaneous application of electrical current. Finally, a very thin, uniform layer of lubricant, usually either dioctyl sebecate or acetyl tributyl citrate, is electrostatically applied.

Therefore, as supplied to the canmaker, the typical tinplate product consists of five layers, the innermost being a steel sheet about 200 to 300 μm (7.8 to 11.7 mils) thick. This steel is covered on each side with perhaps 0.08 μm (0.004 mil) of tin-iron intermetallic compound. The next layer is free tin that is perhaps 0.3 μm (0.012 mil) thick, with a passivation film of about 0.002 μm (0.00008 mil) and an oil film also about 0.002 μm (0.00008 mil) thick. All five layers affect corrosion behavior. Reference 44 is an excellent source of information on the corrosion characteristics of tinplate.

Metal Cladding

Carbon steels can be bonded to more corrosion-resistant materials, such as copper and stainless steels, by a variety of techniques. The resulting lamellar composite material has specific properties not obtainable in a single material.

The principal cladding techniques include hot roll bonding, cold roll bonding, explosive bonding, centrifugal casting, brazing, and weld cladding, although adhesive bonding, extrusion, and hot isostatic pressing have also been used to produce clad metals. With casting, brazing, and welding methods, one of the metals to be joined is molten when a metal-to-metal bond is achieved. With hot/cold roll bonding and explosive bonding processes, the bond is achieved by forcing clean oxide-free metal surfaces into intimate contact; this causes a sharing of electrons between the metals. Gaseous impurities diffuse into the metals, and nondiffusible impurities consolidate by spheroidization. These non-melting techniques involve some form of deformation to break up surface oxides, to create metal-to-metal contact, and to heat in order to accelerate diffusion. The techniques differ in the amount of deformation and heat used to form the bond and in the method of bringing the metals into intimate contact. More detailed information on metal cladding techniques can be found in Ref 45, 46, and 47.

Noble metal clad systems are materials having a relatively inexpensive carbon steel base metal covered with a corrosion-resistant metal. Clad metals of this type are typically used in the form of strip, plate, and tubing. The noble metal cladding ranges from commonly used stainless steels, such as type 304, to high-nickel alloys, such as Inconel 625. These clad metals find various applications in the marine, chemical-processing, power, and pollution control industries. Specific uses include heat exchangers, reaction and pressure vessels, furnace tubes, tubes and tube elements for boilers, scrubbers, and other systems involved in the production of chemicals.

Transition Metal Systems. A clad transition metal system provides an interface between two incompatible metals. It not only reduces galvanic corrosion where dissimilar metals are joined but also allows welding techniques to be used when direct joining is not possible.

The principle of a clad transition metal is illustrated in Fig. 20. In this example, aluminum is joined to low-carbon steel through a steel-clad aluminum transition metal. Steel and aluminum form brittle intermetallic compounds and are difficult to weld directly. The transition metal insert allows steel to be welded to steel and aluminum to aluminum; the actual bond

between the steel and the aluminum occurs in the clad transition. In addition, the dissimilar-metal crevice is eliminated, which reduces susceptibility to galvanic corrosion.

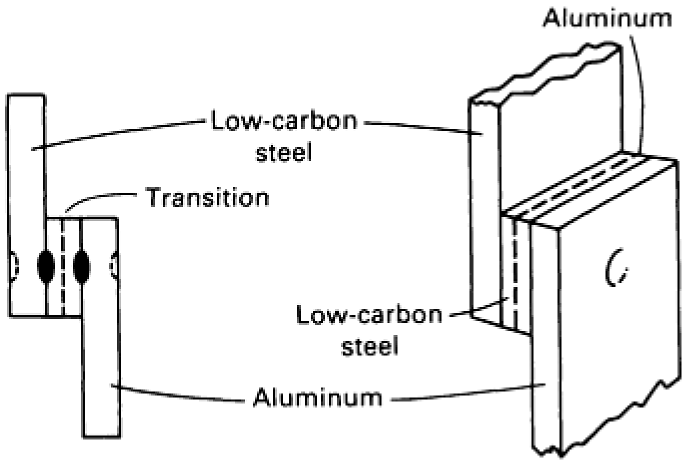

Fig. 20 Illustration of a steel-clad aluminum transition insert used for joining aluminum to carbon steel

Complex Multilayer Systems. In many cases, materials are exposed to dual environments; that is, one side is exposed to one corrosive medium, and the other side is exposed to a different one. A single material may not be able to meet this requirement, or a critical material may be required in large quantity.

Clad metals provide an ideal solution to the materials problem of dual environments. For example, in automobile windshield wiper sockets (Fig. 21), wear resistance is required on the mating surface, atmospheric-corrosion resistance is required on the external surface, and high strength is incorporated into the design. Multilayer phosphor-bronze-clad, steel-clad copper is used in this application. The phosphor bronze provides the required bearing surface, copper provides atmospheric-corrosion resistance, and steel provides the required strength.

Organic Coatings

Paint is applied to a steel sheet or a part for one or both of the following reasons: enhancement of the aesthetic value of the product and/or preservation of structural integrity. The former goal is a consideration for the designer and will receive no further discussion in this section. The latter goal, however, will be discussed as it applies to prepainted steel.

This section will describe how paints deter corrosion, the prepainting process, the primary differences between prepaint paint formulations and postpaint formulations, considerations about part design, and selection criteria for the appropriate paint system. More detailed information on organic coating materials can be found in Ref 48 and the articles "Painting" and "Elastomeric Coatings and Linings" in this Volume.

How Paint Films Deter Corrosion. In the presence of water and oxygen, iron corrodes to form iron oxides and hydroxides. The corrosion rate is accelerated when electrolytic solutes, such as the chloride or sulfate salts of alkali metals, are present. Of course, temperature also increases the corrosion rate, and where possible, decreasing the service temperature will increase the service life of the part. However, because little can usually be done to change service temperature, the exclusion of one or more of the principal reactants (oxygen, water, or electrolytes) from the steel surface will help deter corrosion. Such exclusion of reactants is the purpose of the paint film.

There are primarily three methods of protection: barrier, passivation, and galvanic. In barrier protection, the paint film retards the diffusion of water, oxygen, or salts to the steel substrate. It has been demonstrated that the flow of water and oxygen through the film is rapid; therefore, the contribution of the coating to lowering the corrosion rate is the addition of a high electrolytic resistance (Ref 49). Flake-shaped pigment particles that leaf (overlap) can increase the path length a reactant must traverse before reaching the surface; this increases the effectiveness of the barrier film. Some aluminum and stainless steel pigments protect in this fashion. The reactivity of the steel surface can be decreased when the paint film contains passivating pigments such as chromate salts. As described below in the section on "Painting With Zinc-Rich Paints," paints are also often pigmented with zinc for both barrier and galvanic protection. The zinc loading must be sufficiently high for interparticle contact, a condition that requires that the critical pigment volume be exceeded; that is, the pigment particles are not completely wetted by the paint vehicle. Although some galvanic protection is afforded, most of the protection is provided by the barrier formed by zinc corrosion products (Ref 50).

Prepaint Processing. Much of the painted steel used today is prepainted in coil form (coil coated) before shipment to fabricators. Modern, high-speed paint lines can process bare or coated steel strip, and can be used to apply a wide variety of organic coatings.

After decoiling, the first step in the prepaint process is to clean the steel strip with an alkaline detergent. The steel strip is then brushed with an abrasive roll to remove mill oils and grime and to reduce the level of an amorphous form of surface carbon indigenous to steel strip processing. High levels of surface carbon lower corrosion resistance (Ref 51). Cleaning is usually more effective on flat strip than on a formed part. Next, the strip is rinsed and pretreated to improve paint adhesion and to reduce corrosion. A prepaint treatment may consist of phosphate coating or an organic pretreatment known as wash primer or etch primer. Such pretreatments are described in the article "Painting" in this Volume. Following pretreatment, a paint is then applied and cured in an oven. Depending on the paint formulation and the paint line, the dwell time in the oven is generally between 20 and 50 s. A second coat may then be applied and cured.

Differences Between Prepaint and Postpaint. In formulating a paint designed for a prepaint application, the forming step must be considered. Aside from steel consideration, successful forming of the part will depend on the flexibility and the abrasion resistance of the coating. The paint film must be flexible enough to withstand the strains induced from bending without crazing, which may compromise corrosion resistance. In addition, in the forming stages, the bend radii are often more severe than in the final part.

The coating must also withstand the abrasive forces of handling and forming. For a given coating type, the harder the coating, the more abrasion resistant the coating will be. Unfortunately, flexibility and hardness are inversely related; that is, the more flexible the coating, the softer the coating.

A method for overcoming the problems associated with coating flexibility is covered in the discussion on part design considerations in this section. Flexibility and hardness are considerations only for the end use of postpainted parts, while forming and handling are also factors of concern in the formulation of a paint designed for precoating a steel strip.

The final dried paint thickness, or dry-film thickness, on a prepainted steel strip is usually no more than 0.25 mm (1 mil). Plastisols and organosols are the major exceptions. Therefore, the prepaint dry-film thickness is much less than the typical dry-film thickness on a postpainted part. However, because of the method of application, the film is more evenly distributed; this results in significantly fewer areas of low dry-film thickness and the elimination of many of the appearance defects observed on finished postpainted parts. Many areas on postpainted parts will receive little or no paint because of the part shape. The formulations for prepaints are engineered to account for the lower dry-film thicknesses.

Part Design Considerations. When designing a part to be fabricated from prepainted steel, the maximum bend radius, the forming equipment, and the joining method must be considered. As mentioned earlier, the maximum bend radius is often smaller than that specified on the blueprint of the part. This radius should be as generous as the structural and decorative criteria will allow. In considering the part shape, the avoidance of catchment areas, where possible, will decrease failures due to corrosion.

The forming equipment should be well maintained to avoid marring the surface. Where possible, roll forming is preferable to stamping. In cases in which hard finishes in conjunction with tight radii (high flexibility) are required, the prepainted strip can be warm formed. In warm forming, the paint is heated into or above its glass transition temperature range. In this temperature range, the paint is softer and more flexible, thus allowing tighter radii to be achieved during forming. After cooling, the paint becomes harder and more abrasion resistant.

Lastly, the part may require joining. Welding and mechanical fastening damage the paint film. Therefore, it is necessary to touch up the scars to restore corrosion resistance. Adhesive bonding eliminates the need for touch up of these damage areas. Taking these factors into account, prepainted steel has been successfully fabricated into finished or semifinished (requiring a post finish coat operation) parts in many automotive, appliances, or office furniture manufacturing plants. Prepainted parts have been produced on lines designed for their use and on existing lines, sometimes with no modification to the line.

Selection Guideline. As an aid to understanding the evaluation process, Table 29 compares various common coatings in several categories of performance. Changes in pigmentation and resin source for the vehicle can influence the rating by a factor of one or more. Table 29 is merely a guideline to the performance of these coatings. Comments from technical personnel at a paint company should be sought before making any decision on paint selection.

Table 29 Relative hardness rankings of various coatings in different performance categories

Category key: A, hardness; B, flexibility; C, humidity resistance; D, corrosion resistance to industrial atmospheres; E, salt spray; F, exterior durability, pigmented film; G, exterior durability, clear film; H, paint cure temperature, in °C (°F); I, cost guide. Ratings key: 1, excellent; 2, good; 3, fair; 4, poor; H, high cost; M, moderate cost; L, low cost

Type	A	B	C	D	E	F	G	H	I
Silicone acrylic	1	3	2	2	2	2	1	230 (450)	H
Thermoset acrylic	2	2	1	2	1	2	2	220 (430)	M
Amine-alkyd	2	3	2	2	3	2	3	170 (340)	L
Silicone alkyd	2	3	2	2	2	1	2	215 (420)	H

Vinyl-alkyd	2	2	1	2	2	3	3	170 (340)	M
Straight epoxy	1	2	1	1	1	4	4	205 (400)	H
Epoxy-ester	2	2	1	2	1	4	4	205 (400)	M
Organosol	2	1	1	1	1	2	3	175 (350)	L
Plastisol	3	1	1	1	1	2	3	175 (350)	L
Polyester (oil-free)	1	2	1	2	1	2	3	205 (400)	M
Silicone polyester	2	2	1	2	1	1	2	230 (450)	H
Polyvinyl fluoride	2	1	1	1	1	1	1	230 (450)	H
Polyvinyl idene fluoride	2	1	1	1	1	1	1	230 (450)	H
Solution vinyl	2	1	1	2	1	2	3	150 (300)	M

The columns in Table 29 are self-explanatory, with the exception of those involving exterior durability and salt spray. Exterior durability is the resistance to weathering, particularly the resistance to ultraviolet light. Ultraviolet light causes some coatings to chalk. Proper pigmentation will prevent this phenomenon for some coatings, and this can be determined by comparing the columns for pigmented and clear films.

Salt spray is not a predictor of service life and coatings cannot be compared for end use on this basis. However, salt spray does detect coating defects and can be put to good use for detecting induced flaws by comparing results for flat panels with those of panels with coating defects induced, for example, by forming or abrasion.

The first step in the evaluation is the selection of a steel mill and/or paint company that is willing and able to help evaluate the needs of the final product. These needs can be categorized as either preservice or service. The preservice conditions involve forming, handling, and joining. The service conditions are those to which the customer exposes the product: humidity, temperature, corrosive agents, sunlight, and abrasion. Of course, the preservice conditions can affect the service life of the final product, and these effects should be evaluated.

The next step is the experimental design. The test program compares candidate materials to the current product, if possible. Evaluation in actual service conditions is often not possible because of time limitations. Therefore, accelerated and laboratory tests are needed (see the article "Corrosion Testing" in this Volume). From these results, acceptable candidates are identified and are included in the next level of tests. A set of suitable parts is identified for testing the candidates. After the parts are fabricated, they are inspected to determine whether coating damage occurred and whether corrosion resistance was compromised. In general, one material will not be superior in all aspects. Therefore, the desirable properties must be prioritized.

Advantages of Prepainted Steels. Although the above evaluation sequence may seem formidable, many manufacturers have found the use of prepainted steel to be productive and economical. The use of prepainted steel reduces or eliminates the problems of the waste treatment of the emissions from paint lines. The postpainting line is often the slow step in the process, and using prepainted steel increases output. Although the material cost of prepainted steel is higher than the bare metal, the final part cost is lower because of increased productivity and the reduction of other costs,

such as emissions control. Although prepainted steel cannot replace postpainted steel in every application, prepainted steel has demonstrated its productive and economic advantages.

Painting With Zinc-Rich Paints

Zinc-rich coatings, often called zinc-rich primers, are a unique class of cross-linked coatings that provide galvanic protection to a ferrous substrate. As the name implies, the binder is highly loaded with a metallic zinc dust pigment. After the coating is applied to a thoroughly cleaned substrate, the binder holds the metallic zinc particles in contact with the steel and with each other. Thus, metal-to-metal contact of two dissimilar metals is made, resulting in a galvanic cell. In this couple, zinc becomes the anode and sacrifices itself to protect the underlying cathodic steel.

The major advantage of corrosion protection using zinc-rich coatings is that localized pitting corrosion and subfilm corrosion are eliminated, even at voids, pinholes, scratches, and abrasions in the coating system. This cannot be said of any other type of protective coating, and it is this protective capability that makes zinc-rich coatings unique and widely used.

This advantage, however, comes with certain disadvantages. The underlying steel substrate must be cleaned of all rust, old paint, and other contaminants that may interfere with metal-to-metal contact. Thus, the degree of surface preparation must be quite thorough: blast cleaning should produce a Commercial Blast Cleaning minimum and, for immersion service, a White or Near-White surface. The Steel Structures Painting Council (SSPC), NACE, and other organizations issue standards for the surface preparation of metals for organic coatings: these are discussed in more detail in Ref 48 and also mentioned below.

Zinc Dust/Zinc Oxide Coatings

Zinc dust/zinc oxide paints, also known as metallic zinc paints, contain a pigmentation of approximately 80% zinc dust, 20% ZnO, and approximately 80% pigment by weight. These paints offer excellent rust-inhibitive properties, adhesion, film distensibility, and abrasion resistance. Because they adhere tightly to zinc and other metals, they are ideal for prime and finish coat applications and may be used as a primary first coat even over partially rusted surfaces.

Zinc dust/zinc oxide paints are used for the protection of many types of steel structures under a variety of service conditions. They are particularly well suited to use on galvanized steel; are highly satisfactory for priming steel for atmospheric and underwater exposure; and can be used on many outdoor structures, such as bridges, water tanks, and dams, where rusting must be prevented.

In accordance with Federal Specification TT-P-641 which covers primer paints and zinc dust/zinc oxides for galvanized surfaces, there are three types of zinc dust/zinc oxide paints:

- *Type I:* zinc dust/zinc oxide linseed oil for outdoor exposure, recommended as a primer or finish coat for broad, general use, especially when there is widespread rusting of the steel surfaces; should be air dried only
- *Type II:* zinc dust/zinc oxide alkyd resin paint, a heat-resistant paint sometimes sold as a stack paint, may also be used for outdoor exposures where rust is not severe; quick drying; can be air dried or baked at temperatures to 150 °C (300 °F)
- *Type III:* zinc dust/zinc oxide phenolic resin paint; used for water immersion and other severe moisture conditions; may be air dried or baked at temperatures to 150 °C (300 °F)

These paints, when properly formulated and prepared, can be applied by brushing, dipping, or spraying. Although the presence of ZnO prevents rapid or hard settling, adequate agitation of the paint in the dip tank is necessary to ensure the coating homogeneity necessary for maximum metal protection. Pressure equipment should be used when spraying, and the distance between the paint reservoir and the spray gun should be as short as possible to ensure the proper rate of feed to the nozzle. Again, some agitation of the paint in the reservoir is recommended.

Zinc dust/zinc oxide paints possess high covering power and can hide backgrounds of almost any color when spread at the rate of approximately 20 m^2/L (800 ft^2/gal). However, because the protection afforded by a paint coating is directly related to its thickness, the necessary protection cannot be guaranteed unless the dry film is thick enough for the specific environmental conditions. Therefore, care must be taken to avoid spreading the paints too thin. The natural blue-gray color of zinc dust/zinc oxide paints provides an aesthetic appearance, but if another color is desired, red, buff (orange-yellow), and green can be obtained by varying the pigment.

To prepare surfaces for zinc dust/zinc oxide paints, rust (or scale) and any accumulation of leaves, dirt or other foreign materials should be removed. This may be accomplished on large structures by sandblasting and on small structures or areas with a deck or wire brush.

Zinc-Rich Coatings

In recent years, a number of paints have been developed that will deposit a film of metallic zinc having many properties in common with zinc coatings applied by hot-dip galvanizing, electroplating, thermal spraying, and mechanical plating. Such paint films will protect the underlying steel sacrificially if they contain 92 to 95% metallic zinc in the dry film and if the film is in electrical contact with the steel surface at a sufficient number of points. They are effective where steel is subjected to high humidity and water immersion. Under normal conditions, zinc-rich coatings are long lasting and most effective where a regular maintenance program may be difficult. In applications in which steel is immersed in brackish or salt water, zinc-rich coatings, along with a suitable top coat, should be used. Most zinc-rich paints are of the air-drying type although oven-cured primers containing a high content of zinc dust are available.

The type of zinc dust used is a heavy powder, light blue-gray in color, with spherically shaped particles having an average diameter of approximately 4 mm. Such powder normally contains 95 to 97% free metallic zinc with a total zinc content exceeding 99%.

Surface Preparation. Zinc-rich primers must be applied over clean steel surfaces to provide the metal-to-metal contact essential to successful performance of the coating. Abrasive blasting is the most effective method of cleaning steel. Although white metal blast-cleaning (NACE No. 1) is preferred, near-white SSPC-SP-10 or Commercial Blast Cleaning SSPC-SP-6 is acceptable (Ref 52).

Where the zinc is supplied as a separate component, it should be added slowly to the vehicle with constant agitation. After a homogeneous mix is obtained, the primer may be applied with air spray. Airless spray may also be used, but the nozzles may wear quickly. Because zinc settles rapidly, continuous agitation of the paint is essential during application, and fluid lines should be kept as short as possible.

To obtain a wet coat, the gun should be kept within 30 cm (1 ft) of the surface. Uneven film thickness due to brushing or rolling may result in mudcracking in the thick portions. Zinc-rich primers should be applied at a dry film thickness of 0.06 to 0.08 mm (2.5 to 3.5 mils).

The Nature of the Zinc-Rich Coating. Depending on the binder, zinc-rich coatings fall into two classes: organic and inorganic. The inorganic solvent-base types are derived from organic alkyl silicates, which become totally inorganic upon curing. Each offers particular protection characteristics, and each requires different preparation of the steel surface. The following comparisons should be helpful in selecting the most useful binder system.

The organic zinc-rich coatings are formed by using zinc dust as a pigment in an organic binder. This binder may be any of the well-known coating vehicles, such as chlorinated rubber and epoxy. The zinc dust must be in sufficient concentration so that the zinc particles are in particle-to-particle contact throughout the film. Thus, zinc provides cathodic protection. In the case of the organic binder, there is no reaction with the underlying surface other than for the organic vehicle to wet the steel surface thoroughly and to obtain mechanical adhesion.

Organic zinc-rich coatings do not require a white blast preparation of the steel surface, although a commercial blast should be included if the application is heavy service. For mild-service applications, the organic coating can be applied to a well-hand-cleaned surface, even if traces of rust are present.

Some proponents feel that maintaining proper humidity during surface preparation, application, and curing is not necessary. Because this type of coating is more flexible than inorganic coatings, exacting surface preparation for bonding to a substrate is not required. Finally, although organic coatings are more compatible with top coats, they are somewhat less abrasion resistant than the inorganic types.

As to the advantages of these coatings, organic zinc-rich coatings require less critical surface preparation, allow greater variation in application techniques, are less sensitive to varying climatic conditions during application and curing, and are more flexible and more resistant to chemical environments. Their disadvantages include flammability, blistering, harmful solvent effects, sensitivity to atmospheric influences, and relatively low heat resistance.

For better resistance against continuous exposure to salt water and to acid or alkali chemical fumes, zinc-rich coatings should be top coated with organic topcoats to provide a totally organic system, with optimum intercoat compatibility. A top coating may also be applied to provide color or to prevent gradual erosion of the zinc coating. Although zinc-rich coatings vary in application characteristics, they can be applied by brush or spray, and depending on the specific formulation, one coat can vary in thickness from 0.05 to 0.2 mm (2 to 7 mils).

Inorganic Zinc-Rich Coatings. Many inorganic zinc-rich coatings use water solutions of alkali silicates as vehicles. Others use phosphates, silicones, and modifications of these groups.

Self-cured coatings are two-component materials consisting of zinc dust and a vehicle; they are mixed immediately before application. Postcured coatings are three-component materials that consist of zinc dust, the vehicle to be mixed with it before application, and a curing agent that is applied on top of the coating.

The inorganic zinc coating forms its film and its adhesion to the steel surface by methods quite different from those of the organics. The coating system is a chemically reactive system, and the chemical activity is similar for either the water- or the solvent-base inorganic. Zinc is the principal reactive element in the inorganic coating systems and is primarily responsible for the development of initial insolubility. Depending on the formulation, other metal ions may be present in the system that also react and aid in the insolubilization of the coating. The silicate vehicle can also react with the underlying iron surface to form a chemical bond with the iron or steel substrate.

Inorganic zinc-rich coatings commonly require a white metal blast as preparation for the steel surface. Because inorganic coatings generally have limited flexibility and tend to break or crack upon bending or impact, careful preparation of the steel surface is required to ensure a good bond between the coating and the steel. However, despite the difficulties of preparation, these inorganic coatings are unaffected by solvents, oils, petroleum products, aliphatics, aromatics, ketones, and alcohols. They do not chalk, peel, or lose thickness over long periods of time. Also, they are easier to weld through and have excellent abrasion resistance and surface hardness.

Inorganic zinc-rich coatings offer good conductivity; good adhesion to clean steel; excellent resistance to weather, sunlight, and variations in temperature; resistance to radiation, heat, and abrasion; and reduced undercutting. Conversely, these coatings require unusually good surface preparation, display a lack of distensibility and adhesion to some metals other than steel and zinc, require moderate temperatures and atmospheric humidity for cure, and exhibit unsatisfactory durability under conditions of continuous immersion in electrolytes, and a lack of resistance to strong acids and alkalies.

Zinc Dust/Zinc Oxide Paint Versus Zinc-Rich Coating

Whether to use a zinc dust/zinc oxide paint or a zinc-rich coating depends on a number of factors, including cost of surface preparation, paint application, and anticipated length of surface. Zinc dust/zinc oxide coatings are ideal for rural or semi-industrial atmospheres. They are particularly effective on galvanized surfaces.

The widely used zinc dust/zinc oxide primers based on ordinary drying oil media do not give general electrolytic protection against corrosion and therefore do not fall in the category of zinc-rich paints.

Zinc-rich coatings are preferred for the protection of steel or galvanized steel structures exposed to marine environments or immersed in seawater. Applications include interiors of floating roof tanks, cooling tower piping, pipe racks and

exterior piping in refineries, stacks, chemical plant maintenance, offshore drilling platforms, aboveground pipelines, structural steel before erection, exterior of pressure vessels, ammonia tanks, ship holds, and air conditioning equipment.

A top coat finish may be necessary in aggressive atmospheres. The top coat must adapt to the environment and must guarantee compatibility with, and adhesion to, the zinc-rich primer.

Advantages and Limitations of Zinc-Rich Paints. Zinc-rich primers offer a more versatile form for applying zinc to steel than galvanization; large, continuous complex shapes and fabricated new or existing structures can be easily coated at manufacturing shops or in the field. Their performance has earned them a prominent place in the field of corrosion protection coatings. However, the limitations of zinc-rich paints include cost, difficulty in applying, and the requirement of clean steel surfaces. They must be top coated in severe environments (pH under 6.0 and over 10.5).

Porcelain Enameling

Porcelain enamels are glass coatings applied primarily to products made of steel sheet, cast iron, or aluminum to improve appearance and protect the metal surface from corrosion. Porcelain enamels are distinguished from other ceramic coatings by their predominantly vitreous nature and the types of applications for which they are used, and from paint by their inorganic composition and the fusion of the coating matrix to the substrate metal. Porcelain enamels of all compositions are matured at 425 °C (800 °F) or above.

Several basic methods are used to apply porcelain enamels to the base metal. These include dipping, flow coating, electrodeposition, manual spray, electrostatic spray, and dry-powder spray. The best method of application for a particular part is determined by quantity and quality requirements, the type of material being applied, units produced per hour, capital investment, labor cost, and, ultimately, part cost. Details on application techniques for porcelain enameling are provided in the article "Porcelain Enameling" in this Volume.

Coating Materials The frits for porcelain enamel are designed and manufactured to meet specific end-use applications and processing requirements. Porcelain enamel frits for sheet steel are classified as either ground coat or cover coat types. Ground coat enamels contain metallic oxides that promote adherence to the steel substrate and may be used as a single functional coat or as a base coat for additional cover coats. Table 30 gives the composition of a typical ground coat enamel. Cover coat enamels (Table 31) are normally applied over ground coats for appearance and/or to improve the chemical and physical properties of the coating. Cover coats may also be applied directly to properly prepared decarburized steel substrates.

Table 30 Melted-oxide compositions of frits for ground coat enamels for sheet steel

Because all porcelain enamels are variations of borosilicate glass, they are characterized by end use and not by chemical composition. Some common designations for those with particular characteristics are acid-resistant, alkali-resistant, heat-resistant, glossy, low-gloss, and matte.

Steel Substrates. Typical compositions of the various grades of low-carbon sheet iron or steel that are commercially available for porcelain enameling are listed in Table 32. Cold-rolled sheet steels used for porcelain enameling can be divided into three groups:

- Extra-low carbon steels (a maximum of 0.008% C), including HSLA steels in which the carbon is stabilized by the addition of titanium or niobium
- Low-carbon steels containing about 0.02% C (these steels are suitable for ground or two-coat enameling)
- Conventional cold-rolled sheets with higher carbon contents of about 0.06% (such sheets have a tendency toward primary boiling and sagging and are used in less critical ground coat and two-coat enameling applications)

Table 32 Compositions of low-carbon steels used for porcelain enameling

Type of steel	Composition, %[(a)]

(c) Some steels may be supplied as aluminum-killed products. Data from Porcelain Enamel Institute

Hot-rolled steels are generally used for porcelain enameled water heater tanks and for other applications where thickness and strength requirements dictate their use. When hot-rolled steels are used, components should be coated on one side only to minimize processing defects such as fishscales.

Coating Properties. Porcelain enamel is used extensively because of its resistance to household chemicals and foods. Mild alkaline or acid environments are generally involved in household applications. Special enamels or glass compositions are available to resist most acids--except for hydrofluoric or concentrated phosphoric--to temperatures of 230 °C (450 °F). Compositions may be formulated to resist alkali concentrations up to a pH of 12 at temperatures as high as 95 °C (200 °F).

The hardness of porcelain enamels ranges from 3.4 to 6.0 on the Moh's scale. Porcelain enamels show a high degree of abrasion resistance. Abrasion resistance can be increased by adding crystalline particles to the enamel composition by a devitrification heat treatment.

Thermal Spray Coatings

Thermal spray coatings are surface coatings engineered to provide original equipment with resistance to wear, erosion, abrasion, corrosion, and oxidation. Thermal spraying is also used to repair and upgrade in-service equipment. In general, thermal spray coatings can be applied to a range of substrate materials, including metals, ceramics, plastics, and polymer composites. Such coatings often are used instead of paint because of their predictable service life, increased effectiveness, and lower life-cycle costs.

Thermal spray processes deposit finely divided metallic or nonmetallic feedstock surfacing material in a molten or semimolten condition onto a properly prepared, grit-blasted substrate to form a coating. The thermal spray feedstock material (wire, cored wire, ceramic rod, or powder) is heated to its plastic or molten state by combustion (flame, high-velocity oxygen fuel, or detonation) or by electric (arc or plasma) processes. The material is then accelerated toward the substrate. The particles or droplets strike the surface, flatten, and form thin platelets (splats) that conform, adhere, and interlock with roughened surface irregularities and with each other. As the sprayed particles impinge on the substrate, they cool and build up, particle by particle, into a lamellar-structured coating. Figure 7 in the preceding article "Surface Engineering of Cast Irons" in this Volume shows the lamellar structure of particle splats, oxide inclusions, and unmelted particles in a cross section of a typical thermal spray coating. In general, the substrate temperature can be kept at 200 °C (390 °F) or below to prevent metallurgical changes in the substrate material. Details of the thermal spray process can be found in Ref 53 and the article "Thermal Spray Coatings" in this Volume.

The properties of a thermal spray coating depend on such factors as its porosity, the cohesion between particles, adhesion to the substrate (including interface integrity), and the chemistry of the coating material. The particles bond to the substrate mechanically (the primary mechanism), metallurgically, or chemically. Particle impact velocity, particle size, substrate roughness, particle temperature, and substrate temperature influence bond strength.

Aluminum and zinc thermal spray coatings have a long history of corrosion protection in structural steel work, including:

- Buildings
- Bridges
- Towers
- Radio and TV antenna masts
- Steel gantry structures
- High-power search radar aerials
- Overhead walkways
- Railroad overhead line support columns
- Electrification masts
- Tower cranes
- Traffic island posts
- Street and bridge railings

Corrosion Protection by Thermal Spraying. Thermal spray coatings are used extensively for the corrosion protection of steel and iron in a wide range of environments. Their long-term effectiveness (20 years or more) in rural, industrial, and marine environments is well documented (Ref 54, 55, 56, 57).

The selection of a thermal spray coating depends on the service environment, desired service life, operating duty cycle, and available maintenance and repair support. Tables 33 and 34 give current service-life information for thermal spray coatings in various service environments, and Fig. 22 and 23 plot the corresponding required thickness specifications. The service-life estimates for 85Zn-15Al alloy and 90Al-10MMC (metal-matrix composite) coatings--introduced in the late 1970s and 1980s, respectively--are based on accelerated laboratory tests and service applications through 1992. In a marine environment, powder spray coatings with higher aluminum contents exhibit improved corrosion resistance (Ref 55). Where resistance to wear and/or abrasion is required in addition to corrosion protection, 90Al-10MMC coatings should be considered. The 90Al-10MMC wire is composed of 90 vol% Al and 10 vol% Al_2O_3.

Coatings of aluminum, zinc, and their alloys and composites provide broad atmospheric protection. Aluminum and zinc are anodic to steel and protect the ferrous substrate in electrolytic solutions. When applied sufficiently thick to prevent through-porosity, they provide both barrier and cathodic protection. When applied too thinly or when cut through to expose the underlying steel, these coatings provide galvanic protection. Aluminum corrodes less rapidly than zinc in highly acidic conditions, while zinc performs better in alkaline conditions. Aluminum thermal spray coatings immediately oxidize to form a loosely adherent Al_2O_3 protective film that prevents further oxidation. Thus, there is no advantage to applying aluminum coatings in a thickness greater than that which prevents through-porosity (150 to 200 μm, or 0.006 to 0.008 in.) unless wear or abrasion resistance is required in addition to corrosion resistance. Aluminum thermal spray coatings have greater wear, abrasion, and erosion resistance than zinc coatings.

Zinc alloyed with aluminum forms an effective corrosion-resistant coating, combining the attributes of both elements. The greater electrochemical activity of zinc provides greater galvanic protection than aluminum. Aluminum, with its lower electrochemical activity and a loosely adherent aluminum oxide film, provides long-term protection even when the coating is porous and gives better wear, abrasion, and erosion resistance than zinc.

Aluminum and aluminum composite thermal spray coatings can be used where the temperature is greater than 200 °C (390 °F). Aluminum composite coatings are used when resistance to wear, abrasion, and erosion is required beyond that provided by aluminum and zinc.

Wear coatings applied by thermal spraying are used to resist abrasion, erosion, cavitation, and fretting, and to reduce friction. These coatings consist of a wide range of metals and their alloys, ceramics, cermets, carbides, and even low-friction plastics. Typical coating hardness ranges from 20 to 70 HRC. Table 35 lists friction and wear (hardfacing) applications for various thermal spray materials.

Table 35 Thermal spray coatings used for hardfacing applications

Type of wear	Coating material	Coating process[(a)]	Applications
Adhesive wear	Aluminum bronze	OFW, EAW, OFP, PA, HVOF	Babbitt bearings, hydraulic press sleeves, thrust bearing shoes, piston guides, compressor crosshead slippers
	Soft bearing coatings:		
	Tobin bronze	OFW, EAW	
	Babbitt	OFW, EAW, OFP	
	Tin	OFW,EAW, OFP,	
	Hard bearing coatings:		
	Mo/Ni-Cr-B-Si blend	PA	Bumper crankshafts for punch press, sugar cane grinding roll journals, antigalling sleeves, rudder bearings, impeller shafts, pinion gear journals, piston ring (internal combustion); fuel pump rotors
	Molybdenum	OFW,EAW, PA	
	High-carbon steel	OFW, EAW	
	Alumina/titania	OFP, PA	
	Tungsten carbide	OFP, PA, HVOF	
	Co-Mo-Cr-Si	PA, HVOF	
	Fe-Mo-C	PA	

Abrasive wear	Aluminum oxide	PA	Slush-pump piston rods, polish rod liners, and sucker rod couplings (oil industry); concrete mixer screw conveyors; grinding hammers (tobacco industry); core mandrels (dry-cell batteries); buffing and polishing fixtures; fuel-rod mandrels
	Chromium oxide	PA	
	Tungsten carbide	PA, HVOF	
	Chromium carbide	PA, HVOF

	Ni-Cr-B-SiC (fused)	OFP, HVOF	
	Ni-Cr-B-SiC (unfused)	HVOF	
Surface fatigue wear			
Fretting: Intended motion applications	Molybdenum	OFW, PA	Servomotor shafts, lathe and grinder dead centers, cam followers, rocker arms, piston rings (internal combustion), cylinder liners
	Mo/Ni-Cr-B-SiC	PA	
	Co-Mo-Cr-Si	PA, HVOF	
Fretting: Small amplitude oscillatory displacement applications:			
Low temperature (<540 °C, or 1000 °F)	Aluminum bronze	OFW, EAW, PA, HVOF	Aircraft flap tracks (air-frame component); expansion joints and mid-span supports (jet engine components)
	Cu-Ni-In	PA, HVOF	
	Cu-Ni	PA, HVOF	
High temperature (>540 °C or 1000 °F)	Co-Cr-Ni-W	PA, HVOF	Compressor air seals, compressor stators, fan duct segments and stiffeners (all jet engine components)
	Chromium carbide	PA, HVOF	
Erosion	Chromium carbide	PA,HVOF	Exhaust fans, hydroelectric valves, cyclone dust collectors, dump valve plugs and seats, exhaust valve seats

	Tungsten carbide	PA, HVOF	
	WC/Ni-Cr-B-Si-C(fused)	OFP, HVOF	
	WC/Ni-Cr-B-SiC (unfused)	OFP, HVOF	
	Chromium oxide	PA	
Cavitation	Ni-Cr-B-SiC-Al-Mo	PA	Wear rings (hydraulic turbines), water turbine buckets, water turbine nozzles, diesel engine cylinder liners, pumps
	Ni-Al/Ni-Cr-B-SiC	PA	
	Type 316 stainless steel	PA	
	Ni-Cr-B-SiC (fused)	OFP, HVOF	
	Ni-Cr-B-SiC (unfused)	HVOF	
	Aluminum bronze	PA, HVOF	
	Cu-Ni	PA, HVOF	

(a) OFW, oxyfuel wire spray; EAW, electric arc wire spray;OFP, oxyfuel powder spray; PA, plasma arc spray; HVOF, high-velocity oxyfuel powder spray

Oxidation Protection. Thermal spray coatings are extensively used by industry to protect steel components and structures from heat oxidation at surface temperatures to 1095 °C (2000 °F). By ensuring long-term protection, thermal spray coatings show real economic advantages during the service lives of such items. Coatings such as pure aluminum, aluminum-iron, nickel-chromium, and MCrAlY are particularly effective in protecting low-alloy and carbon steels.

Hardfacing

Hardfacing may be broadly defined as the application of a wear-resistant material, in depth, to the vulnerable (or worn) surfaces of a component by a weld overlay or thermal spray process. This discussion deals with the weld overlay materials used to resist wear; the thermal spray materials are covered in the previous section in this article. More detailed information on hardfacing process and alloy selection can be found in Ref 47 and 53.

Welding processes used to apply hardfacing materials range from the traditional (for example, oxyacetylene torch) to the new and sophisticated (for example, plasma-transferred arc, PTA, and laser methods). To accommodate these different overlay processes, the hardfacing materials are available in a variety of forms. The most popular processes, and the forms most commonly associated with each process, are listed in Table 36.

Table 36 Characteristics of welding processes used in hardfacing

Welding process	Mode of application	Form of hardfacing alloy	Weld-metal dilution, %	Deposition		Minimum thickness[a]		Deposit efficiency, %

(c) With or without tungsten carbide granules.

(d) Varies widely depending on powder feed rate and laser input power

Hardfacing materials fall into six categories:

- Build-up alloys
- Metal-to-metal wear alloys
- Metal-to-earth abrasion alloys
- Tungsten carbides (for extreme earth sliding and cutting wear)
- Nonferrous alloys

- Stainless steels

The build-up alloys are not designed to resist wear but to return a worn part back to, or near, its original dimensions and to provide adequate support for subsequent layers of true hardfacing materials. However, these alloys are sometimes used as wear-resistant materials under mild wear conditions.

The build-up alloys fall into two categories: alloy steels and austenitic manganese steels. The alloy steel build-up materials are used with carbon steel and alloy steel substrates; the austenitic manganese steels are used for the joining, repair, and/or protection of manganese steel components. Specific build-up alloy compositions and properties are given in Table 37. Typical examples of applications where build-up alloys are used include tractor rails, railroad rail ends, steel mill table rolls, and large slow-speed gear teeth.

Table 37 Composition, hardness, and abrasion data for build-up alloys and metal-to-metal wear alloys

(a) Two-layer SMA deposit process.

(b) Two-layer SAW deposit process.

(c) Dry sand/rubber wheel test (ASTM G 65, Procedure B): Load 13.6 kg (30 lb); 200 rev.

(d) Slurry/steel wheel test (ASTM B 611, modified): load 22.7 kg (50 lb); 250 rev

Alloys in the metal-to-metal category (commonly referred to as machinery hardfacing alloys) are martensitic, air-hardening steels that can be applied several layers thick and can be finish machined (although with some difficulty) if adequate equipment is used. They are recommended for wearing, industrial, heavy-duty, nonlubricated parts. These materials are also sometimes referred to as "super build-up" alloys. If a machined finish is required, three layers are generally applied, with the assumption that the top layer will be removed during machining. A single layer is usually adequate because of the effects of substrate/overlay intermixing (dilution).

Typical compositions and properties of metal-to-metal wear alloys are listed in Table 37. In hostile environments, a higher chromium content is beneficial. ER420 (American Welding Society, AWS, classification), and modified versions containing nickel, molybdenum, and niobium (or vanadium), are therefore the natural choice when high temperatures and mildly corrosive environments are encountered. For applications using steel mill hot-work rolls (which demand considerable hot hardness, resistance to oxidation, and resistance to thermal fatigue) both ER420 and EFe3 have been found suitable. Other applications for the metal-to-metal wear alloys in Table 37 include tractor rollers and crane wheels (EFe2), pincer guide shoes (EFe3), and blast furnace bells (ER420).

Most of the materials in the metal-to-earth, carbide, and nonferrous alloy categories consist of hard particles within a metallic matrix, and, for many, it is the hard constituent that provides resistance to wear. The primary function of the metal-to-earth abrasion alloys and tungsten carbides is abrasion resistance. The metal-to-earth alloys are high-chromium white irons in which chromium carbides are formed during alloy solidification. The tungsten carbides are actually composite materials, and their use involves the transfer of discrete tungsten carbide particles (which in the welding consumable forms are encased in a steel tube) across the welding arc and into the molten weld pool, where they are subsequently "frozen" into the overlay structure by the matrix formed from the melting of the steel tube. Typical applications for these material types include shovel teeth, rock crusher parts, plowshares, and auger flights.

The nonferrous hardfacing alloys are used in environments that are too aggressive for the ferrous hardfacing alloys or where high resistance to a specific type of wear (other than abrasion) is required. They are classified as follows:

- Cobalt-base/carbide type
- Cobalt- and nickel-base/Laves type
- Nickel-base/boride type
- Bronze type

Whereas the ferrous hardfacing alloys and tungsten carbide composites find extensive use in agriculture, mining, construction, and the steel industry, the nonferrous alloys are typically used in the chemical processing, power, automotive, and oil industries, all of which require resistance to a hostile environment in addition to resistance to wear. The cobalt-base alloys are especially resistant to deformation and chemical attack at high temperatures (500 °C < $T \leq 900$ °C, or 930 °F < $T \leq 1650$ °F) and are used to protect dies and guide rolls in the steel industry. Other common applications of the nonferrous hardfacing alloys include valve seating surfaces (both control valves and diesel exhaust valves), pump parts, extrusion screw flights, rock bit bearings, marine bearings, and glass molding hardware.

The stainless steel weld overlays include both cobalt-free and cobalt-containing austenitic stainless steels. The cobalt-free grades, which contain nominally 0.8% C, 25% Cr, 4.5% Mn, 3.0% Si, 7.0% Ni, 2.0% Mo, and 0.1% N, have been developed to replace cobalt-base hardfacing alloys in nuclear power plant applications (valve overlays). The cobalt-containing grades, which contain nominally 0.2% C, 17% Cr, 9.5% Mn, 2.5% Si, 9% Co, and 0.2% N, have been developed for the repair of the cavitation erosion damage of turbines used in hydroelectric power plants.

Vapor-Deposited Coatings

Vapor-deposited coatings are sometimes used for the protection of steel, although the cost of such coatings can be prohibitive. In vapor deposition, whether it be physical vapor deposition (PVD) or chemical vapor deposition (CVD), the coating material is transported to the substrate in the form of individual atoms or molecules. A wide range of coating materials can be applied by vapor deposition. If applied to a sufficient thickness, the coating is essentially pore free and dense, thus providing excellent barrier protection. Processing details for various PVD/CVD coating methods can be found in the articles contained in the Section entitled "Vacuum and Controlled-Atmosphere Coating and Surface Modification Processes" in this Volume.

Ion plating of aluminum coatings on steel is used by the aircraft industry to protect high-strength steel components, such as landing gear, and as a fastener coating to reduce the galvanic effects of steel fasteners inserted in an aluminum structure. Ion plating has several advantages over other aluminum coating processes. The aluminum deposit is very adherent and passes the bend-to-break test. The deposit does not affect the mechanical properties of the substrate and can be applied with precise thickness control on a wide range of shapes. Both the coating and the coating process are nontoxic and do not contribute to pollution. Because of these advantages, ion plating of aluminum can be used in a wide range of applications and is particularly effective as a replacement for cadmium coatings, which can cause hydrogen embrittlement of high-strength steels. Vapor deposition of aluminum does not produce hydrogen; therefore, it does not cause embrittlement. Vapor-deposited aluminum protects against stress-corrosion cracking (SCC) and has a temperature limit of 495 °C (925 °F). It is less expensive than most other barrier coatings. Vapor deposition is also replacing hot dipping of aluminum on steel in some applications. During immersion in hot dipping, a brittle intermetallic compound layer of iron-aluminum is formed; this limits the formability of the steel. In addition, the coating contains iron impurities, which may be a severe shortcoming in highly corrosive environments (Ref 58).

Another important application area for vapor-deposited coatings on ferrous alloys is the use of PVD coatings to enhance the service life of high-speed tool steels. Examples of increased tool life obtained when using TiN and/or TiC PVD coated tools are described in the article "Surface Engineering of Specialty Steels" in this Volume.

Surface Modification

Surface modification processes, which involve altering the surface composition or structure of a material by the use of high-energy or particle beams, include ion implantation and laser surface processing. Although used far less on steels than the coating processes described previously in this article, surface modification techniques can significantly improve the wear and corrosion resistance of steel substrates.

Ion Implantation

Ion implantation is the process of modifying the physical or chemical properties of the near surface of a solid by embedding appropriate atoms into it from a beam of ionized particles. The use of accelerated electron beams can produce penetration into a substrate surface on the order of 0.1 to 0.2 μm (1000 to 2000 Å) at 100 kV, and with higher accelerating voltages the potential for depth of penetration is increased. Surfaces may be treated by ion implantation to produce an effective alloyed surface layer where the composition varies as a function of depth.

Although virtually any element in the periodic table can be injected into near-surface regions of a solid using ion implantation, the ions that improve the properties of steels include:

- Adhesive and abrasive wear: Ni, Ti + C, Y, and Ta + C
- Fatigue wear: B, N, and Ti
- Corrosion and oxidation wear: Cr, Ta, and Y
- Friction: Ti, Ti + C, Ag, Sn, and Au

The most common use of ion implantation for improving the properties of ferrous alloys involves tool steels used in metalworking and machining applications (see the article "Surface Engineering of Specialty Steels" in this Volume). Other end-use applications of ion implantation include improved wear, corrosion, and rolling contact fatigue in bearing alloys such as type 440C stainless steel and 52100 bearing steel (Ref 59, 60).

Laser Surface Processing

Lasers with continuous outputs of 0.5 to 10 kW can be used to modify the metallurgical structure of a surface and to tailor the surface properties without adversely affecting the bulk properties. Surface modification of steels via lasers can take the following four forms:

- Laser transformation hardening
- Laser surface melting
- Laser surface alloying
- Laser cladding (hardfacing)

Figure 24 shows typical ranges of conditions for various processes. The laser power, power density, and interaction time are the primary variables. Other variables, such as the composition of the atmosphere during treatment or the rate of material addition, are determined by the details of the processing--for example, the necessity of shielding against oxidation and the desired thickness, composition, and structure of the surface layer.

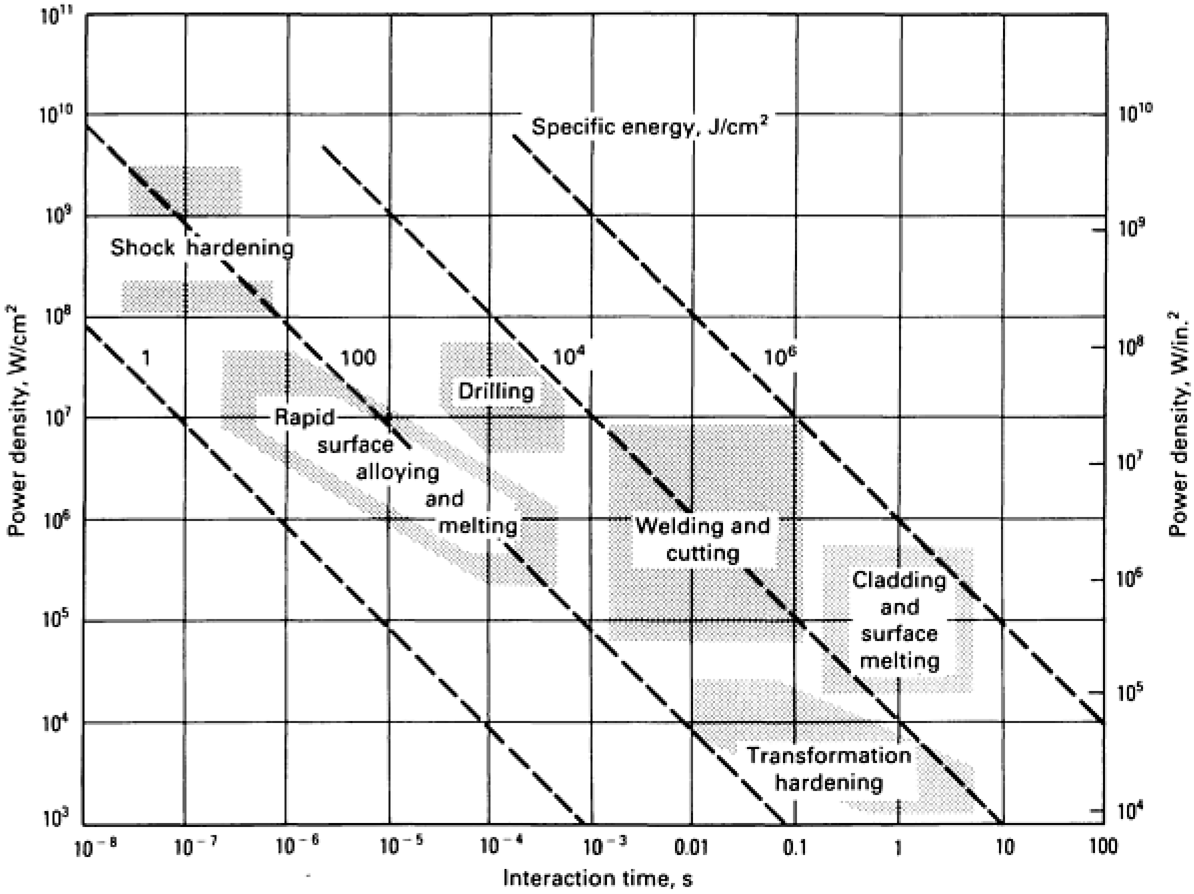

Fig. 24 Interaction times and power densities necessary for various laser surface modification processes

The laser beam modified layer can range in thickness from 0.01 to 5 mm (0.4 to 200 mils), depending on the processing variables, although thicknesses of 0.05 to 1 mm (2 to 40 mils) are more common. The longer the interaction time of the laser beam with the material, the deeper the processed layer will be. Of the processes shown in Fig. 24, the area labeled

"Cladding and surface melting" delineates process parameters that typically affect the material to depths from 0.5 to 5 mm (20 to 200 mils) and result in metallurgical structures similar to welded structures. The parameters designated "Rapid surface alloying and melting" affect a surface layer only 0.02 to 0.6 mm (0.8 to 24 mils) thick, but result in quench rates to 10^7 K/s and therefore allow for the production of novel metallurgical structures and alloys. Because laser transformation hardening is the most commercially viable (with regard to steels) of the laser processing methods listed above, it will be described further below. Additional information on laser surface processing can be found in Ref 61. Laser cladding, or laser hardfacing, is also described in Ref 53.

Laser surface heat treatment is widely used to harden localized areas of steel machine components such as gears and bearings. The heat generated by the absorption of the laser light is controlled to prevent melting, and therefore is used to selectively austenitize local surface regions which transform to martensite as a result of rapid cooling by the conduction of heat into the bulk of the workpiece. This process is referred to as laser transformation hardening to differentiate it from laser surface melting and alloying phenomena (Fig. 24). There is no chemistry change produced by laser surface heat treating of steels.

Laser heat treatment produces thin surface zones which are heated and cooled very rapidly, resulting in very fine martensitic microstructures, even in steels with relatively low hardenability. High hardness and good wear resistance with less distortion result from this process.

Steels which have been successfully laser surface hardened include plain carbon steels (1040, 1045, 1050, 1070) and alloy steels (4140, 4340, 52100) (Ref 62, 63). Typical case depths for steels range from 0.75 to 1.3 mm (0.030 to 0.050 in.) depending on the laser power range (Fig. 25). Hardness values as high as 60 HRC are routinely achieved using laser surface hardening.

Surface Hardening (Ref 64)

Surface hardening is used to extend the versatility of certain steels by producing combinations of properties not readily attainable in other ways. For many applications, wear and the most severe stresses act only on the surface of a part. Therefore, the part may be fabricated from a formable low- or medium-carbon steel, and is surface hardened by a final heat treatment after all other processing has been accomplished. Surface hardening also reduces distortion and eliminates cracking that might accompany through hardening, especially in large sections. While an extensive review is beyond the scope of this article, two major approaches to surface hardening will be described below. One approach does not change composition and consists of hardening the surface by flame, induction, laser, or electron beam heating. The other approach changes surface composition and includes the applications of such diffusion techniques as carburizing, nitriding, and carbonitriding. Table 38 compares the relative benefits of the five most common surface hardening processes. More detailed information on surface hardening of steels can be found in *Heat Treating,* Volume 4 of the *ASM Handbook.*

Table 38 Relative benefits of five common surface-hardening processes

Process	Benefits
Carburizing	Hard, highly wear-resistant surface (medium case depth); excellent capacity for contact load; good bending fatigue strength; good resistance to seizure; excellent freedom from quench cracking; low-to-medium-cost steels required; high capital investment required
Carbonitriding	Hard, highly wear-resistant surface (shallow case depths); fair capacity for contact load; good bending fatigue strength; good resistance to seizure; good dimensional control possible; excellent freedom from quench cracking; low-cost steels usually satisfactory; medium capital investment required
Nitriding	Hard, highly wear-resistant surface (shallow case depths); fair capacity for contact load; good bending fatigue strength; excellent resistance to seizure; excellent dimensional control possible; good freedom from quench cracking (during pretreatment); medium-to-high-cost steels required; medium capital investment required
Induction hardening	Hard, highly wear-resistant surface (deep case depths); good capacity for contact load; good bending fatigue strength; fair resistance to seizure; fair dimensional control possible; fair freedom from quench cracking; low-cost steels usually satisfactory; medium capital investment required
Flame hardening	Hard, highly wear-resistant surface (deep case depths); good capacity for contact load; good bending fatigue strength; fair resistance to seizure; fair dimensional control possible; fair freedom from quench cracking; low-cost steels usually satisfactory; low capital investment required

Flame, Induction, and High-Energy Beam Methods

Flame hardening consists of austenitizing the surface of a steel by heating with an oxyacetylene or oxyhydrogen torch and immediately quenching with water. The result is a hard surface layer of martensite over a softer interior core with a ferrite-pearlite structure. There is no change in composition, and therefore the flame-hardened steel must have adequate carbon content for the desired surface hardness. The rate of heating and the conduction of heat into the interior appear to be more important in establishing case depth than the use of a steel of high hardenability.

Flame-heating equipment may be a single torch with a specially designed head or an elaborate apparatus that automatically indexes, heats, and quenches parts. Large parts such as gears and machine tool ways, with sizes or shapes that would make furnace heat treatment impractical, are easily flame hardened. With improvements in gas-mixing equipment, infrared temperature measurement and control, and burner design, flame hardening has been accepted as a reliable heat-treating process that is adaptable to general or localized surface hardening for small or medium-to-high production requirements.

Induction heating is an extremely versatile heating method that can perform uniform surface hardening, localized surface hardening, through hardening, and tempering of hardened pieces. Heating is accomplished by placing a steel part in the magnetic field generated by high-frequency alternating current passing through an inductor, usually a water-cooled copper coil. The depth of heating produced by induction is related to the frequency of the alternating current: The higher the frequency, the thinner or more shallow the heating. Therefore, deeper case depths and even through hardening are produced by using lower frequencies. The electrical considerations involve the phenomena of hysteresis and eddy currents. Because secondary and radiant heat are eliminated, the process is suited for production line areas.

High-energy beam methods for surface hardening include laser surface transformation hardening described earlier and electron beam (EB) hardening. Electron beam hardening, like laser treatment, is used to harden the surfaces of steels. The EB heat-treating process uses a concentrated beam of high-velocity electrons as an energy source to heat selected surface areas of ferrous parts. Electrons are accelerated and are formed into a directed beam by an electron beam gun. After exiting the gun, the beam passes through a focus coil, which precisely controls beam density levels (spot size) at the workpiece surface and then passes through a deflection coil. To produce an electron beam, a high vacuum of 10^{-5} torr (1.3×10^{-3} Pa) is needed in the region where the electrons are emitted and accelerated. This vacuum environment protects the emitter from oxidizing and avoids scattering of the electrons while they are still traveling at a relatively low velocity.

Like laser beam hardening, the EB process eliminates the need for quenchants but requires a sufficient workpiece mass to permit self-quenching. A mass of up to eight times that of the volume to be EB hardened is required around and beneath the heated surfaces.

Diffusion Methods

As previously mentioned, surface hardening by diffusion involves the chemical modification of a surface. The basic process used is thermochemical because some heat is needed to enhance the diffusion of hardening species into the surface and subsurface regions of a part.

Methods of hardening by diffusion include several variations of hardening species (such as carbon or nitrogen) and of the process method used to handle and transport the hardening species to the surface of the part. Process methods for exposure involve the handling of hardening species in forms such as gas, liquid, or ions. These process variations naturally produce differences in typical case depth and hardness. Table 39 compares the characteristics of various diffusion treatments.

Table 39 Typical characteristics of diffusion treatments

Process	Nature of case	Process temperature, °C (°F)	Case hardness, Typical case depth	HRC	Typical base metals	Process characteristics
Carburizing						
Pack	Diffused carbon	815-1090	125 μm-1.5 mm (5-60	50-	Low-carbon steels, low-	Low equipment costs, difficult to

		(1500-2000)	mils)	63[(a)]	carbon alloy steels	control case depth accurately
Gas	Diffused carbon	815-980 (1500-1800)	75 µm-1.5 mm (3-60 mils)	50-63[(a)]	Low-carbon steels, low-carbon alloy steels	Good control of case depth, suitable for continuous operation, good gas controls required, can be dangerous
Liquid	Diffused carbon and possibly nitrogen	815-980 (1500-1800)	50 µm-1.5 mm (2-60 mils)	50-65[(a)]	Low-carbon steels, low-carbon alloy steels	Faster than pack and gas processes, can pose salt disposal problem, salt baths require frequent maintenance
Vacuum	Diffused carbon	815-1090 (1500-2000)	75 µm-1.5 mm (3-60 mils)	50-63[(a)]	Low-carbon steels, low-carbon alloy steels	Excellent process control, bright parts, faster than gas carburizing, high equipment costs
Nitriding						
Gas	Diffused nitrogen, nitrogen compounds	480-590 (900-1100)	125 µm-0.75 mm (5-30 mils)	50-70	Alloy steels, nitriding steels, stainless steels	Hardest cases from nitriding steels, quenching not required, low distortion, process is slow, is usually a batch process
Salt	Diffused nitrogen, nitrogen compounds	510-565 (950-1050)	2.5 µm-0.75 mm (0.1-30 mils)	50-70	Most ferrous metals including cast irons	Usually used for thin hard cases <25 µm (1 mil), no white layer, most are proprietary processes
Ion	Diffused nitrogen, nitrogen compounds	340-565 (650-1050)	75 µm-0.75 mm (3-30 mils)	50-70	Alloy steels, nitriding steels, stainless steels	Faster than gas nitriding, no white layer, high equipment costs, close case control
Carbonitriding						
Gas	Diffused carbon and nitrogen	760-870 (1400-1600)	75 µm-0.75 mm (3-30 mils)	50-65[(a)]	Low-carbon steels, low-carbon alloy steels, stainless steel	Lower temperature than carburizing (less distortion), slightly harder case than carburizing, gas control critical
Liquid (cyaniding)	Diffused carbon and nitrogen	760-870 (1400-1600)	2.5-125 µm (0.1-5 mils)	50-65[(a)]	Low-carbon steels	Good for thin cases on noncritical parts, batch process, salt disposal problems
Ferritic nitrocarburizing	Diffused carbon and nitrogen	480-590 (900-1090)	2.5-25 µm (0.1-1 mil)	40-60[(a)]	Low-carbon steels	Low-distortion process for thin case on low-carbon steel, most processes are proprietary

Source: Ref 64

(a) Requires quench from austenitizing temperature.

Carburizing is the addition of carbon to the surface of low-carbon steels at temperatures (generally between 850 and 950 °C, or 1560 and 1740 °F) at which austenite, with its high solubility for carbon, is the stable crystal structure. Hardening is accomplished when the high-carbon surface layer is quenched to form martensite so that a high-carbon martensite case with good wear and fatigue resistance is superimposed on a tough, low-carbon steel core. Carburizing steels for case hardening usually have base-carbon contents of about 0.2%, with the carbon content of the carburized layer generally being controlled at between 0.8 and 1% C.

Carburizing methods include:

- Gas carburizing
- Vacuum carburizing
- Plasma carburizing
- Salt bath carburizing
- Pack carburizing

These methods introduce carbon by the use of gas (atmospheric-gas, plasma, and vacuum carburizing), liquids (salt bath carburizing), or solid compounds (pack carburizing). All of these methods have advantages and limitations, but gas carburizing is used most often for large-scale production because it can be accurately controlled and involves a minimum of special handling.

Nitriding is a surface-hardening heat treatment that introduces nitrogen into the surface of steel at a temperature range of 500 to 550 °C (930 to 1020 °F) while it is in the ferritic condition. Thus, nitriding is similar to carburizing in that surface composition is altered but different in that nitrogen is added into ferrite instead of austenite. Because nitriding does not involve heating into the austenite phase field and a subsequent quench to form martensite, nitriding can be accomplished with a minimum of distortion and with excellent dimensional control. Process methods for nitriding include gas, liquid (salt bath), and plasma (ion) nitriding.

Nitrided steels are generally medium-carbon (quenched and tempered) steels that contain strong nitride-forming elements such as aluminum, chromium, vanadium, and molybdenum. The most significant hardening is achieved with a class of alloy steels (nitralloy type) that contain about 1% Al. When these steels are nitrided, the aluminum forms AlN particles, which strain the ferrite lattice and create strengthening dislocations. Titanium and chromium are also used to enhance case hardness, although case depth decreases as alloy content increases. The microstructure also influences nitridability because ferrite favors the diffusion of nitrogen and because a low carbide content favors both diffusion and case hardness. Usually alloy steels in the heat-treated (quenched and tempered) state are used for nitriding.

Carbonitriding is a surface-hardening heat treatment that introduces carbon and nitrogen in the austenite of steel. This treatment is similar to carburizing in that the austenite composition is changed and high surface hardness is produced by quenching to form martensite. However, because nitrogen enhances hardenability, carbonitriding makes possible the use of low-carbon steel to achieve surface hardness equivalent to that of high-alloy carburized steel without the need for drastic quenching, resulting in less distortion and reducing the danger of cracking the work. To some extent, hardening is also dependent on nitride formation.

Although the process of carbonitriding can be performed with gas atmospheres or salt baths, the term carbonitriding often refers solely to treatment in a gas atmosphere. Basically, carbonitriding in a salt bath is the same as cyanide bath hardening. In both processes, nitrogen enhances hardenability and case hardness but inhibits the diffusion of carbon.

Ferritic nitrocarburizing involves the diffusion of carbon and nitrogen into the ferrite phase and the formation of a thin white layer of carbonitrides. The diffusion of nitrogen into the substrate is necessary for fatigue resistance. The case depths are thin (Table 39), but have a reduced tendency to spall, compared to the white layer formed during conventional nitriding. Ferritic nitrocarburizing, which is used to improve the anti-skuffing properties of steels, can be carried out by gas or plasma (ion) methods.

Surface Engineering of Stainless Steels

J.R. Davis, Davis & Associates

Introduction

STAINLESS STEELS are iron-base alloys that contain a minimum of approximately 11% Cr, the amount needed to prevent the formation of rust in unpolluted atmospheres (hence the designation "stainless"). Few stainless steels contain more than 30% Cr or less than 50% Fe. They achieve their stainless characteristics through the formation of an invisible and adherent chromium-rich oxide surface film. This oxide forms and heals itself in the presence of oxygen. Other elements added to improve particular characteristics include nickel, molybdenum, copper, titanium, aluminum, silicon, niobium, nitrogen, sulfur, and selenium. Carbon is normally present in amounts ranging from less than 0.03% to over 1.0% in certain martensitic grades.

Although stainless steel is naturally passivated by exposure to air and other oxidizers, additional surface treatments often are needed to prevent corrosion. Passivation, pickling, electropolishing, and, in some cases, mechanical cleaning are important surface treatments for the successful performance of stainless steel used for piping, pressure vessels, tanks, and machined parts in a wide variety of applications, including pulp mills, nuclear power plants, hospital sterilization systems, food processing equipment, biotechnology processing plants, breweries, electronic-chip washing facilities, swimming pool hardware, water treatment plants, and chemical process plants.

Following a brief overview of the various types of stainless steels, this article will describe the various cleaning, finishing, and coating processes associated with engineered stainless steel surfaces. Determining which treatment should be used for specific applications is sometimes confusing. A good place to start is with ASTM A 380 (Ref 1), which is an excellent resource document for the cleaning and descaling of stainless steel parts, equipment, and systems, although it does not cover electropolishing.

Designations for Stainless Steels

In the United States, wrought grades of stainless steels are generally designated by the American Iron and Steel Institute (AISI) numbering system, the Unified Numbering System (UNS), or by the proprietary name of the alloy. In addition, designation systems have been established by most of the major industrial nations. Of the two institutional numbering systems used in the U.S., AISI is the oldest and most widely used. Most of the grades have a three-digit designation; the 200 and 300 series are generally austenitic stainless steels, whereas the 400 series are either ferritic or martensitic. Some of the grades have a one- or two-letter suffix that indicates a particular modification of the composition.

The UNS system is a broader-based system that comprises a list of all metallic materials, including stainless steel. This system includes a considerably greater number of stainless steels than AISI, because it incorporates all of the more recently developed stainless steels. The UNS designation for a stainless steel consists of the letter S, followed by a five-digit number. For those alloys that have an AISI designation, the first three digits of the UNS designation usually correspond to an AISI number. When the last two digits are 00, the number designates a basic AISI grade. Modifications of the basic grades use two digits other than zeroes.

Table 1 provides the compositional limits for select stainless steels, listed by UNS and AISI type designations and separated into the basic families described below. Where AISI type designations are not available, common trade names

are listed. These names, the third commonly used identification of stainless steels, have often become the popular means of identifying a particular alloy.

Classification of Stainless Steels

Stainless steels can be divided into five families. Four are based on the characteristic crystallographic structure/microstructure of the alloys in the family: ferritic, martensitic, austenitic, or duplex (austenitic plus ferritic). The fifth family, the precipitation-hardenable alloys, is based on the type of heat treatment used, rather than microstructure.

Ferritic stainless steels are so named because their body-centered-cubic (bcc) crystal structure is the same as iron at room temperature. These alloys are magnetic and cannot be hardened by heat treatment. In general, ferritic stainless steels do not have particularly high strength. Their annealed yield strengths range from 275 to 350 MPa (40 to 50 ksi), and their poor toughness and susceptibility to sensitization limit their fabricability and the usable section size. Their chief advantages are their resistance to chloride stress-corrosion cracking, atmospheric corrosion, and oxidation, at a relatively low cost.

Ferritic stainless steels contain between 11 and 30% Cr, with only small amounts of austenite-forming elements, such as carbon, nitrogen, and nickel. Their general use depends on their chromium content.

The low-chromium (11%) alloys (S40500 and S40900, the latter being the most widely used ferritic stainless steel), have fair corrosion and oxidation resistance and good fabricability at low cost. They have gained wide acceptance for use in automotive exhaust systems.

The intermediate-chromium (16 to 18%) alloys (S43000 and S43400) are used for automotive trim and cooking utensils. These alloys are not as readily fabricated as the lower chromium alloys, because of their poor toughness and weldability.

The high-chromium (19 to 30%) alloys (S44200 and S44600), which are often referred to as superferritics, are used for applications that require a high level of corrosion and oxidation resistance. These alloys often contain either aluminum or molybdenum and have a very low carbon content. Their fabrication is possible because of special melting techniques that can achieve very low carbon, as well as very low nitrogen contents. Stabilizing elements, like titanium and niobium, can be added to prevent sensitization and to improve as-welded properties.

Austenitic stainless steels constitute the largest stainless family, in terms of number of alloys and usage. Like the ferritic alloys, they cannot be hardened by heat treatment. However, their similarity ends there. The austenitic alloys are nonmagnetic, and their structure is face-centered-cubic (fcc), like high-temperature (900 to 1400 °C, or 1650 to 2550 °F) iron. They possess excellent ductility, formability, and toughness, even at cryogenic temperatures. In addition, they can be substantially hardened by cold work.

Although nickel is the chief element used to stabilize austenite, carbon and nitrogen are also used, because they are readily soluble in the fcc structure. A wide range of corrosion resistance can be achieved by balancing the ferrite-forming elements, such as chromium and molybdenum, with austenite-forming elements.

Austenitic stainless steels can be subdivided into two categories: chromium-nickel alloys, such as S30400 and S31600, and chromium-manganese-nitrogen alloys, such as S20100 and S24100. The latter group generally contains less nickel and maintains the austenitic structure with high levels of nitrogen. Manganese (5 to 20%) is necessary in these low-nickel alloys to increase nitrogen solubility in austenite and to prevent martensite transformation. The addition of nitrogen also increases the strength in austenitic alloys. Typical chromium-nickel alloys have tensile yield strengths from 200 to 275 MPa (30 to 40 ksi) in the annealed condition, whereas the high-nitrogen alloys have yield strengths up to 500 MPa (70 ksi).

As previously mentioned, austenitic alloys can be substantially hardened by cold working. The degree of work hardening depends on the alloy content, with increasing alloy content decreasing the work-hardening rate. Austenitic stainless steels that have a low alloy content, such as S20100, S20161, S30100, and S30400, often become magnetic because of the transformation to martensite when sufficiently cold worked or heavily deformed in machining or forming operations. The rapid work hardening of S20161 is a major advantage in sliding wear. In S30430, copper is intentionally added to lower the work-hardening rate for enhanced headability in the production of fasteners.

Another property that depends on alloy content is corrosion resistance. Molybdenum is added to S31700 and S31600 to enhance corrosion resistance in chloride environments. High-chromium grades (S30900 and S31000) are used in oxidizing environments and high-temperature applications, whereas a high-nickel grade (N08020) is used in severe reducing acid environments. To prevent intergranular corrosion after elevated-temperature exposure, titanium or niobium is added to stabilized carbon in S32100 or S34700. Also, lower-carbon grades (AISI L or S designations), such as S30403 (type 304L), have been established to prevent intergranular corrosion. Highly alloyed materials (the superaustenitics) containing 20 to 26% Cr, 18 to 26% Ni, 6% Mo, and 0.1 to 0.2% N have been developed for enhanced resistance to chloride stress-corrosion cracking. Some of the more corrosion-resistant alloys, such as N08020 (20Cb-3), have nickel levels high enough (32 to 38% Ni) to rate classification as nickel-base alloys.

Martensitic stainless steels are similar to iron-carbon alloys that are austenitized, hardened by quenching, and then tempered for increased ductility and toughness. These alloys are magnetic, and their heat-treated structure is body-centered tetragonal (bct). In the annealed condition, they have a tensile yield strength of about 275 MPa (40 ksi) and are generally machined, cold formed, and cold worked in this condition.

The strength obtained by heat treatment depends on the carbon content of the alloy. Increasing carbon content increases strength, but decreases ductility and toughness. The most commonly used alloy in this family is S41000, which contains about 12% Cr and 0.1% C. This alloy is tempered to a variety of hardness levels, from 20 to 40 HRC. Both chromium and carbon contents are increased in alloys S42000, S44002, S44003, and S44004. The first of these contains 14% Cr and 0.3% C and has a hardness capability of 50 HRC. The other three alloys contain 16% Cr and from 0.6 to 1.1% C. These alloys are capable of 60 HRC, and a tensile yield strength of 1900 MPa (280 ksi). The amount of primary carbides increases with increased carbon content in these three alloys.

Wear resistance for martensitic stainless steels is very dependent on carbon content. S44004 (1.1% C) has excellent adhesive and abrasive wear, similar to tool steels, whereas S41000 (0.1% C) has relatively poor wear resistance. The key to adhesive wear resistance is a high hardness. Abrasive wear resistance requires both high hardness and primary carbides. Molybdenum and nickel can be added to martensitic stainless steel to improve corrosion and toughness properties. Nickel also serves to maintain the desired microstructure, preventing excessive free ferrite when higher chromium levels are used to improve corrosion resistance. However, the addition of these elements is somewhat restricted, because higher amounts result in a microstructure that is not fully martensitic.

Precipitation-hardenable (PH) stainless steels are chromium-nickel grades that can be hardened by an aging treatment. These grades are classified as austenitic (such as S66286), semi-austenitic (such as S17700), or martensitic (such as S17400). The classification is determined by their solution-annealed microstructure. The semi-austenitic alloys are subsequently heat treated, so that the austenite transforms to martensite. Cold work is sometimes used to facilitate the aging reaction. Various alloying elements, such as aluminum, titanium, niobium, or copper, are used to achieve aging. They generally form intermetallic compounds, but in S17400, fine copper precipitates are formed.

Like the martensitic stainless steels, PH alloys can attain high tensile yield strengths, up to 1700 MPa (250 ksi). Cold working prior to aging can result in even higher strengths. The PH grades generally have good ductility and toughness with moderate-to-good corrosion resistance. A better combination of strength and corrosion resistance is achieved than with the martensitic alloys. These improved properties are related to their higher chromium, nickel, and molybdenum contents, as well as their restricted carbon (0.040 max) levels. The low carbon content of the martensitic PH stainless

steels is especially critical for toughness and good ductility. However, this low carbon content reduces the wear resistance of these alloys.

The most well-known precipitation-hardenable stainless steel is S17400. It contains chromium and nickel, as do all precipitation-hardenable stainless steels, with copper for age hardening and niobium for stabilizing the carbon. The age-hardening agents used in other alloys include titanium (S45500), aluminum (S13800), and niobium (S45000). Molybdenum can be added to improve mechanical properties or corrosion resistance. Both molybdenum and copper are added for corrosion resistance in S45000. Carbon is normally restricted, except in semiaustenitic alloys such as S35500, which require it to provide the desired phase transformations.

Duplex stainless steels are chromium-nickel-molybdenum alloys that are balanced to contain a mixture of austenite and ferrite, and are magnetic, as well. Their duplex structure results in improved stress-corrosion cracking resistance, compared with the austenitic stainless steels, and improved toughness and ductility, compared with the ferritic stainless steels. They are capable of tensile yield strengths ranging from 550 to 690 MPa (80 to 100 ksi) in the annealed condition, which is approximately twice the strength level of either phase alone.

The original alloy in this family was the predominantly ferritic S32900. The addition of nitrogen to duplex alloys, such as S32950 and S31803, increases the amount of austenite to nearly 50%. In addition, nitrogen improves as-welded corrosion properties, chloride corrosion resistance, and toughness. The improvement in toughness is probably related to the higher amount of austenite present, which makes it possible to produce heavier product forms, such as plates and bars.

Stainless Steel Mill Finishes (Ref 2)

The standard industry designations for stainless steel finishes are classified by mill form, as there are separate finishes (or conditions) for sheet, strip, plate, bar, rod, wire, and tubing. Table 2 classifies the various stainless steel product forms. More detailed information on stainless steel product forms can be found in Ref 3.

Table 2 Classification of stainless steel product forms

Item	Description	Thickness		Width		Diameter or size	
		mm	in.	mm	in.	mm	in.
Sheet	Coils and cut lengths:						
	Mill finishes No. 1, 2D, and 2B	<5	$< \frac{3}{16}$	≥ 610	≥ 24	. . .	. . .

Sheet Finishes

Stainless steel sheets are produced on continuous mills or hand mills. The steel is usually cast in ingot form and rolled on a slabbing or a blooming mill to slabs or sheet bars. Alternatively, the steel may be cast directly in slab form ready for finish hot rolling.

Sheets produced on continuous mills from slabs are rolled into coils and are further processed by annealing, descaling, and cold reducing to specified thickness, then further annealing and descaling. Coils or lengths cut from coils may then be subjected to light cold rolling for finish on dull or bright rolls.

Sheet finishes (Table 3) are designated by a system of numbers: No. 1, 2D, and 2B for rolled (unpolished) finishes; and No. 3, 4, 6, 7, and 8 for polished finishes.

Table 3 Standard mechanical sheet finishes

Finish	Description
Unpolished or rolled finishes	
No. 1	A rough, dull surface that results from hot rolling to the specified thickness followed by annealing and descaling
No. 2D	A dull finish that results from cold rolling followed by annealing and descaling, and may perhaps get a final light roll pass through unpolished rolls. A 2D finish is used where appearance is of no concern.
No.	A bright, cold-rolled finish resulting in the same manner as No. 2D finish, except that the annealed and descaled sheet receives a

2B	final light roll pass through polished rolls. This is the general-purpose cold-rolled finish that can be used as is, or as a preliminary step to polishing.
Polished finishes	
No. 3	An intermediate polished surface obtained by finishing with a 100-grit abrasive. Generally used where a semifinished polished surface is required. A No. 3 finish usually receives additional polishing during fabrication.
No. 4	A polished surface obtained by finishing with a 120 to 150-mesh abrasive, following initial grinding with coarser abrasives. This is a general-purpose bright finish with a visible "grain" that prevents mirror reflection.
No. 6	A dull satin finish having lower reflectivity than No. 4 finish. It is produced by tampico brushing the No. 4 finish in a medium of abrasive and oil. It is used for architectural applications and ornamentation where a high luster is undesirable, and to contrast with brighter finishes.
No. 7	A highly reflective finish that is obtained by buffing finely ground surfaces but not to the extent of completely removing the grit lines. It is used chiefly for architectural and ornamental purposes.
No. 8	The most reflective surface, which is obtained by polishing with successively finer abrasives and buffing extensively until all grit lines from preliminary grinding operations are removed. It is used for applications such as mirrors and reflectors.

Source: Ref 2

No. 1 is a very dull finish produced by first hot rolling the steel on hand sheet mills to the specified thickness and then annealing and descaling. It is used in industrial applications for resistance to heat or corrosion, where a smooth finish is not of particular importance.

No. 2D is a dull finish produced on either hand sheet mills or continuous mills by cold rolling to the specified thickness, annealing, and descaling. The dull finish may result from the descaling operation or may be developed by a final light cold roll pass on dull rolls. This finish is favorable to the surface retention of lubricants in deep drawing operations. It generally is used in forming deep-drawn articles that may be polished after fabrication.

No. 2B is a bright, cold-rolled finish commonly produced in the same way as No. 2D, except that the annealed and descaled sheet receives a final light cold-roll pass on polished rolls. It is a general-purpose finish used for all but exceptionally difficult deep drawing applications. This finish is more readily polished than No. 1 or 2D.

No. 3 is an intermediate polished finish for use where a semifinished polished surface is required and a further finishing operation follows fabrication. For sheets or articles that will not be subject to additional finishing or polishing, No. 4 finish is recommended.

No. 4 is a general-purpose polished finish widely used for architectural panels and trim, and for dairy, restaurant, and kitchen equipment. Following initial grinding with coarser abrasives, sheets are finally finished with lubricated 120- to 150-mesh abrasive belts.

No. 6 is a dull satin finish having lower reflectivity than No. 4. It is produced by tampico brushing No. 4 finished sheets in a medium of abrasive and oil and is used for architectural applications and ornamentation where a high luster is undesirable. It also is used to contrast with brighter finishes.

No. 7 is a finish with a high degree of reflectivity, produced by buffing a finely ground surface without removing the grit lines. It is used chiefly for architectural and ornamental purposes.

No. 8 is the most reflective finish and is obtained by polishing with successively finer abrasives and buffing extensively with very fine buffing rouges. The surface is essentially free of grit lines from preliminary grinding operations. This finish

is most widely used for press plates, as well as for small mirrors and reflectors. Sheets can be produced with one or both sides polished. When polished on one side only, the other side may be rough ground in order to obtain the necessary flatness. The relationship between abrasive grit numbers and surface roughness in terms of microinches is sometimes a basis for specification. The values are approximately as follows:

Abrasive grit no.	Surface roughness	
	μm	μin.
500	0.10 to 0.25	4 to 10
320	0.15 to 0.38	6 to 15
240	0.20 to 0.51	8 to 20
180	0.64 max	25 max
120	1.14 max	45 max

Strip Finishes

Hot-rolled stainless steel strip is a semifinished product obtained from the hot rolling of slabs or billets and is produced for conversion by cold rolling. Cold-rolled stainless steel strip is manufactured from hot-rolled, annealed, and pickled strip by cold rolling on polished rolls. Depending on the thickness desired, the cold rolling requires various numbers of passes through the mill to effect the necessary reduction and to secure the desired surface characteristics and mechanical properties. Only three rolled (unpolished) finishes (No. 1, No. 2, and bright annealed) and one polished finish (mill buffed) are commonly supplied on stainless steel strip.

No. 1 finish is produced by cold rolling, annealing, and pickling. Appearance varies from dull gray matte to fairly reflective, depending largely on stainless steel type. This finish is used for severely drawn or formed parts, as well as for applications where the brighter No. 2 finish is not required, such as parts to be used at high temperatures. No. 1 finish for strip approximates No. 2D finish for sheet in corresponding chromium-nickel or chromium-nickel-manganese types.

No. 2 finish is produced by the same treatment used for No. 1 finish, followed by a final light cold-rolling pass, which generally is done using highly polished rolls. This final pass produces a smoother and more reflective surface, the appearance of which varies with stainless steel type. No. 2 finish for strip is a general-purpose finish widely used for household appliances, automotive trim, tableware, and utensils. No. 2 finish for strip approximates No. 2B finish for sheet in corresponding chromium-nickel or chromium-nickel-manganese stainless steels.

Bright annealed finish is a bright, cold-rolled, highly reflective finish retained by final annealing in a controlled-atmosphere furnace. The purpose of atmosphere control is to prevent scaling or oxidation during annealing. The atmosphere usually consists of either dry hydrogen or dissociated ammonia. Bright annealed strip is used most extensively for automotive trim.

Mill-buffed finish is a highly reflective finish obtained by subjecting either No. 2 or bright annealed coiled strip to a continuous buffing pass. The purpose of mill buffing is to provide a finish uniform in color and reflectivity. It also can

provide a surface receptive to chromium plating. This type of finish is used chiefly for automotive trim, household trim, tableware, utensils, fire extinguishers, and plumbing fixtures.

Grade Limitations. Not all of the standard compositions of stainless steel strip are available in each of the standard mill finishes. Surface finishes of these products depend on end use rather than any restriction imposed by the supplier. Table 4 lists the finishes most often applied to sheet and strip of a number of standard grades of austenitic, martensitic, and ferritic steels.

Table 4 Mill finishes available on stainless steel sheet and strip

See text for explanation of numerical designations of finishes

Type	Sheet		Strip
	Unpolished	Polished	
Austenitic steels[(a)]			
201	2D, 2B	[(b)]	1, 2
202	2D, 2B	3, 4	1, 2
301	2D, 2B	[(b)]	1, 2
302	2D, 2B	3, 4, 6, 7	1, 2
302B	2D	[(b)]	. . .
304	2D, 2B	3, 4, 6, 7	1, 2
304L	2D, 2B	4	1, 2
305	2D, 2B	[(b)]	1, 2
309, 309S	2D	[(b)]	1, 2
310	2D	[(b)]	1, 2
316	2D, 2B	4	1, 2
316L	2D, 2B	[(b)]	1, 2
321	2D, 2B	[(b)]	1, 2
347	2D, 2B	[(b)]	1, 2

348	2D, 2B	(b)	1, 2
Martensitic steels			
403	2D, 2B	(b)	1, 2
410	2D, 2B	(b)	1, 2
420	(c)	(c)	1, 2
440A, B, and C	(c)	(c)	(d)
Ferritic steels[a]			
430	2D, 2B	3, 4	1, 2
446	2D, 2B	(b)	1, 2

(a) All grades listed, in both sheet and strip form, are regularly available in the smooth rolled and bright annealed condition.

(b) Usually not polished.

(c) Not available in sheet form.

(d) Material available in strip form on special order only; finish negotiated with supplier

Plate Finishes

Stainless steel plates usually are produced by hot rolling from slabs, which have been directly cast or rolled from ingots; some plates may be produced by direct rolling from the ingot. Plates are generally produced in the annealed condition and are either blast cleaned or pickled. When blast cleaned, the plates are subjected to further cleaning in appropriate acids to remove possible iron contamination. Stainless steel plate can be produced in the conditions and surface finishes shown in Table 5.

Table 5 Conditions and surface finishes for stainless steel plate

Condition and finish	**Description and remarks**
Hot rolled	Scale not removed; not heat treated; plate not recommended for final use in this condition[a]
Hot or cold rolled, annealed or heat treated	Scale not removed; use of plate in this condition generally confined to heat-

	resisting applications; scale impairs corrosion resistance.[(a)]
Hot or cold rolled, annealed or heat treated, blast cleaned or pickled	Condition and finish commonly preferred for corrosion-resisting and most heat-resisting applications
Hot or cold rolled, annealed, descaled, and temper passed	Smoother finish for specialized applications
Hot rolled, annealed, descaled, cold rolled, annealed, descaled, optionally temper passed	Smooth finish with greater freedom from surface imperfections than any of the above
Hot or cold rolled, annealed or heat treated, surface cleaned and polished	Polished finishes similar to the polished finishes on sheet

Source: Ref 2

(a) Surface inspection is not practicable for plate that has not been pickled or otherwise descaled.

Table 5 indicates that polished finishes similar to those for sheet are available for plate. Technically speaking, there is no No. 4 finish for plate, nor is there a No. 8 finish. However, arrangements can be made either with a mill or an independent polisher to grind and polish plate in the same manner as sheet. This work should be specified on the basis of submitted samples.

Plate commonly is conditioned by localized grinding to remove surface imperfections on either or both surfaces; ground areas are well flared and the thickness is not reduced below the allowable tolerance in any of these areas.

Bar Finishes

Hot-finished bars are commonly produced by hot rolling, forging, or pressing ingots to intermediate-size blooms or billets, which are subsequently hot rolled, forged, or extruded to final dimensions. (In some mills, the process starts with continuous cast sections.) The selection of rolling, forging, or extruding as the finishing method depends on several factors, including the composition of the steel and the final size. It is common practice to process bars in straight lengths, although smaller bars produced by rolling may be coiled.

Following hot rolling or forging, hot-finished bars may be subjected to various operations, including annealing or other heat treating; cleaning by pickling, blast cleaning, or other methods of descaling; rough turning; and machine straightening. When only improved surface is required, as for bars intended for forging, bars can be turned or ground.

Cold-finished bars are produced from hot-finished bars by additional operations to give close tolerance, improved surface finish, or specific mechanical properties.

Stainless steel bar is produced in the conditions and surface finishes given in Table 6. It is important that both condition and finish be specified, because each finish is applicable only to certain conditions.

Table 6 Conditions and surface finishes for stainless steel bar

Condition	**Surface finish**
Hot worked only	Scale not removed (except for spot conditioning)

	Rough turned[a][b]
	Blast cleaned
Annealed or otherwise heat treated	Scale not removed (except for spot conditioning)
	Rough turned[a]
	Pickled or blast cleaned and pickled
	Cold drawn or cold rolled
	Centerless ground[a]
	Polished[a]
Annealed and cold worked to high tensile strength[c]	Cold drawn or cold rolled
	Centerless ground[a]
	Polished[a]

Source: Ref 2

(a) Applicable to round bar only.

(b) Bar of 400-series stainless steels that are highly hardenable, such as types 414, 420, 420F, 431, 440A, 440B, and 440C, are annealed before rough turning. Other hardenable types, such as types 403, 410, 416, and 416Se, also may require annealing, depending on composition and size.

(c) Produced only in mill orders; made predominantly in types 301, 302, 303Se, 304, 304N, 316, and 316N.

The finish on stainless steel bar is generally the result of processes used to size the bar or to improve the surface and usually not for purposes of achieving a certain surface appearance. Turning, for instance, improves the surface by removing undesirable defects. It is difficult, if not impossible, to obtain a hot-rolled surface that the customer can use without removal of a portion of the "skin." Turning is accomplished by passing the bar through a turning machine or lathe, using one or more passes depending on the amount of material to be removed.

Sometimes the final surface or dimension of round bar can be achieved only by centerless grinding. Centerless grinding differs from turning in that a grinding wheel is used for metal removal instead of a cutting tool, and more accurate dimensions and better surface finish are obtained. The centerless grinding machine is constructed so that the bar is supported under the greater portion of its length as well as under the grinding wheel, other than at the ends.

In some cases, a highly polished bar is desired rather than the standard centerless ground finish. In this case, centerless ground bars are passed through a polishing or lapping machine that imparts a higher degree of polish. Flat or shaped bars cannot be centerless ground, so any finish requirements are achieved by methods similar to those used for strip.

Wire Finishes

Stainless steel wire is a product derived by cold finishing a coiled hot-rolled and annealed rod for the purpose of obtaining desired size with dimensional accuracy, improved surface, and specific mechanical properties. Wire is produced in a number of tempers and finishes. The finishes on wire are usually applied to meet the requirements of further processing, such as drawing, forming into parts, or coiling into springs.

Oil- or grease-drawn finish is a special bright finish for wire intended for uses such as racks and handles, where the finish supplied is to be the final finish of the end product. In producing this finish, lower drawing speeds are necessary and additional care in processing is needed to provide a surface with few scratches and with only a very light residue of lubricant.

Diamond-drawn finish is a very bright finish generally limited to wet-drawn stainless steel wire in fine sizes. Drawing speeds are necessarily reduced to obtain the desired brightness.

Copper-coated wire is supplied when a special finish is required for lubrication in an operation such as spring coiling or cold heading. Generally, copper-coated wire is drawn after the coating, the amount depending on the desired cold-worked temper of the wire.

Tinned wire is coated by passing single strands through a bath of molten tin. Tinned wire is used in soldering applications. The temper of the finished wire is controlled by processing prior to tinning.

Lead-coated wire is coated by passing single strands through, or immersing bundles of wire in, a bath of molten lead. The wire is then drawn to final size, with the lead forming a thin coating over the entire surface. This coating is useful on wire for coil springs, where it serves as a lubricant during coiling operations.

Tubing and Pipe Finishes

Hot-finished tubular products produced by the seamless processes have a surface finish comparable to hot-rolled bars. Welded tubular products produced from hot-rolled sheets, strip, or plate retain the general surface finish of those flat rolled products. Thin-wall tubular products, due to greater reduction during the rolling operation and the lower finishing temperatures, may have a smoother surface than those with heavy walls.

Stainless steel tubular products are cold worked to improve dimensional limits or--in the case of welded tubing--to control the weld bead on the inside, or to condition the weld for grain refinement during the annealing operation. Cold finishing may include cold drawing, tube reducing, or swaging. Tubes may also be rough turned (machined) or honed, such as for hydraulic cylinders.

Tubular products may be polished, but instead of "typical" finish designations, the polished finishes for tubing are usually indicated by the grit size, such as 80, 120, 180, or 320 grit. Note that for the exterior surface of round tubing, grit lines are longitudinal. Tubing may be specified polished on the outside, the inside, or both surfaces. Welded and cold-finished seamless tubing is suitable for grinding or polishing and is produced in sizes up to 168 mm ($6\frac{5}{8}$ in.) OD with polished outside surfaces. It is not practical to polish interior surfaces or tubes with an inner diameter of less than 19 mm ($\frac{3}{4}$ in.).

Preservation of Mill Finishes

In making a finished part, the original mill finish may be retained with little or no modification, depending on fabrication requirements. If this finish is satisfactory, no additional finishing operations are necessary. Therefore, every effort should be made to preserve the mill finish while the steel is in storage or being processed. The following preventive measures will serve to minimize additional cleaning and polishing:

- Steel should be kept in original containers or wrappers until fabrication actually begins.
- Steel should be stored indoors, on clean racks, shelves, or platforms, and should be covered wherever possible.
- Storage areas should be kept free of shop dirt, pickling or plating fumes, particles of scale from steel fabrication, and other contaminants.
- Storage areas should not be located beneath line shafting from which lubricating oils and grease may fall.
- Fabricating equipment should be cleaned of all residues before being used for a new operation on stainless steel.
- Steel should be handled with clean gloves or cloths, to avoid fingerprints.
- Only marking materials that leave no permanent blemishes on work should be used.
- Whenever feasible, paper or other protective covering should be placed on all surfaces between processes.
- Chips should not be removed by compressed air, which may contain oil or other contaminants.

Abrasive Blast Cleaning

Aspects of abrasive blast cleaning that apply particularly or exclusively to stainless steel include sandblasting, shot blasting, and wet blasting. For more complete information, see the article "Mechanical Cleaning Systems" in this Volume.

Sandblasting is effective for rapidly removing heavy or tightly adhering scale before acid pickling. Applied to stainless steel, it is not a complete cleaning procedure. Types of work for which it is frequently used include heavily scaled plate sections, forgings and castings, and parts made of straight chromium steel that have developed a tightly adhering scale during annealing. It is fast and economical when used in conjunction with a final pickling treatment.

Only clean silica sand should be used. If the sand is iron-bearing or becomes contaminated with scale, minute particles of these contaminants can become embedded in the metal. The only sure way to remove such contaminants and to produce a thoroughly clean, rust-free surface is to follow the blasting with an acid pickling treatment.

Sandblasting should not be used on materials that are too light to stand the blast pressure, because distortion results from the local stretching caused by impingement of the sand. The blast should be kept moving to avoid excessive cutting at localized points.

Shot Blasting. The use of carbon steel shot, steel wire, or iron grit as blasting media is not recommended as they may cause particles of iron to become embedded and seriously detract from the corrosion resistance of stainless steel surfaces. Unless these contaminants are completely removed by acid pickling, they can rust and begin pitting.

The use of stainless steel shot or grit reduces the danger of rusting, but it cannot eliminate the possibility of residual oxide scale. Final pickling is mandatory for maximum corrosion resistance of surfaces so treated.

Stainless steels, and particularly those of the 300 series, work harden when they are subjected to cold working. Therefore, if work hardening of the surface is undesirable for a particular application, shot blasting should not be used.

Wet blasting is adaptable for use with stainless steel. Various abrasives conveyed in liquid carriers are discharged at the work by compressed air. A variety of finishes can be obtained through selection of abrasives and adjustment of pressures. Finishes that are much smoother than those resulting from blasting with dry sand and that are similar in appearance to a No. 6 (tampico-brushed) finish may be obtained by wet blasting. As in sandblasting, a final pickling treatment and water washing are required.

Acid Descaling (Pickling)

Acid descaling, or pickling, is the removal of heavy, tightly adherent oxide films resulting from hot-forming operations, thermal treatments (such as annealing or hardening), or welding (Ref 4). Because most stainless steel products received from the producing mill have been pickled, descaling is required only as a result of subsequent manufacturing operations.

In evaluating the different methods for removing scale, it should be kept in mind that scale on stainless steel is far more complex than scale formed on plain carbon steel. The scale on stainless steel consists of oxides of chromium, nickel, and/or other alloying elements--in addition to iron--and the ease by which it can be removed depends on base metal composition and the thermal treatment to which it is exposed. The problem may be further complicated by the presence of lubricants. Lubricants and other contamination should be removed before thermal treatment.

When the metal is exposed to hot gases containing oxygen, a heavy scale is formed. A heavy scale, because it is readily exposed to the oxygen only near the surface, may be oxygen rich at the surface and metal rich near the base metal. Most oxygen-rich scale is readily soluble in common pickling acids, but the metal-rich scale may require acids aggressive to the base metal itself. For this reason, pickling is sometimes preceded by a preconditioning step, such as an alkaline salt bath, or scale removal by mechanical means, such as shot blasting.

The final step, however, involves elimination of scale and other surface defects through removal of the normal, protective oxide layer and 25 to 40 μm (0.001 to 0.0015 in.) of the substrate metal by pickling the surface in a nitric-hydrofluoric acid (HNO_3-HF) bath. The protective film then reforms in air over the freshly cleaned surface. This oxide film is uniform and leaves the stainless surface in its normal passive condition.

Although pickling is not strictly a passivating treatment, it provides many of the same benefits. Pickling is most useful for localized cleaning of welded areas, but also can be used to improve the corrosion resistance of mechanically cleaned surfaces.

Disposal of pickle liquor is a growing problem that tends to limit pickling by immersion to those fabricator and chemical cleaning contractors who have pickle tanks and approved arrangements for disposal.

Pickling at the steel mill removes the oxide scale that forms during annealing. Mill pickling also removes manganese sulfides or other inclusions in the surface and removes surface layers that may have been depleted of chromium during annealing.

ASTM A 380 (Ref 1) lists three pickling solutions for stainless steel (Table 7). Fabricated austenitic stainless steels can be pickled by immersion in a standard 10% HNO_3, 2% HF bath at 50 °C (120 °F). For localized pickling or if the fabricated component is too large to be immersed, commercial HNO_3-HF pickle pastes can be just as effective. Pickle paste can be applied with a paint roller or nylon brush.

Table 7 Acid descaling (pickling) of stainless steel

Alloy[(a)]	Condition[(b)]	Code	Treatment			Time[(e)], min
			Solution, vol%[(c)]	Temperature		
				°C	°F	
200, 300, and 400 series, precipitation hardening, and maraging alloys (except free-machining alloys)	Fully annealed only	A	H_2SO_4 (8-11)[(d)] Follow by treatment D or F, Annex A2 (ASTM A 380), as appropriate	66-82	150-180	5-45 max
200 and 300 series; 400 series containing 16% Cr or more; precipitation-hardening alloys (except	Fully annealed only	B	HNO_3 (15-25%) plus HF (1-8%)[(f)(g)]	21-60 max	70-140 max	5-30

free-machining alloys)						
All free-machining alloys and 400 series containing less than 16% Cr	Fully annealed only	C	HNO_3 (10-15%) plus HF ($\frac{1}{2}$-1 $\frac{1}{2}$%)[f][g]	20 (up to 60 with caution)	70 (up to 140 with caution)	5-30

Source: Ref 1

(a) This table is also applicable to the cast grades equivalent to the families of wrought materials listed.

(b) Other heat treatments may be acceptable if proven by experience: see sections 5.2.1, A2.4, and A2.5 of ASTM A 380 for further information.

(c) Solution prepared from reagents of following weight percent: H_2SO_4, 98; HNO_3, 67; HF, 70.

(d) Tight scale may be removed by a dip in this solution for a few minutes followed by water rinse and HNO_3-HF treatment as noted.

(e) Minimum contact times necessary to obtain the desired surface should be used in order to prevent overpickling. Tests should be made to establish correct procedures for specific applications.

(f) For reasons of convenience and handling safety, commercial formulations containing fluoride salts may be found useful in place of HF for preparing HNO_3-HF solutions.

(g) After pickling and water rinsing, an aqueous caustic permanganate solution containing 10% NaOH and 4 wt% $KMnO_4$, 71 to 82 °C (160 to 180 °F), 5 to 60 min, may be used as a final dip for removal of smut, followed by thorough water rinsing and drying.

Paste must be washed off within 15 to 30 min of application, or corrosion will initiate. Personnel need protective clothing and training in safe handling procedures.

Although postfabrication pickling improves the performance of stainless steels in a variety of applications, until recently there has been very little research data to support field experience. Quantitative data on the increase in critical pitting temperature in ferric chloride ($FeCl_3$) (ASTM G 48) shows that pickling provides a 2.5 to 10 °C (4.5 to 18 °F) improvement in performance (Fig. 1). While not large, the improvements in lightly ground surfaces and glass-bead-blasted surfaces are uniformly positive, indicating that pickling provides benefits beyond those obtained with the best controlled mechanical treatments. Additional information on acid pickling of stainless steels can be found in the article "Pickling and Descaling" in this Volume.

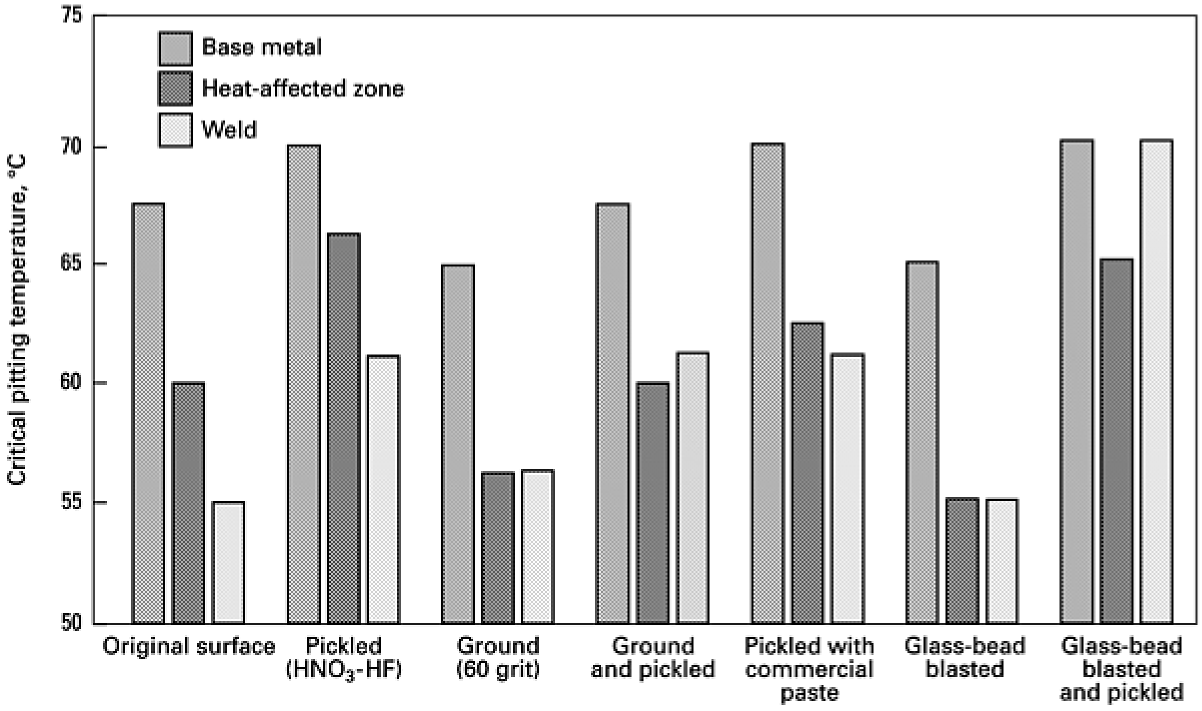

Fig. 1 Pickling of stainless steel increases the critical pitting temperature in $FeCl_3$ in the base metal, heat-affected zone, and weld areas. Mechanical cleaning treatments that are performed without a subsequent pickling treatment decrease the critical pitting temperature. Source: Ref 5

Salt Bath Descaling

The removal of oxide scale can be accelerated by using baths of molten sodium hydroxide (NaOH) to which certain reagents are added. These baths can be used with virtually all grades of stainless steel. Salt bath descaling has several advantages:

- It acts only on the scale and does not result in metal loss or etching.
- It does not preferentially attack areas in which intergranular carbides are present.
- It is particularly useful in descaling the straight chromium grades without the preliminary sandblasting that is frequently required prior to acid descaling.

Use of molten salts is not recommended for those stainless steels that precipitation harden at the operating temperature of the bath. Procedures and equipment for descaling in molten salt are described in the article "Molten Salt Bath Cleaning" in this Volume.

Sequence of Descaling Methods

Usually, more than one method of cleaning is used to remove scale from stainless steel. For instance, in mill processing sheet, salt bath descaling and acid pickling often are used for a cold-rolled product and abrasive blast cleaning and acid pickling for a hot-rolled product.

In a continuous annealing and pickling line, multistep cleaning usually occurs twice in producing stainless steel sheet. The sequence of operations is: hot roll, anneal, descale, pickle, cold reduce 30 to 50%, anneal, descale, and pickle. As shown in Fig. 2, salt descaling is used for cold-rolled sheet, whereas the salt is bypassed and abrasive blast cleaning is used when a hot-rolled product is being cleaned. Salt also can be eliminated on low-chromium cold-rolled sheet.

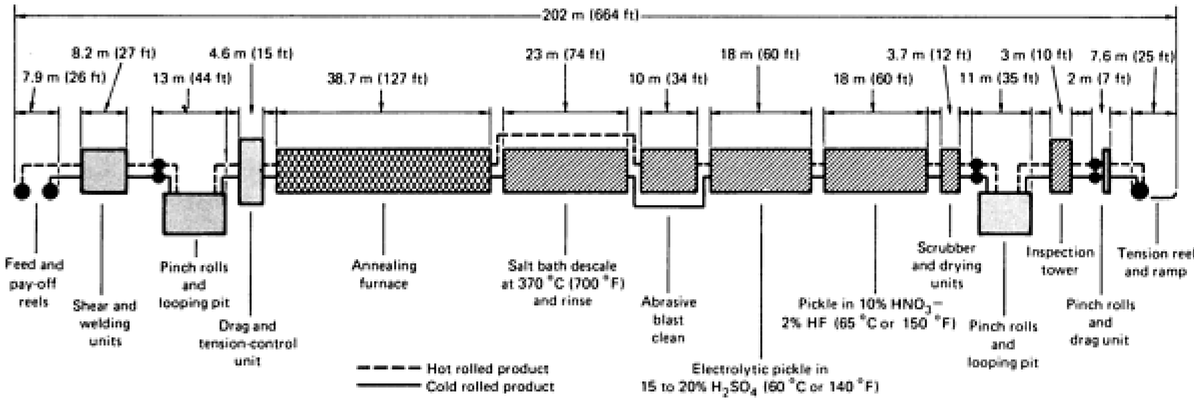

Fig. 2 Sequence of annealing and scale-removing operations in mill processing of stainless steel sheet

Cold-rolled sheet is left in the salt bath 10 to 15 min. Oxides are not removed from the surface. The rack of hot sheet is transferred to a water bath, and the violent reaction that results on immersion blasts much of the scale from the steel. The surface is essentially free of scale, but quite dull and dirty. To remove the last remnants of oxide, the rack is transferred to a 10 to 15% sulfuric acid (H_2SO_4) solution at 70 °C (160 °F) for 3 to 5 min. After removal from the H_2SO_4 tank, the rack of sheet steel is rinsed and then immersed for 1 to 2 min in HNO_3-HF (8 to 10% HNO_3, 1 to 2% HF) at 60 °C (140 °F). This removes all smut and residue and produces a white finish. The sheet is finally rinsed, removed from the rack, scrubbed, and dried with an air blast.

Cleaning Stainless Steels

Cleaning includes all operations necessary for the removal of surface contaminants from metals to ensure maximum corrosion resistance of the metal, prevention of product contamination, and achievement of desired appearance (Ref 1). Selection of cleaning processes is influenced mainly by the type of contaminant to be removed, the required degree of cleanliness, and cost.

Dirt deposits on stainless steel, which include accumulated dust and dirt, finger marks, and identification markings, are easily removed (Ref 4). Frequently, warm water with or without detergent is sufficient. Next in order are mild nonscratching abrasive powders such as typical household cleaners. These can be used with warm water, bristle brushes, stainless steel brushes, sponges, or clean cloths. Ordinary carbon steel brushes or steel wool should be avoided as they may leave particles embedded on surfaces which can lead to rusting. For slightly more aggressive cleaning, a small amount of vinegar can be added to the scouring powder. Cleaning should always be followed by rinsing in clean hot water. When water is known to contain mineral solids, which leave water spots, it is good practice to wipe the surfaces completely with dry towels. Some companies use oil impregnated cloths to remove water spots and enhance appearance. Commercial metal cleaners may also be considered, but it is important to make certain that they can be used on stainless steels.

Finger marks are probably the most troublesome of unwanted marks on stainless steel (Ref 4). They not only detract from overall appearance of smoothly polished or bright finishes, but they also can "burn in" quite deeply during annealing or other thermal treatments, leaving permanent marks which can be removed only by grinding. Fortunately, they can be easily prevented through the use of clean gloves, or they can be removed by gentle rubbing with a paste of soda ash (sodium carbonate) and water applied with a soft rag. Again, this should be followed by a thorough warm water rinse.

Most inspection stamps and identification marks applied at the mill are ink, which can be removed by applying a solvent on a rag and rubbing (Ref 4). Selection of solvent is determined by the type of ink used. Solvents should be rinsed from the stainless steel with warm water, repeating the treatment if necessary.

Commonly used methods for the removal of greases, drawing compounds, and machining oils include:

- Alkaline cleaning
- Emulsion cleaning
- Solvent cleaning
- Vapor degreasing
- Ultrasonic cleaning
- Acid cleaning

Each of these are described briefly below and in greater detail in the articles contained in the Section "Surface Cleaning" in this Volume. Additional information can also be found in ASTM Standard A 380 (Ref 1).

Alkaline cleaning is used to remove soils from the surface of metals. Soils removed through alkaline cleaning include oil, grease, waxy solids, metallic particles, dust, carbon particles, and silica. Alkaline cleaners are applied by immersion or spray, and the metal is cleaned by emulsification, dispersion, saponification, or combinations of these mechanisms. The cleaning step is usually followed by a water rinse and a drying stage. Alkaline cleaner compositions are discussed in the article "Alkaline Cleaning" in this Volume.

Emulsion cleaning is a process for removing oily deposits and other common contaminants from metals by solution with the aid of a soap or other emulsifying agent (an emulsifying agent is one which increases the stability of a dispersion of one liquid in another). It is effective for removing a wide variety of contaminants including pigmented and unpigmented drawing compounds and lubricants, cutting fluids, and residues resulting from liquid penetrant inspection. Emulsion cleaning is used when rapid, superficial cleaning is required and when a light residual film of oil is not objectionable. Depending on the solvent used, cleaning is done at temperatures from 10 to 80 °C (50 to 180 °F). Compositions and operating temperatures for emulsion cleaners are described in the article "Emulsion Cleaning" in this Volume.

Solvent cleaning is a process for removing contaminants from metal surfaces by immersion or by spraying or swabbing with common organic solvents such as the aliphatic petroleums, chlorinated hydrocarbons, or blends of these two classes of solvents. Cleaning is usually performed at, or slightly above, room temperature. Parts are cleaned by being immersed and soaked in the solvent, with or without agitation. Parts that are too large to be immersed are sprayed or wiped with the solvent. Properties of cleaning solvents are described in the article "Solvent Cold Cleaning and Vapor Degreasing" in this Volume.

Vapor degreasing is a generic term applied to a cleaning process that uses the hot vapors of a chlorinated or fluorinated solvent to remove soils, particularly oils, greases, and waxes. The cleanliness and chemical stability of the degreasing solvent are critical factors in the efficiency of the vapor and possible chemical attack of the metal. Water in the degreasing tank or on the item being cleaned may react with the solvent to form hydrochloric acid, which may be harmful to the metal. No water should be present in the degreasing tank or on the item being cleaned. Acids, oxidizing agents, and cyanides must also be prevented from contaminating the solvent. Vapor degreasing systems and procedures are described in the article "Solvent Cold Cleaning and Vapor Degreasing" in this Volume.

Ultrasonic Cleaning. Ultrasonic transducers, which convert electrical energy into ultrasonic vibrations, can be used in conjunction with some solvent cleaning systems to loosen and remove contaminants from deep recesses and other difficult to reach areas, particularly in small workpieces. Cavitation in the liquid produced by the high-frequency sound causes microagitation of the solvent in even tiny recesses of the workpiece, making the method especially desirable for cleaning parts or assemblies having an intricate configuration. More detailed information can be found in the article "Ultrasonic Cleaning" in this Volume.

Acid cleaning is a process in which a solution of a mineral acid, organic acid, or acid salt, in combination with a wetting agent and detergent, is used to remove oxide, shop soil, and similar contaminants from metal surfaces, with or without application of heat. Acid cleaning is not generally effective for removal of oils, greases, and waxes. Surfaces

should be precleaned to remove oils and greases before acid cleaning. Common techniques for acid cleaning are immersion, swabbing, and spraying. Maximum surface quality is best achieved by using a minimum cleaning time at a given acid concentration and temperature. After acid cleaning the surfaces must be thoroughly rinsed with clean water to remove all traces of the acid and thoroughly dried after the final water rinse. To minimize staining, surfaces must not be permitted to dry between successive steps of the acid cleaning and rinsing procedure. A neutralizing treatment may be required under some conditions; if used, neutralization must be followed by repeated water rinsing to remove all trace of the neutralizing agent followed by thorough drying after the final water rinse. Suggested solutions, contact times, and solution temperatures for acid cleaning of stainless steels are given in ASTM A 380. Additional information can also be found in the section "Passivation Treatments" in this article and in the article "Acid Cleaning" in this Volume.

Mass Finishing

Mass finishing provides methods that can be advantageously used for surface treating stainless steels include barrel finishing, vibratory finishing, and centrifugal barrel finishing. Mass finishing methods are adaptable to removal of burrs, scale, and residual flux, and they also can be used for light surface treatment, such as cleaning, burnishing, or coloring. For more information, see the article "Mass Finishing Methods" in this Volume.

Post-Treatments. Once a mass finishing treatment is completed, stainless steel parts are rinsed thoroughly in water and dipped in a 20 vol% solution of HNO_3 at 50 °C (120 °F) for 10 to 15 min. This is followed by another water rinse. If any oxide scale remains on the work after mass finishing, it must be removed by acid pickling.

Finishing Methods

This section deals with the finishing of stainless steels as practiced by the fabricator or manufacturer--specifically, grinding (used here to mean metal removal for the purpose of altering surface finish, not to achieve close dimensional tolerances), polishing, and buffing. Table 8 summarizes the sequence of operations for the grinding, polishing, and buffing of stainless steels.

Table 8 Sequence of grinding, polishing, and buffing operations for stainless steels

Operation	Stage	Wheels	Grit size	Abrasive	Method	Purpose
Grinding	Rough	Solid wheels; rubber or bakelite bonded, soft body	20-30	Manufactured types, such as Al_2O_3 or SiC	Dry	For rough work on castings, forgings, and weld beads that may require it. Castings usually sandblasted initially
Grinding	Finish	Same as above; or setup disk wheels or abrasive belts	36-80	Manufactured types, such as Al_2O_3 or SiC	Dry	For subsequent operations on the above and also preliminary to polishing operations on hot-rolled plate. May also be employed for touch-up work (removing deep scratches and tool marks prior to polishing)
Polishing	Rough	Setup disk canvas	80-100	Manufactured types,	Grease stick	To produce a rough polished finish and to remove imperfections left

		compress wheels or abrasive belts		such as Al_2O_3 or SiC		by hand wheel grinding. Also use as a preparatory operation for a final polish corresponding to standard No. 4 mill finish. This is the usual starting on cold-rolled sheet.
Polishing	No. 4 finish	Setup disk canvas compress wheels or abrasive belts	120-150	Manufactured types, such as Al_2O_3 or SiC	Grease stick	To provide a finish similar to standard No. 4 mill finish. Variations in fineness of finish should be expected with variations in condition of grit as between a new or worn belt.
Polishing	No. 6 finish (tampico)	Tampico brush type	Start with No. 4 finish	. . .	Pumice pastes made up on the job, or commercially available manufactured compositions	To provide a finish corresponding to standard No. 6 mill finish
Polishing	Pre-No. 7 finish	Made-up cloth wheels or abrasive belts	180	Manufactured types	Grease stick	To provide a finish preparatory to buffing for standard No. 7 finish. May be used as final finish on drawn parts and architectural trim
Polishing	Pre-No. 8 finish	Made-up cloth wheels or abrasive belts	240 to flour	Manufactured types or Turkish emery	Grease stick	To provide a final polished finish preliminary to a mirror finish
Polishing	Satin finishing	Full disk buffs, loose or concentric sewed		Greaseless compounds applied to the wheel as required. These are available in many grit sizes.	. . .	A method of producing satin finishes. Fineness of finish varies with composition employed.
Buffing	Cutting	Bias-type, sewed piece, or fill disk buffs		Use stainless steel cutting compound on buff.	. . .	Apply as needed to remove any residual polishing lines or other imperfections prior to color buffing for high-luster finishes such as No. 7. May be applied directly to bright cold-rolled strip
Buffing	Coloring	Full disk or bias-type buff		Use stainless steel coloring compound.	. . .	For final coloring to bright lusters such as No. 7 and mirror. High speeds for brightness (approximately 50 m/s, or 10,000 sfm). Lower speeds for satinlike finish (approximately 20 to 30 m/s, or 3500 to 6000 sfm)

Before discussing each of these processes, it is useful to review the inherent characteristics of stainless steels that set these materials apart from other metals, and to emphasize the ever-present need to avoid any practices that may result in a loss

in corrosion resistance or a reduction in mechanical property values. For example, stainless steels, as a group, are characterized by:

- *High tensile strength.* This fact determines the power necessary for efficient metal removal in grinding and polishing.
- *High surface hardness.* This governs the selection of abrasive materials and their cutting behavior.
- *Low heat conductivity.* This requires attention to precautionary measures that will prevent rapid or excessive rise in temperature, which can cause heat tint discoloration and, possibly, a reduction in corrosion resistance.
- *Rapid work hardening.* This necessitates proper grinding techniques, especially of austenitic grades in which residual stresses at the metal surface may affect in-service corrosion resistance.
- *Need for cleanliness.* This means attention must be given to grinding and polishing media to keep it clean and free of iron particles, which can be picked up if used with carbon or alloy steel products.

Grinding

Grinding is used for preliminary surface conditioning before polishing, and as a means of removing excess metal from weld beads and flash from forgings and castings. It also is used for dressing gas-cut welding edges. These operations usually require coarse or rough grinding. However, as the refinement of the surface increases with the use of finer abrasives, grinding begins to approach polishing; the dividing line between fine grinding and polishing is seldom clear cut.

Solid wheels are used for coarse grinding and include the vitreous and rubber-bonded or plastic-bonded types. They should be free-cutting to avoid loading and glazing. Abrasives frequently used are aluminum oxide (Al_2O_3) and silicon carbide (SiC), in grit sizes ranging from 20 to 36 (for initial or coarse cutting) to 60 (for subsequent finishing work). Surface speeds for solid wheels usually range between 25.5 and 30 m/s (5000 and 6000 sfm). For safety, wheels should never be operated above their maximum permissible speed. To realize the maximum cutting efficiency of which they are capable, they should not be run at less than recommended speeds.

Wheel Operation. Grinding wheels should never be forced; forcing causes excessive wheel breakdown and localized high temperature in the workpiece. In addition, the wheel should not be allowed to ride on the workpiece with insufficient pressure, because this causes rapid glazing of the wheel.

The elimination of heat buildup in localized zones is of major importance with stainless steel. The low thermal conductivity of stainless steel contributes to increased thermal distortion. This applies particularly to the chromium-nickel grades, of which the coefficients of thermal expansion are relatively high. Holding the metal at low temperature avoids heat tinting, which becomes evident at 230 to 260 °C (445 to 500 °F) and above. Marked increases in metal temperature can reduce the hardness of heat-treated grades and precipitate carbides in the unstabilized chromium-nickel grades, which are susceptible to intergranular corrosion.

Rough surfaces on weldments, castings, and forgings are cut down to the general finish contour with a solid wheel of either Al_2O_3 or SiC of grit size from 20 to 40, and with a bond loose enough to allow the wheel to remain open and free-cutting without excessive wheel wear. Again, it is important to prevent local overheating, which can cause either mechanical or metallurgical damage, and to avoid excessive metal removal, allowing sufficient material for further finishing. Surface contamination is not important at this stage of finishing.

The next roughing operation, which in many applications may replace the solid-wheel operation, requires the use of a portable disk grinder, powered by air or electricity, using abrasive disks coated with Al_2O_3 ranging in grit size from 80 to 120. Localized overheating may be prevented by applying a small stream of water or water-soaked rags to the side not being ground.

Weld Beads. Excess metal in weld beads ordinarily is removed by grinding, although an initial cut may be made with a cold chisel when the size of the bead warrants. Grinding procedures and precautions conform to those previously described, except that the width of weld beads precludes right-angle cutting with successive grit sizes. Usually, a raised bead will take a fairly coarse grit at the outset. Canting of wheels must be avoided; otherwise, grooves may be cut parallel to the bead and undesirable thinness will result. Limiting stops attached to portable grinders may be installed to prevent canting and excessive metal removal.

When grinding is to be followed by polishing, as for weld joints on polished sheet, the grinding operation must terminate sufficiently above the level of the base metal to allow enough metal for final polishing to finish flush, without a ridge or groove. Limiting stops on grinding machines are helpful.

For economic reasons, grinding of weld joints in cold-rolled or polished sheet should be held to a minimum by using welding procedures that avoid high beads of excess metal. The grinding step can often be eliminated, allowing the workpiece to go directly into the polishing operations where finer abrasives are used.

Metal adjacent to beads that are being ground should be protected from flying bits of metal cuttings by shields of material such as paper. Wet rags may be laid on the workpiece to absorb heat and reduce thermal distortion, particularly on thin-gage material.

Progressive Grinding. To remedy an existing surface condition, such as removing scale patterns or indentations from hoisting clamps on an annealed plate, a series of wheels of decreasing grit size is often needed. The initial grit size is selected on the basis of which coarseness is needed to remove the major portion of the unwanted condition. After the workpiece has been partly dressed down, the operation is completed by using a graduated series of successively finer wheels until the desired final finish is attained. The use of a relatively soft plastic wheel impregnated with fine, sharp grit makes it possible to reduce the number of finishing operations, because of the combination of free cutting and wheel resilience for ease in blending.

The direction of wheel traverse across the work is changed by 90° with each change in grit size to remove residual grinding lines. As each change is made, workpiece surfaces should be brushed thoroughly to remove any particles of the preceding abrasive or of metal cuttings that mar the performance of the finer grit to follow. The progression from coarse to fine grit size may be made in steps of 20 to 40 mesh.

When using a flat disk grinder, with which cutting is performed against the face (instead of the rim) of the wheel, a rotary or circular traversing motion is most frequently used. This eliminates the need for reversing the direction of grinding with each change of grit size.

Belt Grinding. Belts carrying abrasives of various grit sizes are widely used for grinding and polishing stainless steel surfaces. Although many complex shapes can be belt ground, a simple projection may make belt grinding impossible; for example, the studs welded to a cookware pot or pan to which the handle is affixed. In this application, the finishing operations, from grinding to color buffing, must be completed before the studs are welded in place. Grit sizes and belt speeds for abrasive grit roughing and polishing are given in Table 9.

Table 9 Grit sizes and belt speeds for abrasive belt roughing and polishing of stainless steels[a]

(a) Abrasive belts coated with Al_2O_3, unless grit size is footnoted to indicate otherwise.

(b) G, grease; O, oil; WSO, water-soluble oil.

(c) Silicon carbide.

(d) Fixture abrasive, reciprocating.

Mechanized Belt Grinding. In mechanized belt grinding, longer belts provide a longer belt life and dissipate heat more effectively. Thus, longer belts frequently are operated without a coolant, eliminating a post-grinding cleaning operation.

In belt grinding of rectangular stainless steel sinks, for example, it was necessary to use short belts to reach all internal surfaces. Each sink was ground in a machine with four grinding heads indexing about the main column of the machine while the sink was held in a cradle that rotated in a horizontal plane. A narrow belt ground the radii between the bottom and the side walls of the sink. Wider belts were used to grind the side walls; these belts were comparatively short and required the use of a coolant. Belt abrasives varied in grit size from 80 to 220 mesh, depending on the desired finish.

On a typical grinding machine using a 2200 mm (86 in.) wide abrasive belt and powered by a 250-hp ac motor, a positive hydraulic reciprocating drive permits instantaneous variations in table speed; belt speed is fixed at 25.5 m/s (5000 sfm). The 2200 mm (86 in.) belt travels over a conventional vertical-head assembly consisting of a dynamically balanced upper idler roll of steel and a rubber-covered serrated lower contact roll. A pneumatic belt-centering device ensures positive tracking of the abrasive belt and is adjustable to compensate for belts of different widths. Incorporated into the entire worktable is a 2200 mm (86 in.) wide vacuum chuck 4.9 m (16 ft) long. To produce single or compound tapers, a worktable can be tilted to any angle, for either right-hand or left-hand tapered sheets.

Belt life is influenced primarily by belt speed, type of material being ground and its hardness, pressure of the belt against the work, type of contact roll, type of lubricant (if a lubricant is required), and uniformity of the finish desired. In belt grinding of stainless steel, the recommended belt speed is approximately 20 m/s (4000 sfm).

With the exception of the precipitation-hardening stainless steels, the hardness of the steel has a greater effect on the life of a grinding belt than its composition. Hardness also affects surface finish, and a high-quality finish is easier to obtain on a harder stainless than on one that is softer. With precipitation-hardening alloys, best grinding results are obtained with a waterproof cloth abrasive belt and a water-soluble oil lubricant.

Pressure of the workpiece against the abrasive belt is probably the most important factor affecting belt life. Excessive pressure on a new belt causes glazing of the abrasive and greatly reduces cutting action. Therefore, new belts should be subjected to very light pressures during the break-in period and until the belt is capable of maintaining a uniform cutting action. A light belt pressure is preferred, and increased stock removal should be obtained by changing to a coarser belt.

The contact roll that backs up the abrasive belt is another important factor; a properly serrated contact roll may increase belt life by as much as 60%. The angle of the serration affects both belt life and finish. To obtain fine finishes, contact rolls serrated at an angle of 75° to the axis of the spindle should be used. Rough finishing requires a 30° angle. For general work, contact rolls may be made with a 45° serration, using a 9.5 mm ($\frac{3}{8}$ in.) groove and 9.5 mm ($\frac{3}{8}$ in.) land. Hardness of the contact roll should range between 50 to 65 on the Shore scleroscope A-scale.

When lubricants are used, they should maintain free-cutting (nonloading) edges, add color to the finished product, maintain a cool cutting surface, and be easy to apply. Lubricants may be in the form of grease sticks, waxes, or cutting oils. Cutting oils generally are more effective when they are diluted as much as 4 to 1 with kerosene.

Safety. Metal fines collected in a container near machines during the belt grinding of stainless steel should be removed regularly, because the fines, together with polishing compounds or oils that are collected with them, constitute a potential fire hazard. Fires in the duct system can be extremely serious because of the high air flow in the ducts. Fire-extinguishing equipment should be close to any machines using abrasive belts.

When wide abrasive belts are used, equipment with automatic tracking to center the belt in relation to the work is advantageous. All abrasive belt machinery should be equipped with motors that are totally enclosed.

Safety training for operators should begin with thorough instruction in the proper use of equipment, because most severe injuries result from improper use. Most common injuries are burns, cuts, and eye injuries. Serious accidents may arise

from the snagging of parts because of improper loading, improper use of lubricating devices, and careless placement of hands and arms while the machine is in operation.

Polishing

Polishing operations use abrasives that are mounted on prepared shaped wheels or on belts that provide a resilient backing. The stainless steel to be polished may be in either a smooth rolled or a previously ground condition. For the smooth rolled condition, the starting grit size should be selected in a range of 150 to 220. For the ground condition, the initial grit should be coarse enough to remove or smooth out any residual cutting lines or other surface imperfections left from grinding. In either instance, the treatment with the initial grit should be continued until a clean, uniform, blemish-free surface texture is obtained. The initial grit size to use on a preground surface may be set at about 20 numbers finer than the last grit used in grinding and may be changed, if necessary, after inspection. A tallow lubricant may be used to reduce the sharpness of cutting. With broad-belt grinding of stainless steel sheet, the use of a lubricant or coolant is mandatory.

After completion of the initial stage of polishing, wheels or belts are changed to provide finer grits. The step-up in fineness is usually by 30 to 40 numbers. Each succeeding treatment is continued until all residual marks of the preceding cut are removed. Grease in stick form is applied to wheels carrying abrasives of 150 mesh and finer. Aluminum oxide buffing compounds and powdered pumice are preferred for use with abrasives of 200 mesh and finer grit size.

Polishing speeds are generally somewhat higher than those used in grinding. A typical speed for a coated-wheel operation is 38 m/s (7500 sfm).

The same precautions that must be observed in the grinding of stainless steel are equally applicable to polishing:

- Avoidance of iron or other contamination
- Care of wheels and belts when not in use
- Restriction of the use of wheels and belts to stainless steel only
- Avoidance of excessive pressure while polishing
- Operation at proper speeds
- Avoidance of localized heat buildup because of dwelling at one spot
- Removal of loose cuttings and bits of abrasive from work surfaces before changing from one grit size to another

Buffing

Buffed finishes are produced on stainless steel surfaces by using equipment, materials, and techniques that are similar to those used on other materials (see the article "Finishing Methods Using Multipoint or Random Cutting Edges" in this Volume). However, the skill needed for producing the high lusters obtainable on stainless steel is gained only through actual experience. Buffed finishes are not recommended for the stabilized grades of stainless steel, such as types 321 and 347, because these materials contain fine, hard particles of titanium or niobium compound that show up as pits on bright finishes.

The first step in applying a buffed finish of desired luster and color is that of providing a smooth surface, free of scratches and any other defects. For this reason, buffing is generally performed in two stages: the first is known as hard buffing (or cutting down); the second, as color buffing.

Hard buffing follows polishing, which generally ends with the use of abrasives of 200- to 250-mesh grit size. The fine scratches left by polishing are cut down with a buff that carries no previously glued on abrasive. Instead, such abrasive as is needed is applied intermittently to the buffing wheel as it rotates, either by rubbing a cutting compound in bar or stick form against it or by spraying it with a liquid compound. These cutting compounds contain (1) very fine artificial abrasives, such as Al_2O_3, of about 300-mesh grit size; and (2) a stiff grease or other material that acts as a binder. They adhere to the wheel by impregnating the cloth disks. Hard buffing may be conducted at from 33 m/s (6500 sfm) up to a maximum of 51 m/s (10,000 sfm).

Color buffing is performed in the same manner as hard buffing, except that a coloring compound is substituted for the cutting compound and speeds are held below 36 m/s (7000 sfm). Various compounds (rouges and other extremely fine

abrasives) for use on stainless steel are available commercially, both in bar form for hand application and in liquid form for automatic application. The use of any material that may result in loss of corrosion resistance by stainless steel surfaces should be avoided.

Direct color buffing, without previous polishing or hard buffing, may be satisfactory for certain applications, such as:

- A color-buffing wheel may be applied directly on type 430 that has been given a finishing pass on a polished mill roll after final pickling.
- Small articles blanked from bright finished straight chromium steel strip and then tumbled for burr removal may have a satisfactory appearance if run under a color buff for brightening.
- Smooth, defect-free surfaces that have been electrolytically polished provide a good base for color buffing. By masking before buffing, contrasting surface effects can be obtained, as a result of the difference in reflectivity obtainable by electrolytic polishing and by color buffing.

Color buffing, however, does not remove scratches or other surface defects because cloth wheels without coarse abrasives, which are used for color buffing, do not remove surface imperfections. Therefore, the continued presence of such imperfections on finished products must be expected.

Effect of Polishing and Buffing on Corrosion Resistance. In addition to altering the appearance of stainless steels, polishing and buffing may have a considerable effect on the corrosion resistance of these materials. For example, a steel with a No. 2B finish as received from the mill has excellent corrosion resistance. This can be adversely affected by polishing with coarse abrasive, but it can be fully restored by polishing to a No. 4 finish or higher. Polishing to a No. 7 or 8 finish, by removing very fine pits and other surface defects, improves corrosion resistance over that afforded by the original No. 2B finish.

Tanks for storing raw milk provide a commercial example of the importance of a polished finish to sanitary and corrosion-resistance properties. According to the sanitary codes, these tanks must be made of 300-series stainless steel, and all surfaces that come in contact with the milk must be polished to a pit-free No. 4 finish or better. The high finish not only promotes sanitary properties, but also provides improved resistance to corrosion by the chlorine-bearing chemical used in scouring the tanks after each use.

Several polishing and buffing compounds contain iron and iron compounds, which can be highly deleterious to the corrosion resistance of stainless steel. The amount of iron in these compounds that can be tolerated is extremely small (for maximum protection, less than 0.01% Fe). If more than one polishing operation is involved, slightly more iron can be tolerated in the early stages of polishing, but the final stage should be virtually iron-free. Magnetic oxides of iron are as damaging as iron powder; the oxides generally occur in Turkish emery as well as in several synthetic abrasives. Their presence is most accurately determined by chemical analysis.

Cleaning and Passivation After Buffing. Cleaning is always required after a final buffing operation in which a surface finish of No. 4 or finer is achieved. The workpiece is vapor degreased or is cleaned with whiting (precipitated calcium carbonate), powdered chalk, or dehydrated lime, which is applied with a soft flannel cloth. This picks up the grease or lubricant from a color-buffing operation. The workpiece must then be protected from damage in handling.

Passivation is not required after buffing or fine polishing if the surface obtained is chemically clean and free of oil, grease, or adhesives used in the polishing media. A clean surface passivates itself naturally when it is exposed to air. However, if foreign metal, such as iron, has been picked up in the buffing operation, it must be removed by pickling or passivation.

Matching Mill Finishes

In the fabrication of No. 4 polished sheet, it frequently is necessary to refinish weld zones to blend them with the original finish. Although it is virtually impossible to match a machine-polished surface except by duplicating the original polishing, a close blending may be obtained by skillful use of manual methods.

If the original machine-polished lines are parallel with the line of the weld, the bead can be dressed down by grinding with a hard or soft wheel and then finished by polishing with, progressively, No. 80 and No. 120 (and possibly No. 150) grit on a setup wheel driven by a portable machine. The traversing of this wheel should be kept in line with the run of the bead so that its cut lines are kept parallel with those of the original machine-polished surface.

To avoid residual ridges or grooves, the metal of the joint should be brought flush with that of the base metal. For a given starting grit size, the depth of the scratches produced depends on the amount of use it has received; thus, samples should be run before starting on finish work.

If the machine-polished lines are not parallel with the line of the weld, final manual polishing should be done in the direction of the machine polishing. If the original polish lines on the two sides of a joint are not parallel with each other (for example, if they are parallel with the bead on one side and perpendicular to the bead on the other) the best procedure is to run the polishing cut lines along (not across) the bead. The girth weld between a tank shell and head exemplifies this problem. The cut lines of the shell extend around the unit and lie parallel with the girth joint, whereas the cut lines on the head are perpendicular, parallel, and at an angle around the periphery. Swinging such an assembly on the faceplate of a large lathe would permit repolishing the head and dressing the weld joint on the same setup, thus rendering parallel all of the cut lines on the head, joint, and shell. For this application, abrasive paper (or pieces cut from a belt) may be backed up with a block of wood or some softer material and guided by hand along the line of the weld joint.

Electrocleaning and Electropolishing

Electrocleaning, an electropolishing technique, is a useful alternative to pickling treatments (Ref 5). Although electrocleaning is not covered under ASTM A 380, it is widely used to remove imperfections from the surface of stainless steel after fabrication. It removes embedded iron particles and similar film defects as does pickling. Unlike pickling, electrocleaning does not roughen the surface, but makes it smoother. A 12 V dc power source with variable current capability is connected to the stainless steel, making it the anode. A copper cathode and an electrolyte--usually phosphoric acid (H_3PO_4)--are then used to corrode away the protective film and several layers of the surface in a controlled manner by varying the current and dwell time.

Electrocleaning can be performed in most plating shops by immersion. Localized electrocleaning with field kits is widely practiced to remove heat tint and weld-related defects from the heat-affected zone (see Fig. 3).

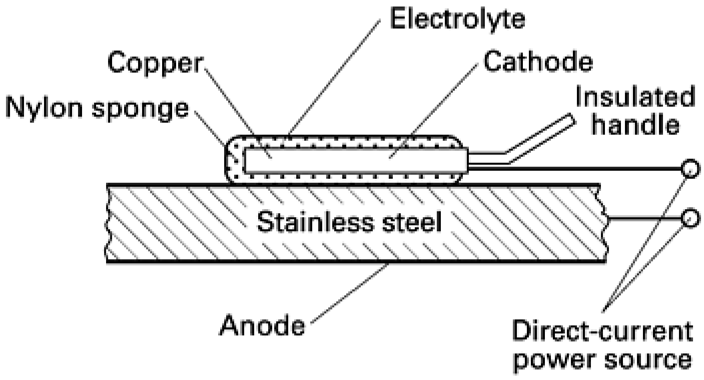

Fig. 3 Equipment for localized electrocleaning of heat tint from the surface of stainless steel. Source: Ref 5

Electropolishing is the same process as electrocleaning, but is generally performed for a longer time (Ref 5). Electropolishing is used primarily to produce a very smooth, bright, easily cleaned surface with maximum corrosion resistance. It removes the surface layer of a metal by anodic treatment in an acid bath. Conditions for electropolishing of stainless steels in acid electrolytes are given in Table 10.

Table 10 Conditions for electropolishing in acid electrolytes

Type of metal (and product)	Purpose of treatment	Bath volume		Installed power		Current density		Polishing cycle, min	Daily production			Oper-ators
									No. of parts	Area		
		L	gal	A	V	A/dm^2	A/ft^2			m^2	ft^2

Electropolishing is applicable to all stainless steel grades, hot or cold finished, cast or wrought. The amount of metal removed is subject to close control, depending on the desired result. The resulting surfaces have a bright, passive finish. The process is most frequently applied to cold-finished surfaces, because they yield a smoother finish than can conventionally be obtained on hot-finished surfaces. As in electroplating, the results depend on the contour and shape of the part. The end-grain surfaces of the free-machining stainless grades, such as types 303 and 416, will appear frosty after electropolishing due to removal of the sulfide inclusions.

Electropolishing can be used as a preliminary brightening operation before final buffing, particularly on drawn parts with burrs, sharp radii, or recessed areas, and it serves to reduce the amount of buffing required. Electropolishing is applied to decorative automotive parts and accessories, conveyor systems for food-handling equipment, animal cages, and pharmacy equipment. It provides an economical finish on many parts that are difficult or impossible to finish by conventional polishing, such as items made from wire.

In contrast to mechanical finishing methods, electropolishing may make inclusions in the material more visible. Some types of inclusions are dissolved out, whereas others remain in relief. Electropolishing has been used as a surface inspection technique to reveal residual foreign material, such as embedded scale and particles of iron, carbide precipitation, and weld defects. The surface obtained by electropolishing is directly related to the original surface quality--the process cannot be used to remove digs, gouges, scratches, and the like.

Chemical polishing is another method for providing a smooth and bright surface on stainless steel. Unlike electropolishing, chemical polishing can be done without the use of electricity and without racking of individual parts. Thus, chemical polishing offers significant savings in capital investment and labor. In addition, chemical polishing offers a greater degree of freedom in polishing items with blind holes and other recessed areas. However, it does not produce the high specular reflectivity (brightness) obtained with electropolishing.

Proprietary products for chemical polishing are available on the market. Generally, they are based on combinations of H_3PO_4, HNO_3, H_2SO_4, hydrochloric acid (HCl), organic acids, and special surfactants and stabilizers to promote a high degree of brightness and long bath life. Unlike the HNO_3-HF mixtures that are used in chemical cleaning, the proprietary chemical bright dips do not cause severe attack on the grain boundaries or intergranular corrosion.

Passivation Treatments

Exposure to air is the natural, primary passivation treatment for stainless steel. This exposure produces a thin, durable chromium oxide film that forms rapidly on the alloy surface and gives stainless steel its characteristic "stainless" quality. Exposure of the surface to water or other oxidizing environments also produces this passivating film. Additional passivation is called for in many specifications to remove light surface contamination from machined stainless steel parts, including shop dirt, iron particles from cutting tools, and machining lubricants. Passivation treatments of stainless steel with HNO_3 or mild organic acids are useful mild cleaning operations performed after machining to enhance the protective nature of the natural, air-formed film. Nitric acid treatment enhances the level of chromium in the protective film on stainless steels. DeBold (Ref 6) has published an excellent practical review of HNO_3 passivation of stainless steel machined parts.

ASTM A 380 (Ref 1) describes eight HNO_3-based cleaning/passivation treatments and four cleaning treatments using other chemicals (Table 11). None of these passivation treatments corrodes or etches the surface. Several are designed to clean bright or polished surfaces by removing loosely adherent foreign matter. The most common treatment is immersion in a 20 to 40% solution of HNO_3 at a temperature of 50 to 60 °C (120 to 140 °F).

Table 11 Acid cleaning and passivation of stainless steel

Alloy	Condition	Treatment				
		Code	Solution, vol%[a]	Temperature		Time, min
				°C	°F	
Part 1: Cleaning with HNO_3-HF						
Purpose: For use after descaling by mechanical or other chemical methods as a further treatment to remove residual particles of scale or products of chemical action (i.e., smut), and to produce a uniform "white pickled" finish						
200 and 300 series, 400 series containing 16% Cr or more, and precipitation-hardening alloys (except free-machining alloys)	Fully annealed only	D	6-25% HNO_3 plus $\frac{1}{2}$ to 8% HF[b][c]	20-60	70-140	As necessary
Free-machining alloys, maraging alloys, and 400 series containing less than 16% Cr	Fully annealed only	E	10% HNO_3 plus $\frac{1}{2}$ to 1 $\frac{1}{2}$% HF[b][c]	20 (up to 60 with caution)	70 (up to 140 with caution)	1-2
Part 2: Cleaning/passivation with HNO_3solution						
Purpose: For removal of soluble salts, corrosion products, and free ion and other metallic contamination resulting from handling, fabrication, or exposure to contaminated atmospheres						
200 and 300 series, 400 series, precipitation hardening and maraging alloys containing 16% Cr or more (except free-machining alloys)[d]	Annealed, cold rolled, or work hardened, with dull or nonreflective surfaces	F	20-50% HNO_3	50-70	120-160	10-30
				20-40	70-100	30-60[c]
	Annealed, cold rolled, or work hardened, with bright-machined or polished surfaces	G	20-40% HNO_3 plus 2-6 wt% $Na_2CrSO_7 \cdot 2H_2O$	50-70	120-155	10-30
				20-40	70-100	30-60[c]
400 series, maraging and precipitation-hardening alloys containing less than 16% Cr, and high-carbon/straight-chromium alloys (except free-machining alloys)[d]	Annealed or hardened, with dull or nonreflective surfaces	H	20-50% HNO_3	45-55	110-130	20-30
				20-40	70-100	60
	Annealed or hardeneith bright-machined or polished surfaces	I[f]	20-25% HNO_3 plus 2-6 wt% $Na_2Cr_2O_7 \cdot 2H_2O$	50-55	120-130	15-30
				20-40	70-100	30-60

200, 300, and 400-series free-machining alloys[d]	Annealed or hardened, with bright-machined or polished surfaces	J[f]	20-50% HNO_3 plus 2-6 wt% $Na_2Cr_2O_7 \cdot 2H_2O$[g]	20-50	70-120	25-40
		K[e]	1-2% HNO_3 plus 1-5 wt% $Na_2Cr_2O_7 \cdot 2H_2O$	50-60	120-140	10
		L[f]	12% HNO_3 plus 4 wt% $CuSO_4 \cdot 5H_2O$	50-60	120-140	10
Special free-machining 400-series alloys with more than 1.25% Mn or more than 0.40% S[d]	Annealed or hardened, with bright-machined or polished surfaces	M[f]	40-60% HNO_3 plus 2-6 wt% $Na_2Cr_2O_7 \cdot 2H_2O$	50-70	120-160	20-30
Part 3: Cleaning with other chemical solutions						
200, 300, and 400 series (except free-machining alloys), precipitation hardening and maraging alloys	Fully annealed only	N	1 wt% citric acid plus 1 wt% $NaNO_3$	20	70	60
		O	5-10 wt% ammonium citrate	50-70	120-160	10-60
Assemblies of stainless and carbon steel (for example, heat exchanger with stainless steel tubes and carbon steel shell)	Sensitized	P	Inhibited solution of 2 wt% hydroxyacetic acid and 1 wt% formic acid	95	200	6 h
		Q	Inhibited ammonia-neutralized solution of EDTA (ethylene-diamene-tetraacetic acid) followed by hot-water rinse and dip in solution of 10 ppm ammonium hydroxide plus 100 ppm hydrazine	Up to 120	Up to 250	6 h

Source: Ref 1

(a) Solution prepared from reagents of following weight percent: HNO_3, 67; HF, 70.

(b) For reasons of convenience and handling safety, commercial formulations containing fluoride salts may be found useful in place of HF for preparing HNO_3-HF solutions.

(c) After acid cleaning and water rinsing, a caustic permanganate solution containing 10 wt% NaOH and 4 wt% $KMnO_4$, 70 to 80 °C (160 to 180 °F) 5 to 60 min, may be used as a final dip for removal of smut, followed by thorough water rinsing and drying.

(d) The purchaser shall have the option of specifying in his purchase documents that all 400-series ferritic or martensitic parts receive additional treatment as follows: Within 1 h after the water rinse following the specified passivation treatment, all parts shall be immersed in an aqueous solution containing 4 to 6 wt% $Na_2Cr_2O_7 \cdot 2H_2O$, at 60 to 70 °C (140 to 160 °F) 30 min. This immersion shall be followed by thorough rinsing with clean water. The parts then shall be thoroughly dried.

(e) Shorter times may be acceptable where established by test and agreed upon by the purchaser.

(f) The high-carbon and free-machining alloys may be subject to etching or discoloration in nitric acid. This tendency can be minimized by the use of high acid concentrations with inhibitors such as $Na_2Cr_2O_7 \cdot 2H_2O$ and $CuSO_4 \cdot 5H_2O$. Oxidizing action increases with increasing concentration of nitric acid; additional oxidizing action is provided by $Na_2Cr_2O_7 \cdot 2H_2O$. Avoid acid cleaning when possible; use mechanical cleaning followed by scrubbing with hot water and detergent, final thorough water rinsing, and drying.

(g) If flash attack (clouding of stainless steel surface) occurs, a fresh (clean) passivating solution or a higher HNO_3 concentration will usually eliminate it.

The complete passivation treatment includes degreasing, immersion, and rinsing. Degreasing, preferably in a nonchlorinated solvent, removes organic contaminants from the surface.

Degreasing. Neither air nor HNO_3 can form or enhance the protective film when grease, oil, fingerprints, or other organic contamination is present on the surface. Parts must be thoroughly degreased prior to any passivation treatment. The water-break test, described in ASTM A 380 (Ref 1), is easy to apply and is effective in detecting residual organic matter that may not have been removed in the degreasing operation. A sheet of water directed over the surface will "break" around oil, grease, and other organic contaminants not completely removed from the surface. Specifications can simply call for no break in the film as it drains from the vertical surface.

Immersion. The part is immersed in a passivating solution selected from Table 11 (Part 2 or 3). In addition to the standard HNO_3 solution, there are a number of solution variations appropriate for all grades of 200, 300, and 400 series, maraging, precipitation hardening, and free-machining alloys in various heat treatment conditions and surface finishes.

Rinsing. Immediate and thorough rinsing in clean water of pH 6 to 8 is mandatory. In many instances neutralization prior to rinsing is helpful. Immersion, neutralization, and rinsing must follow one another without allowing the surface to dry between steps. When passivating stainless steel sheet material, each sheet must be completely dry before it is stacked to avoid marks.

In addition to the cleaning precautions given in ASTM A 380 (Ref 1), different grades of stainless steel should not be mixed in the same passivating bath, as this can initiate corrosion where surfaces come in contact.

Although HNO_3 does not normally corrode stainless steel, it will corrode surfaces that are significantly altered. Acid cleaning should not be used for carburized and nitrided stainless steel parts or for improperly heat-treated high-carbon/high-chromium martensitic grades that have not been fully hardened.

Passivating Free-Machining Steels. The procedure for passivating free-machining stainless steels is somewhat different from that used for non-free-machining grades; that is because sulfides of sulfur-containing free-machining grades, that are totally or partially removed during passivation, create microscopic discontinuities in the surface of the machined part. Even normally efficient water rinses can leave residual acid trapped in these discontinuities after passivation. This acid can then attack the surface of the part unless it is neutralized or removed. For this reason, a special passivation process is required for free-machining grades.

The alkaline-acid-alkaline (A-A-A) method described in Ref 6 neutralizes trapped acid and is accomplished in less than two hours. The A-A-A method consists of the following steps:

- After degreasing, the parts are soaked for 30 min in a 5% solution of sodium hydroxide at 70 to 80 °C (160 to 180 °F)
- Water rinse
- The parts are then immersed for 30 min in a 20% HNO_3 solution containing 22 g/L (3 oz/gal) of sodium dichromate at 50 to 60 °C (120 to 140 °F)
- Water rinse
- Immerse the part for another 30 min in the sodium hydroxide solution at 70 to 80 °C (160 to 180 °F)

- Water rinse and dry (passivation is now complete)

Electroplating

Stainless steels may be plated with copper, brass, chromium, nickel, cadmium, and the precious metals for such purposes as:

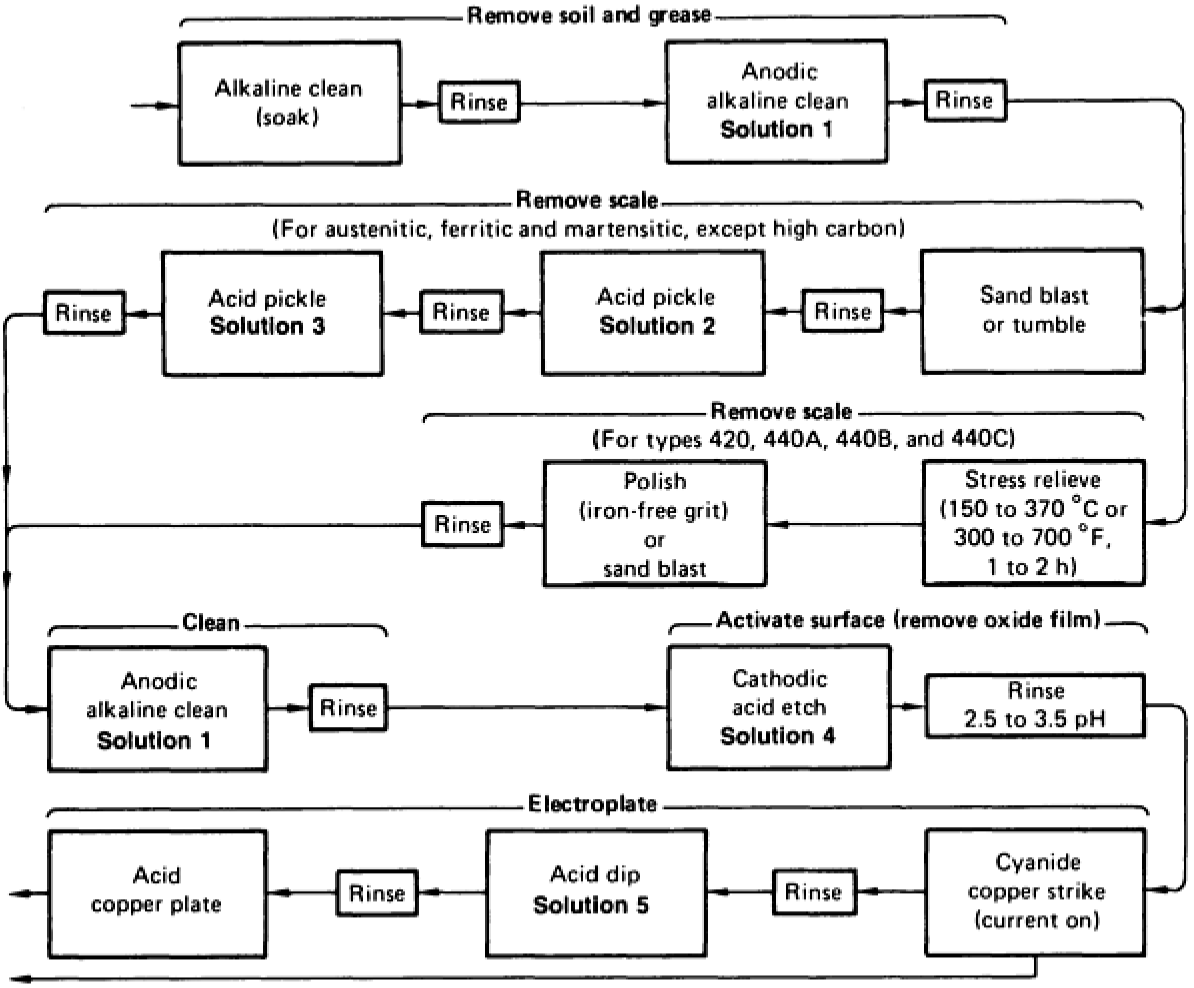
- Color matching
- Lubrication during cold heading, spring coiling, or wire drawing
- Reduction of scaling at high temperature
- Improvement of wettability or of conductance of heat or electricity
- Prevention of galling
- Decorative uses in such applications as jewelry
- Prevention of superficial rusting

Detailed information on plating bath compositions, control of bath composition, bath temperature, plating equipment, process limitations or advantages, and applications for electrodeposits can be found in the articles contained in the Section on "Plating and Electroplating" in this Volume.

Although a stainless steel surface may be clean and scale-free, an adherent electrodeposit cannot be obtained until the surface is activated for removal of its normally ever-present oxide film. Activation, which is performed immediately before plating, may be accomplished by cathodic treatments, immersion treatments, or simultaneous activation-plating treatments. These treatments, together with other procedures necessary for preparing stainless steel for electroplating, are fully described in ASTM B 254 (Ref 7).

Figure 4 summarizes some of the data from ASTM B 254. The same cleaning procedures would be appropriate before electrodeposition of other metals. When preparing stainless steel for electroplating, the following should be considered:

- *Electrocleaning:* When bright plating is desired, the alkalinity, current density, and temperature of the cleaning bath should be kept as low as possible, especially for the high-chromium alloys. To minimize the severity of electrocleaning when a bright finish is desired, a short electropolishing treatment may be used in lieu of electrocleaning, provided that the preliminary cleaning is adequate.
- *Acid pickling:* Freshly prepared pickling baths should be activated by dissolving some iron in them before using the bath; otherwise, the rate of pickling is slow until the bath has dissolved some iron from the steel being treated.
- *Activating:* The activation step is the most important in surface preparation of stainless steel for electroplating. If the simultaneous activation-plating treatment is used, where the anodes are nickel, the nickel content of the solution gradually increases because of the low cathode efficiency. This can be compensated for by removing a portion of the solution and replenishing with HCl. The activation-plating treatment is usually preferred for stainless steel parts that are to be copper plated.
- *Plating:* After activating and rinsing, the work should be entered directly into the electrolyte. When possible, the rinse water should be slightly acid (2.5 to 3.5 pH); the required acidity is usually provided by the dragout of acid from the activation treatment. Stainless steel has much lower electrical conductivity than most other metals, and thus adequate attention should be paid to racking when introducing work into copper electrolyte, to ensure an adequate number of contacts to obtain complete coverage in minimum time.



Solution no.	Type of solution	Composition of solution	Operating temperature		Cycle time, min
			°C	°F	
1	Anodic alkaline cleaner[(a)]	Alkali, as low as possible	[(b)]	[(b)]	[(b)]
2	Acid pickle	H_2SO_4, 8-11%	65-70	150-70	10-45

Other Coating Processes (Ref 2)

Painting. In the painting of stainless steel surfaces, the main requirement to be satisfied is that of providing a good permanent bond. Stainless steel surfaces are dense, hard, and smooth, particularly when in the cold-rolled or polished condition. For that reason, it is usually advisable to roughen them by means of strong pickling or sandblasting. The latter is advantageous because it can be readily confined to limited areas by masking.

In the transportation industry, acid etching is usually favored as a preliminary step in painting stainless steels. The etchants are solutions of either HCl or HF:

Solution 1

- 25 parts water by volume
- 75 parts HCl by volume
- 5 parts HNO_3 by volume
- 20 wt% $FeCl_3$

Solution 2

- 10 to 20 vol% HNO_3
- 3 to 5 vol% HF
- Remainder water

The stainless steel has either a No. 2D or 2B finish. Paint companies are best qualified to suggest paint types and procedures for prime and finish coats.

Cleanliness is a key element in painting stainless steels. The surface must be clean, and it is good practice to paint only in a clean, dust-free atmosphere. Use thin coats and allow plenty of time to dry between coats.

Sandblasting is best accomplished with clean, hard sand of relatively small grit size driven by an air blast that is entirely free of compressor oil. (Glass beads are sometimes used.) Thin-gage material should be backed up to avoid distortion. Surfaces should be dry and completely free of grease, oil, or any other foreign material before applying the ground coat. More detailed information on the selection and application of various paint types can be found in the article "Painting" in this Volume.

Surface Blackening. Stainless steel surfaces can be readily blackened by immersion in a molten salt bath of sodium dichromate. This practice, which is not complicated to set up and operate, is widely used by the automotive industry to blacken stainless steel parts, such as windshield wipers, and it is used by manufacturers of stainless steel solar collector panels.

The process applies a very thin, smooth black oxide film to the surface of all stainless steel types. The film is normally dull black in color, but it can be brightened by the application of oils or waxes. The film shows no tendency to age or lose color in service. It is ductile, will not chip or peel, and is resistant to heating to the normal scaling temperature of the stainless steel. A blackened stainless steel can be deformed moderately without harm, and the film exhibits good resistance to abrasion.

The salt bath operates at approximately 400 °C (750 °F), and dip time varies from 5 to 30 min, followed by a wash-water rinse. Solar panels achieve an ideal blackening in 5 min, while auto trim parts require about 30 min to obtain a deeper black color.

Coloring. A proprietary process used for coloring stainless steels involves immersing the material in a hot chromic-sulfuric acid solution, followed by a cathodic hardening treatment in another acidic solution. The reaction of the base material with the hot acid produces a transparent film which in itself is basically colorless, but which shows colors through the phenomenon of light interference. Colors produced, in normal time sequence, are bronze, blue, gold, red, purple, and green, and within this range a wide variety of shades are possible. A black finish is also available. Appearance is also dependent on the nature of the starting surface: matte and satin surfaces produce matte colors; polished surfaces exhibit a high degree of metallic luster. The process is being used throughout the world for architectural applications, furniture, bathtubs, consumer products, and automotive trim.

Different effects can be achieved, for example, by alternating bright polished and satin finished sheets, by selective polishing prior to coloring, and by using cold-embossed colored stainless steel. Masking, screen printing, and photo-resist techniques can be employed to achieve patterned effects and for the reproduction of photographic images. Colored stainless steel can be subjected to considerable deformation without detriment. It can, for example, be drawn, bent through quite sharp angles, and embossed without any deleterious effects or reduction of color intensity. Corrosion resistance of colored stainless is at least as good as that of the untreated material, and exposure tests extending over a number of years have shown no deterioration of color.

Terne coatings can be applied to stainless steels by hot dipping sheet in a lead-tin alloy that typically consists of 80% Pb and 20% Sn. Terne coatings were used as early as the 11th century on church roofs in western Europe. Terne-coated stainless steel, however, was introduced only in the 1960s. Since then it has grown in popularity, particularly for architectural (roofing) applications, because of its strength, long life, and attractive patina acquired with age.

The stainless steel that forms the core is usually S30400 or S31600. As well as providing corrosion resistance, the stainless steel offers superior strength and ductility compared to other roofing materials and, because of its high-temperature strength, provides enhanced structural integrity and safety in case of fire.

The terne-coated stainless steel sheet (minimum of 20 μm of coating per side) weathers in one to two years to a uniform gray, the precise shade depending on the sulfur content of the atmosphere. The result is a material with an aged appearance that can blend in with existing roofing or give a new building a distinctive appearance. Because terne coatings are anodic to stainless steel, corrosion resistance can be further improved.

Thermal Spraying. Wear-resistant coatings and thermal barrier coating systems have been applied to stainless steel substrates by plasma spraying and high-velocity oxyfuel (HVOF) thermal spray processes. Most of the work has centered around the use of stainless steels, such as S17400 (17-4 PH), in diesel engines. Plasma sprayed thermal barrier coatings on 17-4 PH piston rings include composite zirconia (ZrO_2)/NiCrAlY coatings (Ref 8). Wear resistant coatings include Cr_3C_2-20% NiCr cermets deposited by the HVOF process and plasma sprayed chromium oxide-based coatings (Ref 9).

Surface Modification

Surface modification is the alteration of surface composition or structure by the use of energy or particle beams. Elements may be added to influence the surface characteristics of the substrate by the formation of alloys, metastable alloys or phases, or amorphous layers. Surface-modified layers are distinguished from conversion or coating layers by their greater similarity to metallurgical alloying versus chemically reacted, adhered, or physically bonded layers.

Ion implantation is one of a number of surface modification processes that is emerging as an economical and viable process for improving the near-surface tribological properties of engineering components. In many engineering situations, material selection is often based on a compromise of bulk mechanical properties and near-surface tribological properties, with neither at their optimum values. As a result, there is considerable interest in fabrication processes, such as ion implantation, that make it possible to retain the bulk properties of a given compound yet still achieve desirable tribological properties in near-surface regions.

Ion implantation is a process by which virtually any element in the periodic chart can be injected into near-surface regions of any solid using a beam of high-velocity ions with energies typically ranging from 10 keV up to several MeV. As the ions slow down in the material, they are distributed at depths ranging from a few nanometers to several micrometers, depending on the particle energy, angle of incidence, and substrate composition. Depending on the ion type, mass, energy, dose, deposition temperature, and substrate composition, the chemical, electrical, thermal, microstructural, and crystallographic properties of near-surface regions can be significantly altered to improve the friction and wear performance of the component.

Examples of end-use applications of ion implanted stainless steels are bearing rings and ball bearings made from S44004 (type 440C) that are used in the Space Shuttle (Ref 10). The corrosive wear performance of the bearing rings was improved by implanting chromium plus nitrogen (CrN) ions. Significantly lower friction and wear rates were achieved in the ball bearings via ion implantation with titanium plus carbon (TiC) ions and titanium ions alone.

Laser surface processing includes laser transformation hardening, laser melting, laser alloying, laser cladding, and laser melt/particle injection. Of these five method, laser alloying and laser melt/particle injection have been carried out the most on stainless steels. A review of laser surface processing can be found in Ref 11.

Laser Alloying. A technique of localized alloy formation is laser surface melting with the simultaneous, controlled addition of alloying elements in powder form. These alloying elements diffuse rapidly into the melt pool, and the desired depth of alloying can be obtained in a short period of time. By this means, a desired alloy chemistry and microstructure can be generated on the sample surface; the degree of microstructural refinement will depend on the solidification rate.

Laser surface alloying was performed to incorporate molybdenum in type 304 stainless steel (Ref 12). The 304-3Mo material was similar in pitting resistance to type 316 stainless steel. The 304-9Mo material was superior to type 316 stainless steel and showed no pitting up to oxygen evolution potentials. Table 12 shows some of the results for the 304-Mo materials.

Table 12 Effect of laser surface alloying with molybdenum on pitting potentials of austenitic stainless steels in 0.1 *M* NaCl

Sample	Composition, %			Pitting potential (E_{pit}), (V vs SCE)
	Cr	Ni	Mo	
Type 304	18-20	8-10	0	0.300

Type 316	16-18	10-14	2-3	0.550
304-3Mo	18.9	9.1	3.7	0.500
304-9Mo	19.2	11.7	9.6	Did not pit

Laser melt/particle injection produces an *in situ*, metal-matrix/particulate composite surface layer by mixing, but not melting, the second phase with the substrate. The particulate material is injected with sufficient velocity as a spray into the melt pool formed by the laser beam. If the second phase is hard, such as a carbide, the injected layer can be made to resist wear. Reference 13 describes the processing and properties of a type 304 stainless steel workpiece that was injected with titanium carbide.

Surface Hardening

In certain applications, surface hardening is performed to improve the resistance of stainless steel alloys to galling and wear through the formation of hard dispersions. The more soft, tough interior of the alloy remains unaffected, and thus provides impact resistance. The process encompasses a variety of techniques, including nitriding, carburizing, boriding, and flame hardening.

Gas Nitriding

Gas nitriding is a case-hardening process whereby nitrogen is introduced into the surface of an alloy by holding the metal at a suitable temperature in contact with a nitrogenous gas, usually ammonia. Quenching is not required for the production of a hard case. The nitriding temperature for all steels is between 495 and 565 °C (925 and 1050 °F).

Because of the absence of a quenching requirement, with attendant volume changes, and the comparatively low temperatures employed in this process, nitriding produces less distortion and deformation than either carburizing or conventional hardening. Some growth occurs as a result of nitriding, but volumetric changes are relatively small. Although at suitable temperatures all steels are capable of forming iron nitrides in the presence of nascent nitrogen, nitriding results are more favorable in those steels that contain one or more of the major nitride-forming alloying elements. Aluminum is the strongest nitride former, but chromium can approximate the results obtainable with aluminum if the chromium content is high enough.

Because of their chromium content, all stainless steels can be nitrided to some degree. Although nitriding adversely affects corrosion resistance, it increases surface hardness and provides a lower coefficient of friction, thus improving abrasion resistance.

Austenitic and Ferritic Alloys. Austenitic stainless steels of the 300 series are the most difficult to nitride; nevertheless, types 301, 302, 303, 304, 308, 309, 316, 321, and 347 have been successfully nitrided. These nonmagnetic alloys cannot be hardened by heat treating; consequently, core material remains relatively soft, and the nitrided surface is limited as to the loads it can support. This is equally true of the nonhardenable ferritic stainless steels. Alloys in this group

that have been satisfactorily nitrided include types 430 and 446. With proper prior treatment, these alloys are somewhat easier to nitride than the 300-series alloys.

Hardenable Alloys. The hardenable martensitic alloys are capable of providing high core strength to support the nitrided case. Hardening, followed by tempering at a temperature that is at least 15 °C (25 °F) higher than the nitriding temperature, should precede the nitriding operation. Precipitation-hardening alloys, such as 17-4 PH, 17-7 PH, and A-286, also have been successfully nitrided.

Prior Condition. Before being gas nitrided, 300-series steels and nonhardenable ferritic steels should be annealed and relieved of machining stresses. The normal annealing treatments generally employed to obtain maximum corrosion resistance are usually adequate. Microstructure should be as nearly uniform as possible. Observance of these prior conditions will prevent flaking or blistering of the nitrided case. Martensitic steels should be in the quenched and tempered condition.

A special pretreatment for 410 stainless steel is hardening from a lower than normal temperature. This results in a very uniform nitrided case with reduced internal stresses. Cracking or spalling of the case is avoided; formation of brittle grain-boundary carbonitrides is suppressed. Austenitizing at 860 °C (1580 °F), followed by tempering at 595 °C (1100 °F), uniformly distributes carbides and provides low residual stress. Case growth is accommodated by a hardness of about 25 HRC.

Surface Preparation. The nitriding of stainless steels requires certain surface preparations that are not required for nitriding low-alloy steels. Primarily, the film of chromium oxide that protects stainless alloys from oxidation and corrosion must be removed. This can be accomplished by dry honing, wet blasting, pickling, chemical reduction in a reducing atmosphere, submersion in molten salts, or one of several proprietary processes. Surface treatment must precede placement of the parts in the nitriding furnace. If there is any doubt of the complete and uniform depassivation of the surface, further reduction of the oxide may be accomplished in the furnace by means of a reducing hydrogen atmosphere or halogen-based proprietary agents. Of course, hydrogen must be dry (free of water and oxygen).

Before being nitrided, all stainless parts must be perfectly clean and free of embedded foreign particles. After depassivation, care should be exercised to avoid contaminating stainless surfaces with fingerprints. Sharp corners should be replaced with radii of not less than 1.6 mm ($\frac{1}{16}$ in.).

Nitriding Cycles. In general, stainless steels are nitrided in single-stage cycles at temperatures from about 495 to 595 °C (925 to 1100 °F) for periods ranging from 20 to 48 h, depending on the depth of case required. Dissociation rates for the single-stage cycle range from 20 to 35%; a two-stage cycle using 15 to 30% in the first phase and 35 to 45% in the second phase is also used. Thus, except for the prior depassivation of the metal surface, the nitriding of stainless steels is similar to the single-stage nitriding of low-alloy steels.

Nitriding Results. Hardness gradients are given in Fig. 5 for types 302, 321, 430, and 446. These data are based on a 48-h nitriding cycle at 525 °C (975 °F), preceded by suitable annealing treatments. A general comparison of the nitriding characteristics of series 300 and 400 steels is presented in Fig. 6; the comparison reflects the superior results that are obtained with series 400 steels, as well as the effects of nitriding temperature on case depth. Data are plotted for single-stage nitriding at temperatures of 525 and 550 °C (975 and 1025 °F). For steels of both series, greater case depths were obtained at the higher nitriding temperature.

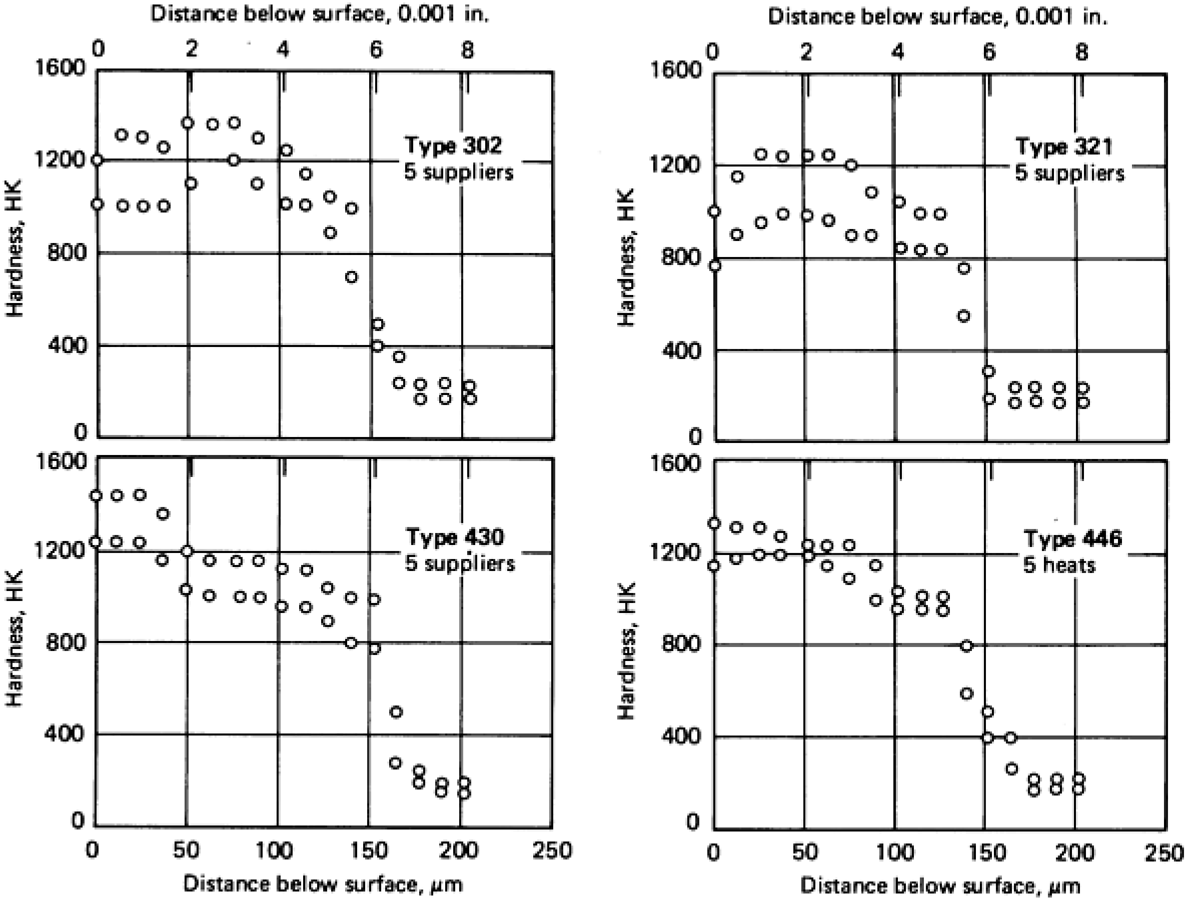

Fig. 5 Hardness range as a function of case depth for four stainless steels that were annealed prior to nitriding. Annealing temperature: types 302 and 321, 1065 °C (1950 °F); type 430, 980 °C (1800 °F); and type 446, 900 °C (1650 °F)

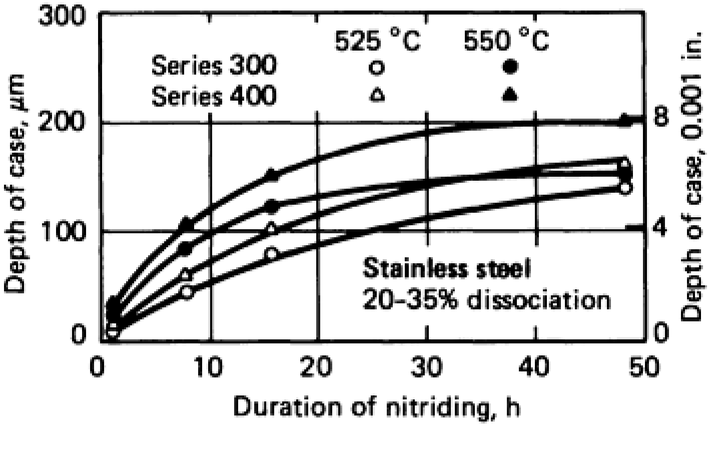

Fig. 6 Comparison of the nitriding characteristics of series 300 and 400 stainless steels, single-stage nitrided at 525 and 550 °C (975 and 1025 °F)

Applications. Although nitriding increases the surface hardness and wear resistance of stainless steels, it decreases general corrosion resistance by combining surface chromium with nitrogen to form chromium nitride. Consequently, nitriding is not recommended for applications in which the corrosion resistance of stainless steel is of major importance. For example, a hot-air valve made of cast type 347 and used in the cabin-heating system of a jet airplane was nitrided to

improve its resistance to wear by the abrading action of a sliding butterfly When the valve remained in the closed position for an extended period, the corrosive effects of salt air froze the valve into position so that it could not be opened.

In contrast, a manufacturer of steam-turbine power-generating equipment has successfully used nitriding to increase the wear resistance of types 422 and 410 stainless steel valve stems and bushings that operate in a high-temperature steam atmosphere. Large quantities of these parts have operated for 20 years of more without difficulty. In a few instances, a light-blue oxide film formed on the valve stem diameter, causing it to "grow" and thus reduce the clearance between stem and bushing; the growth condition, however, was not accompanied by corrosive attack.

Nitrided stainless steel is also being used in the food-processing industry. In one application, nitrided type 321 was used to replace type 302 for a motor shaft used in the aeration of orange juice. Because the unhardened 302 shaft wore at the rubber-sealed junction of the motor and the juice, leaks developed within 3 days. The nitrided 321 shaft ran for 27 days before wear at the seal resulted in leakage. In machinery used in the preparation of dog foods, nitrided type 420 gears have replaced gears made of an unhardened stainless alloy and have exhibited a considerable increase in life.

Modern synthetic fibers, several of which are highly abrasive, have increased the wear of textile machinery. Mechanical parts in textile machines are subjected to high humidity, absence of lubrication, high-speed movements with repeated cycling, and the abrasive action of fibers traveling at high speeds. A shear blade made of hardened (62 to 64 HRC) 1095 steel experienced a normal life of about one million cuts (4 weeks of service) in cutting synthetic fibers at the rate of 90 cuts per minute. In contrast, a nitrided type 410 blade with 0.04 mm (0.0015 in.) case depth showed less wear after completion of five million cuts.

With nitrided stainless steels, the case almost always has lower corrosion resistance than the base material; nevertheless, the corrosion resistance of the case can be adequate for certain applications. For example, nitrided types 302 and 410 stainless steel resist attack from warp conditioner and size in the textile industry but do not resist attack from the acetic acid used in dyeing liquors.

Nitrided stainless steel is not resistant to mineral acids and is subject to rapid corrosion when exposed to halogen compounds. However, a nitrided type 302 piston lasted for more than 5 years in a liquid-ammonia pump; it replaced a piston made of an unnitrided 300-series alloy that lasted approximately 6 months. Nitrided 17-4 PH impellers have performed satisfactorily and without corrosion in various types of hydraulic pumps.

Plasma (Ion) Nitriding and Liquid Nitriding

Plasma, or ion, nitriding is a method of surface hardening that uses glow discharge technology to introduce nascent (elemental) nitrogen to the surface of a metal part for subsequent diffusion into the material. In a vacuum, high-voltage electrical energy is used to form a plasma, through which nitrogen ions are accelerated to impinge on the workpiece. This ion bombardment heats the workpiece, cleans the surface, and provides active nitrogen. Ion nitriding provides better control of case chemistry and uniformity and has other advantages, such as lower part distortion than conventional gas nitriding.

The diffusion zone of a nitrided case can best be described as the original core microstructure with some solid solution and precipitation strengthening. In iron-base materials, the nitrogen exists as single atoms in solid solution at lattice sites or interstitial positions until the limit of nitrogen solubility (!0.4 wt% N) in iron is exceeded. This area of solid-solution strengthening is only slightly harder than the core. The depth of the diffusion zone depends on the nitrogen concentration gradient, time at a given temperature, and the chemistry of the workpiece.

As the nitrogen concentration increases toward the surface, very fine, coherent precipitates are formed when the solubility limit of nitrogen is exceeded. The precipitates can exist both in the grain boundaries and within the lattice structure of the grains themselves. These precipitates, in the form of nitrides, distort the lattice and pin crystal dislocations and thereby substantially increase the hardness of the material. Hardness profiles for various ion-nitrided materials, including stainless steels, are shown in Fig. 7.

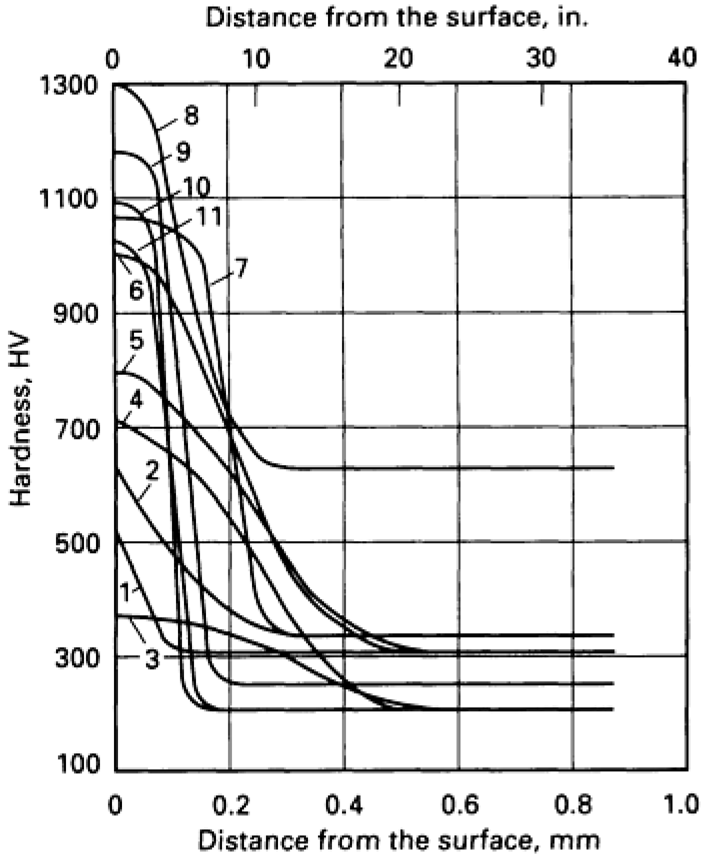

Fig. 7 Hardness profiles for various ion-nitrided materials. 1, gray cast iron; 2, ductile cast iron; 3, AISI 1040; 4, carburizing steel; 5, low-alloy steel; 6, nitriding steel; 7, 5% Cr hot-work steel; 8, cold-worked die steel; 9, ferritic stainless steel; 10, AISI 420 stainless steel; 11, 18-8 stainless steel

In most ferrous alloys, the diffusion zone formed by nitriding cannot be seen in a metallograph because the coherent precipitates generally are not large enough to resolve. In stainless steels, however, the chromium level is high enough for extensive nitride formation, which can be seen in etched cross section (Fig. 8).

Fig. 8 Observable diffusion zone on the unetched (white) portion of an ion-nitrided 416 stainless steel. Nital etched. 500×

Ion nitriding has a strong advantage over competing processes in the case of stainless steels, particularly austenitic or 300-series materials. The chromium oxide passive layer on the surface represents a barrier to nitriding and must be removed prior to processing. When gas nitriding stainless steels, this passive layer is removed by wet blasting, pickling, or chemical reduction. With ion nitriding, however, this layer can be removed by sputtering in hydrogen in the vessel itself just before introduction of the process gas. With most materials, even the sputtering that occurs naturally during the actual nitriding process is enough to yield good nitriding results.

Liquid nitriding is performed in a molten, nitrogen-bearing, fused-salt bath containing either cyanides or cyanates. Unlike liquid carburizing and cyaniding, which employ baths of similar composition, liquid nitriding is a subcritical (that is, below the critical transformation temperature) case-hardening process. Thus, processing of finished parts is possible because dimensional stability can be maintained. Also, liquid nitriding adds more nitrogen and less carbon to ferrous materials than that obtained through higher-temperature diffusion treatments.

Cyanide-free liquid nitriding salt compositions have also been introduced. However, in the active bath, a small amount of cyanide, generally up to 5%, is produced as part of the reaction. This is a relatively low concentration, and these compositions have gained widespread acceptance within the heat treating industry because they contribute substantially to the alleviation of a potential source of pollution.

The wear and gall resistance of stainless steels can be improved by aerated liquid nitriding, a proprietary process (U.S. Patent 3,022,204) in which measured amounts of air are pumped through the molten bath. Immersion in the molten salt at 570 °C (1060 °F) develops a physical compound zone in stainless steels that, depending on treatment time, varies between 0.005 and 0.025 mm (0.0002 and 0.001 in.). Although the hardness of this wear-resistant surface measures 70 to 72 HRC, the surface is tough and ductile (Ref 14).

Liquid nitriding treatments result in some loss in corrosion resistance, because the formation of nitrides and carbides depletes adjacent matrix areas. Corrosion data based on weight loss indicate that liquid-nitrided stainless steels lose approximately 50% of their corrosion resistance; however, these materials remain substantially superior to untreated carbon and low-alloy steels (Ref 14).

Liquid nitriding is one of the few heat treatments that can produce a wear-resistant hard surface, improve fatigue properties, and retain to a significant extent the good corrosion resistance of stainless steels in a single operation. In addition, subsequent quenching is not required, allowing flexibility in design and final machining (Ref 14).

Carburizing, Boriding, and Flame Hardening

Carburizing is a case-hardening process in which carbon is dissolved in the surface layers of a steel part at a temperature sufficient to render the material austenitic, followed by quenching and tempering to form a martensitic microstructure. The resulting gradient in carbon content below the surface of the part causes a gradient in hardness, producing a strong, wear-resistant surface layer. In gas carburizing, commercially the most important variant of carburizing, the source of carbon is a carbon-rich furnace atmosphere produced either from gaseous hydrocarbons (e.g., methane, propane, or butane) or from vaporized hydrocarbon liquids.

Stainless steels can be carburized to improve surface hardness and resistance to galling. The availability of substantial amounts of chromium promotes the rapid formation of chromium carbides at the surface, and surface hardness values of 700 to 750 HV have been measured. Precipitation-hardenable stainless steels can be gas carburized to improve resistance to galling. Treatment temperatures up to 1010 °C (1850 °F) may be required (Ref 14).

In austenitic grades, much of the chromium carbide formed migrates and is precipitated in the grain boundaries, promoting susceptibility to intergranular corrosion. Carbide distribution tends to be less segregated in the martensitic grades, but they are also subject to localized corrosion and particularly SCC (Ref 14).

Carburizing is not generally recommended for stainless steels because of the reduction in corrosion resistance brought on by chromium precipitation. Since the precipitated chromium tends to exist at the expense of adjacent areas, localized galvanic cells may develop. In the carburizing process, surface physical properties are obtained at the expense of surface chemical properties (Ref 14).

Because of these disadvantages, most of the carburizing of stainless steel is "accidental" and can be traced to surface contamination. Carbonaceous compounds such as charcoal, coke, oil, and grease can promote carburization under the

proper conditions. Molten salt baths that contain cyanide to prevent decarburization may also become carburizing in contact with stainless steels (Ref 14).

Boriding, or boronizing, is a thermochemical surface hardening process that involves heating well-cleaned material in the range of 700 to 1000 °C (1300 to 1830 °F), preferably for 1 to 12 h, in contact with a boronaceous solid powder (boronizing compound), paste, liquid, or gaseous medium.

The resultant diffusion zone is known for its low coefficient of friction and high surface hardness, which may reach values of 1800 HV. Case depths of 0.05 mm (0.002 in.) can be achieved with 1 to 5 h treating time (Ref 14). Figure 9 shows the influence of steel composition on abrasive wear resistance. Boriding can considerably enhance the corrosion-erosion resistance of ferrous materials in nonoxidizing dilute acids (Fig. 10) and alkali media, and is increasingly used to this advantage in many industrial applications (Ref 17).

Chromium considerably modifies the structure and properties of iron borides. As the chromium content in the base material increases, progressive improvements in the following effects are observed: formation of boron-rich reaction products, decrease in boride depth, and flattening or smoothening of the coating/substrate interface (Ref 19). A reduction of boride thickness has also been noticed in ternary Fe-12Cr-C steels with increasing carbon content (Ref 20).

Flame hardening is a heat treating process in which a thin surface shell of a steel part is heated rapidly to a temperature above the critical point of the steel. After the grain structure of the shell has become austenitic (austenitized), the part is quickly quenched, transforming the austenite directly to martensite while leaving the core of the part in its original state.

Flame hardening employs direct impingement of a high-temperature flame or high-velocity combustion product gases. The part is then cooled at a rate that will produce the desired levels of hardness and other properties. The high-temperature flame is obtained by combustion of a mixture of fuel gas with oxygen or air; flame heads are used for burning the mixture. Depths of hardening from about 0.8 to 6.4 mm ($\frac{1}{32}$ to $\frac{1}{4}$ in.) or more can be obtained, depending on the fuels used, the design of the flame head, the duration of heating, the hardenability of the work material, and the quenching medium and method of quenching used.

Hardening by flame differs from true case hardening because the hardenability necessary to attain high levels of hardness is already contained in the steel, and hardening is obtained by localized heating. Although flame hardening is mainly used to develop high levels of hardness for wear resistance, the process also improves bending and torsional strength and fatigue life.

Flame hardening can be applied to martensitic stainless steels. The nature of flame hardening, however--especially the relatively high temperature gradients and higher than normal surface temperatures-- may cause the retention of excessive amounts of austenite in many highly alloyed materials, with possible low hardness and transformation to untempered martensite in service, accompanied by brittleness. Typical hardnesses obtained for martensitic stainless steels by flame heating and quenching in air or oil are given in Table 13.

Table 13 Response of martensitic stainless steels to flame hardening

Material	Typical hardness, HRC, as affected by quenchant	
	Air[(a)]	Oil[(b)]
410, 416	41-44	41-44
414, 431	42-47	42-47
420	49-56	49-56

(a) To obtain the hardness results indicated, those areas not directly heated must be kept relatively cool during the heating process.

(b) Thin sections are susceptible to cracking when quenched with oil.

Surface Engineering of Specialty Steels

J.R. Davis, Davis & Associates

Introduction

SPECIALTY STEELS encompass a broad range of ferrous alloys noted for their special processing characteristics (powder metallurgy alloys), corrosion resistance (stainless steels), wear resistance and toughness (tool steels), high strength (maraging steels), or magnetic properties (electrical steels). Each of these material groups--with the exception of stainless steels, which were discussed in the previous article in this Section--will be reviewed below. Additional information on these materials can be found in Volumes 1 and 2 of the *ASM Handbook*.

Ferrous Powder Metallurgy Alloys

Powder metallurgy (P/M) in its simplest form consists of compressing metal powders in a shaped die to produce green compacts. These are then sintered, or diffusion bonded, at elevated temperatures in a furnace with a protective atmosphere. During sintering, the constituents usually do not melt, and the compacts become substantially strengthened by the development of bonds between individual particles.

For a specific metal powder and sintering condition, increased compact density results in improved mechanical properties. The density of sintered compacts may be increased by re-pressing. When re-pressing is performed primarily to increase dimensional accuracy rather than density, it is termed sizing. When re-pressing is intended to change the contour of the surface in contact with the punches, it is termed coining. For example, a sintered blank could be coined so that the surface is indented with small slots or letters and numbers. The re-pressing may be followed by re-sintering, which relieves the stresses due to cold work and may further strengthen the compact. More detailed information on consolidation practices for ferrous P/M parts can be found in Ref 1 and 2.

By pressing and sintering only, parts are produced at 80 to 93% of theoretical density. By re-pressing, with or without sintering, the materials may be further densified to 85 to 96% of theoretical density. High-temperature sintering will also produce parts at these high densities. The density of pressed parts is limited by the size and shape of the compact. The most common P/M materials for structural parts are iron-copper-carbon, iron-nickel-carbon, and iron-carbon. Parts made from these materials respond to heat treatment with a defined hardenability band. Iron parts that are low in carbon and high in density can also be case hardened.

Designation of Ferrous P/M Materials

Ferrous P/M materials are customarily designated by the specifications or standards to which they are made, such as those listed in Table 1. Comparable standards are published by ASTM, SAE, and MPIF (Metal Powder Industries Federation).

Table 1 Compositions of ferrous P/M structural materials

(a) Designations listed are nearest comparable designations; ranges and limits may vary slightly between comparable designations.

(b) MPIF standards require that the total amount of all other elements be less than 2.0%, except in infiltrated steels, for which the total amount of other elements must be less than 4.0%.

The MPIF designations for ferrous P/M materials, described in detail in Ref 3, include a prefix of one or more letters (the first of which is F to indicate an iron-base material), four numerals, and a suffix. The second letter in the prefix identifies the principal alloying element (if one is specified); the percentage of the element is indicated by the first two digits. The third and fourth digits indicate the amount of carbon in the compacted and sintered part; the code designation 00 indicates less than 0.3%, 05 indicates 0.3 to 0.6%, and 08 indicates 0.6 to 0.9%. The suffix is used to indicate the minimum 0.2% yield strength of as-sintered parts and the minimum ultimate tensile strength of heat-treated materials in units of 1000 psi (6.894 MPa). The letters HT designate heat treated.

Commercially produced iron-base powders often contain controlled amounts of alloying elements other than those specified by any of the designations listed in Table 1. Manganese and molybdenum may be added to improve strength and the response to heat treatment. Sulfur may be added to enhance machinability. Additions of 0.45 to 0.80% P can improve the toughness of the part and reduce magnetic hysteresis losses. These powders are usually identified by the trade name of the producer even though the amounts of alloy additions are small enough that the designations listed in Table 1 could be applied to the powders. Commercially produced iron-base powders usually contain very little carbon because carbon lowers compressibility and the amount of carbon in the finished part is readily controlled by the amount of admixed graphite and the composition of the sintering atmosphere.

Deburring P/M Parts (Ref 4)

Although cleaning and deburring generally are considered different operations, they are often accomplished simultaneously. Therefore, much of the discussion on deburring is applicable to the subsequent section of this article on cleaning.

The inherent porosity in P/M parts demands special considerations in all secondary operations. This is also true for cleaning and deburring; the relatively small size and complex shape of the parts also require special procedures and/or precautions that are not required for wrought or cast parts. The P/M parts shown in Fig. 1 are typical of small, intricate parts that frequently present deburring problems.

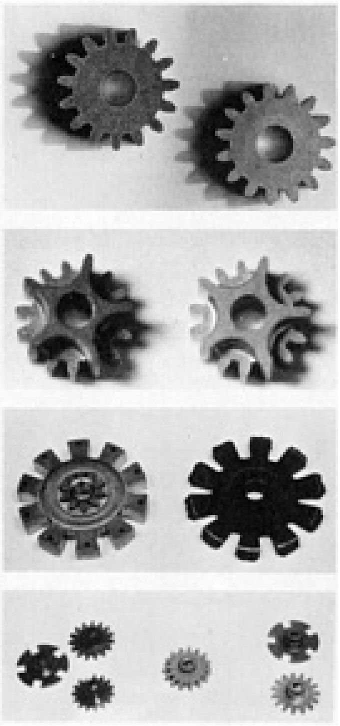

Fig. 1 Typical shapes of P/M parts that present deburring or cleaning difficulties

Deburring Methods. Due to the nature of the P/M process, burrs typically form on the edges and surfaces of P/M parts. In many simple shapes, deburring is almost automatic--that is, burrs are broken off during handling operations. If parts are surface hardened or steam treated, subsequent deburring may be unnecessary. However, for intricate parts such as those shown in Fig. 1, separate deburring operations generally are required.

The use of liquid deburring methods is not usually suitable, especially if such liquids are corrosive. Thus, acid pickling is not recommended, because acid may be entrapped in the pores, resulting in severe corrosion. Tumbling in a wet medium is used frequently as a deburring method, but removal of the liquid from the pores requires extra drying time. Preferred methods of deburring include:

- Rotary tumbling (self or with abrasive)
- Vibratory
- Abrasive blasting
- Centrifugal or high-energy methods

These methods, which are used for deburring and sometimes for cleaning, are described in the articles "Mechanical Cleaning Systems" and "Mass Finishing Methods" in this Volume. The discussions that follow are unique to P/M parts.

Rotary Tumbling. Self-tumbling, tumbling with dry abrasive, and tumbling with abrasive in a liquid medium are suitable for deburring of P/M parts. Wet tumbling is not suitable for deburring P/M parts because of the difficulty of removing the tumbling liquid from the pores of the parts.

During self-tumbling, the workpieces are tumbled in a revolving barrel. This method provides an economical and efficient means of deburring, but is effective only on relatively simple parts. For parts such as those shown in Fig. 1, the internal surfaces and recesses are not completely deburred by this method. For more complete deburring, an abrasive is added. Size of the abrasive is important. At least a portion of the added abrasive should have a mesh size that is smaller than the smallest hole or recess in the workpiece; otherwise, not all surfaces will be reached.

Over-tumbling of P/M parts must be avoided, because it peens the surfaces and may partially close pores (not necessarily desirable). Over-tumbling also may damage gear teeth or other protrusions by removing too much metal or by excessive peening. Tumbling cycles should be based on the minimum time that will provide acceptable deburring.

Vibratory processing is similar to rotary tumbling in principle. However, the shaking involved in the vibratory method is faster and provides more uniform results compared to rotary tumbling. As in rotary tumbling, care must be taken to prevent over-tumbling.

Abrasive blasting, in which various materials are propelled by air or centrifugal force, offers another method of deburring. For practical reasons, it is used less frequently than tumbling or vibrating. The abrasive must be selected carefully. Coarse shot or grit tends to peen the surfaces and close the pores. Also, abrasive blasting can "hammer" bits of abrasive into the workpiece, thus "charging" it.

Another disadvantage of conventional abrasive blasting is that, especially for large volumes of small workpieces, results are likely to be nonuniform. One type of blasting machine, which tumbles and blasts simultaneously, has been used successfully for deburring of P/M parts. Silica sand or a milder abrasive is suitable and is less likely to damage intricate workpieces. As with other deburring methods, overprocessing must be avoided.

Centrifugal or High-Energy Methods. Centrifugal finishing combines rotating action with high centrifugal force, which results in a more severe abrading action than can be obtained by conventional rotary tumbling. This action is obtained by revolving several rotating barrels around the periphery of a large carrier disk.

As a result, the action within one barrel consists of a combination of rotating motion and high centrifugal forces, which provides pressures up to 25 times the weight of the abrasive medium (if used) and the workpiece. As the disk rotates in one direction, the barrels rotate at a faster speed in the opposite direction. This counter movement within the entire mass accomplishes the desired results in a shorter time compared to other abrading processes. An advantage of this process is that it drives the abrasive into relatively inaccessible areas where burr removal may present problems.

Cleaning of P/M Parts (Ref 4)

Some of the deburring methods discussed above also may be considered as methods of cleaning. Frequently, however, methods such as tumbling and blasting are considered as preliminary cleaning operations to be followed by a more thorough cleaning, especially if the parts are to be coated.

Cleaning Methods. The inherent porosity in P/M parts imposes restrictions on selection of cleaning method. The use of a cleaning solution that is corrosive to the metal being cleaned is not recommended, because even the most thorough washing is not likely to remove all of the fluid, which presents a corrosion problem. Acid cleaning is therefore not recommended.

Because of porosity, thorough cleaning of P/M parts is more difficult than their wrought counterparts; P/M parts require more attention than is provided in many conventional cleaning systems. Preferred methods are hot caustic washing, ultrasonic degreasing, and electrolytic alkaline cleaning.

Ultrasonic Degreasing. Oils, greases, and other shop soil may be removed by vapor degreasing techniques such as vapor phase, vapor-spray-vapor, warm liquid-vapor, or boiling liquid-warm liquid-vapor techniques. For most P/M parts, especially if the degree of soiling is severe and/or part density is low, the boiling liquid-warm liquid-vapor process is preferred. This technique should be used in conjunction with an ultrasonic transducer, which literally shakes all entrapped contaminants out of the pores, resulting in a thorough and safe method of cleaning.

Electrolytic Alkaline Cleaning. Ferrous P/M parts can be cleaned, deoxidized, and stripped of nonmetallic coatings by subjecting them to electrolysis in a strongly alkaline aqueous solution. In this method the base metal is not attacked, and the possibility of rusting is minimal. Typical alkaline solutions are comprised of a:

- Source of caustic to aid cleaning
- Chelating agent to detach scale or rust
- Complexing agent to hold relatively large amounts of iron in solution

Electrolytic alkaline cleaning bath compositions and operating conditions are described in the article "Alkaline Cleaning" in this Volume. This cleaning process is well suited to cleaning of P/M parts, because the electrolytic action provides additional energy required to dislodge contaminants from pores or from relatively inaccessible areas.

Steam Treating of P/M Parts (Ref 5)

Ferrous P/M parts have traditionally been steam treated for improved wear resistance, corrosion resistance, and sealing capacity. Here, P/M parts are heated in a specific manner under a steam atmosphere at temperatures between 510 to 595 °C (950 to 1100 °F) to form a layer of black iron oxide (magnetite, or ferrous-ferric oxide, $FeO\text{-}Fe_2O_3$) in the surface porosity according to the chemical reaction:

$$3Fe + 4H_2O\ (\text{steam}) \rightarrow Fe_3O_4 + 4H_2(\text{gas}) \qquad \textbf{(Eq 1)}$$

Steam treating cannot be described as a heat treatment because no structural changes occur in the matrix. In this process, magnetite (Fe_3O_4) is formed at the interconnecting surface porosity, filling the porosity with a second phase. Magnetite has a microhardness equivalent to HRC 50.

The process itself is straightforward, the primary variables being temperature, time, and steam pressure. Caution must be used to prevent the formation of hydroxides and lower oxides such as ferrous oxide (FeO) and ferric oxide (Fe_2O_3), which is red rust.

The recommended procedure for steam treating is:

- Preclean parts to remove any oil or lubricants that may have been absorbed into the porosity from prior machining, sizing, or finishing operations
- Load clean sintered parts in loosely packed baskets and place fixture into a furnace preheated to 315 °C (600 °F)
- Heat parts in air until the center of the load has stabilized at the set temperature
- Introduce superheated steam at a line pressure of 35 to 105 kPa (5 to 15 psi) and allow furnace to purge for at least 15 min
- Increase furnace temperature to desired set point and hold for no longer than 4 h at heat
- Upon completion of cycle, reduce furnace temperature to 315 °C (600 °F). When parts reach this temperature, the steam can be shut off and the parts unloaded

Caution should be used when opening the furnace door after the steam cycle. As shown in Equation 1, hydrogen is produced during this process and can ignite. It is recommended that a nitrogen purge be applied prior to unloading. This process, when correctly applied, can impart improved surface properties, and, depending upon steel composition, increased compressive yield strength.

In all steam-treated P/M steels, the ductility is significantly reduced due to the internal stresses created by the formation of the iron oxide. Care must be taken when treating high-carbon P/M steels because these internal stresses can initiate microcracking and cause severe loss of ductility. Many cases have been reported in which parts were accidentally dropped on the floor after being steam treated, and the parts subsequently shattered like glass. The best recommendation for preventing such an incident is to specify a 0.5% C (max) content on materials that are to be steam treated.

Figure 2(a) shows that transverse rupture strength increases proportionately with sintered density. Upon steam treating, low-carbon P/M steels exhibit a uniform increase in strength, whereas the high-carbon P/M steels show only a small incremental increase in strength.

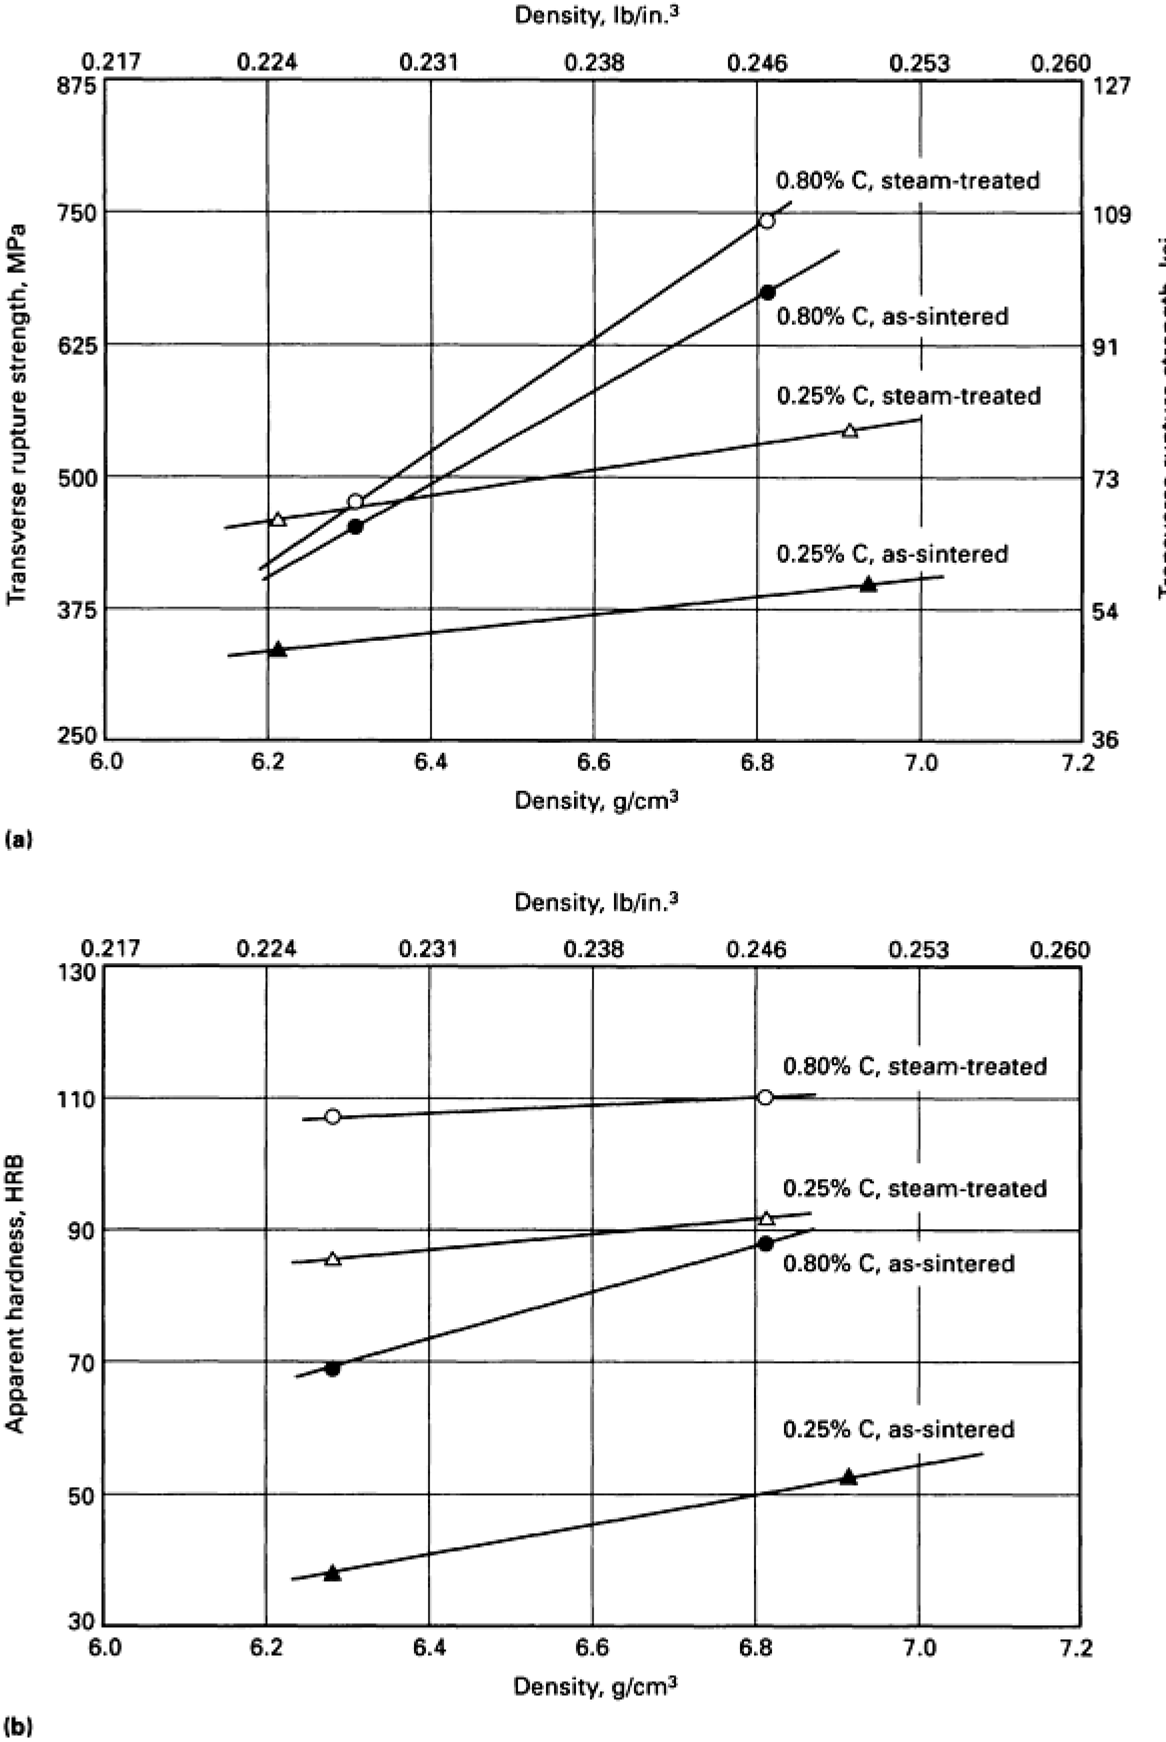

Fig. 2 Effect of steam treating on the mechanical properties of sintered carbon P/M steels as a function of density. (a) Transverse rupture strength. (b) Apparent hardness. Source: Ref 5

Apparent hardness also is improved as shown in Fig. 2(b). By filling the porosity with a hard second phase, the P/M steel can offer better support to an indentation hardness test. As with rupture strength, the incremental increase in hardness of high-carbon steels is less than that of low-carbon steels. Additional information on the properties of steam-treated P/M steels can be found in Ref 6.

Coating of P/M Parts (Ref 4)

In addition to the surfaces provided by steam treatment, P/M parts are frequently coated by mechanical means, painting, or electroplating. The blue-black oxide-covered surface produced by exposure to steam is often the final finish for a variety of hardware items. It may also be used as a preliminary coating for a final finishing process, such as painting.

Regardless of the method used for coating, major emphasis must be placed on initial cleaning. If liquid contaminants are allowed to remain in the pores of parts, bleeding occurs, and defective coatings result. Steam treatment provides an excellent paint base.

Mechanical coating uses kinetic energy to deposit metallic coatings on parts. This process is also known as mechanical plating, or peen plating, when the coating is less than 25 μm (1 mil) thick. Coating is accomplished by placing the workpiece, glass beads, water, and the metal plating powder in a tumbling barrel.

Zinc is most commonly used as a plating material, although a wide range of metals and mixtures of metals can be mechanically plated on ferrous metal parts. For example, a mixture of 75% Zn and 25% Sn is commonly used. Metal powders are added to the mixtures to be tumbled. Complete details on the mechanical coating process may be found in the article "Mechanical Plating" in this Volume.

Powder metallurgy parts with densities not less than 83% can be mechanically plated without special considerations for porosity. When density drops below 83%, tests should be conducted to determine whether moisture is entrapped, which is detrimental to the finished parts. Generally, when density is below 83%, parts must be impregnated with wax or resin.

Painting. Usually, P/M parts are ideal candidates for coating by painting; the porosity enhances paint adhesion. Furthermore, P/M parts can be painted by spraying, dipping, or the contact transfer method. Air-drying types are suitable only for indoor protective coatings. Baking produces finishes of higher quality that are well suited for outdoor exposure.

Spray painting has several advantages over dipping, including improved control of dimensions and coating quality, and the ability to coat localized areas. However, higher labor costs and more paint loss from overspray are associated with spraying.

For spraying, baking types of alkyds are reduced with solvents to a spraying viscosity of 35 s through a No. 4 Ford Cup. Parts are sprayed and then air dried for 10 min, after which they may be baked for 30 min at a temperature compatible with the type of paint being used. This practice results in a dry film coating 38 to 46 μm (1.5 to 1.8 mils) thick.

In paint dipping, the parts to be coated are placed in baskets or on racks, immersed in the paint, and then allowed to drain. Dipping saves labor and paint, compared to spraying, but general quality of dipped parts is lower, notably because of edge buildup.

Roll painting and lithographing (transfer coating) is a process in which paint is applied to external surfaces of cylindrical P/M parts, followed by the application of lithographing ink. Typically parts are roll coated and oven baked. The initial coating is usually a background color. Numbers of characters, as required, are then roll coated over the background coating, followed by baking dry.

Advantages of this painting procedure include:

- Precision painting can be achieved without applying paint to areas that do not require a coating

- With proper design of parts, areas can be painted with sharply defined edges
- Coating thickness can be closely controlled by varying the number of revolutions the part is permitted to make
- An unlimited number of character forms can be applied at relatively low cost

Principal limitations of the process are:

- Special handling is required
- Internal surfaces are not coated

Types of paint used in general procedures for painting of P/M parts are similar to those used for wrought counterparts, all of which are covered in detail in the article "Painting" in this Volume.

Electroplating. Powder metallurgy parts can be electroplated with various metals like their wrought counterparts. Methods used for plating of cast parts generally can be used for very dense parts (95% or more of theoretical). Plating of castings is described in the article "Surface Engineering of Cast Irons" in this Volume. For parts of lower densities, special preparation procedures are required.

During plating of P/M parts, the pores act as thermal pumps. Plating solutions are released from or absorbed by the pores, depending on the temperature differential between the workpiece and the solution. Interconnecting pores entrap solutions, which are then released slowly. Part density should be known before the sequence of cleaning and plating operations begins, and suitable precautions should be taken to prevent solution entrapment.

Entrapped solutions not only cause spotty plating and staining, which may develop within days, but also can cause contamination and depletion of all solutions used in the production process. It is therefore necessary that, if part density is below about 95%, pores must be closed before coating by electroplating.

Methods of closing pores that have proved successful include burnishing, buffing, rolling, heat treating, steam treating, and impregnation. All of these methods, except impregnation, provide varying degrees of closure. Mechanical methods are often excluded because of dimensional tolerances. Consequently, impregnation is the most suitable approach to closing pores.

Infiltration of iron compacts with metals such as copper is common practice and completely solves the porosity problem for subsequent electroplating. However, the cost of metal infiltration usually cannot be justified only to ensure satisfactory electroplating.

Impregnation with plastic seals P/M parts for further processing, such as electroplating. Pressure tightness and frequently an improvement in machining characteristics are added benefits derived from plastic impregnation. The process is not unlike the plastic impregnation process used to attain pressure tightness in porous castings. Optimum results are obtainable with various types of plastic sealants, although the most commonly used are polyester resins and anaerobic sealants.

A typical processing cycle consists of:

- Cleaning thoroughly
- Baking at 120 to 150 °C (250 to 300 °F) to drive off all moisture or solvent
- Applying sealant under vacuum, such as in an autoclave
- Removing excess sealant by means of an emulsion cleaner
- Curing at 120 to 150 °C (200 to 250 °F)
- Tumbling, polishing, or abrasive blasting to remove excess cured sealant

Parts are now ready for routine cleaning and plating cycles, as required by the plating method used. Plating procedures are the same as those used for wrought parts (see the articles contained in the Section "Plating and Electroplating" in this Volume).

Case Hardening of P/M Parts (Ref 5)

Powder metallurgy parts can be case hardened by several processes, although various available processes are not equally suited to every application. Generally the best results (a clear case/core relationship) are obtained with P/M parts with densities exceeding 7.2 g/cm^3 (90% of theoretical density). More detailed information on each of the processes described below can be found in *Heat Treating*, Volume 4 of the *ASM Handbook.*

Carburizing is normally specified in parts with a large cross-sectional thickness to attain maximum fatigue and impact properties. The material usually specified for carburizing contains hardenability agents such as nickel, molybdenum, and copper with relatively low carbon content. To develop optimum dynamic properties at porosity levels between. 10 to 15%, a combined carbon level of 0.30 to 0.35% is recommended. As porosity is reduced below 10%, combined carbon can be reduced to 0.15 to 0.25% C. Because improved dynamic properties are also associated with high densities, it is recommended that combined carbon be adjusted to a level best suited for re-pressing after sintering.

In wrought steel, carburizing is normally characterized by a surface hardness range and an effective case depth. Microhardness measurements can accurately show the hardness profile in wrought steel but can be erratic when used on P/M steels. With P/M steels, however, subsurface porosity can influence the microhardness readings, resulting in false hardness readings. It is recommended that at least three hardness readings be taken at each level below the surface and averaged to determine effective case depth.

Carburizing of P/M steels is usually done at temperatures between 900 to 930 °C (1650 to 1705 °F). Time cycles are normally short because of the rapid diffusion of carbon through the interconnected porosity. Therefore, atmosphere carbon potentials need to be somewhat higher than those required for wrought steels of similar composition.

Carbonitriding is probably the more common case-hardening treatment used on P/M parts. Here process temperatures are lower (800 to 850 °C, or 1470 to 1560 °F) and ammonia additions to approximately 10% are made. Ammonia dissociates on the parts, allowing nitrogen to diffuse into the surfaces. This retards the critical cooling rate upon quenching and provides a more consistent martensite transformation. It also produces a more consistent surface hardness, which improves wear resistance and toughness of the P/M steel. Because lower temperatures can be used, carbonitriding provides better control of distortion compared to carburizing. Care must be taken when adding ammonia, however, since excessive nitrogen diffusion into the internal pore surfaces can cause embrittlement.

Carbonitriding is a shallow case-hardening treatment. Case depths greater than 0.50 mm (0.020 in.) deep are seldom specified. For this reason, cycle times are relatively short, usually on the order of 30 to 60 min. As in neutral hardening, carbon control is a critical aspect of the treatment. Normally carbon potentials of 1.0 to 1.2% are specified to maintain the carbon profile in the part.

Tempering is usually required after case hardening when densities exceed 90%. In this case, significantly high stresses that could initiate cracking are developed upon quenching. As porosity increases, this stress level is reduced to a level at which a posttemper is not necessary. However, judgment should be used when deciding whether tempering is required. If a substantial amount of retained austenite is formed upon carbonitriding, a temper is advisable.

If the part has thin cross sections, sharp corners, or undercuts that would act as stress raiser, then tempering would also be advisable. Recommended tempering temperatures for P/M parts range from 105 to 200 °C (220 to 390 °F). Above this temperature, entrained quench oil can ignite, creating a hazardous condition in the furnace. Tempering above 200 °C (390 °F) will result in improved toughness and fatigue properties of the heat-treated P/M steel. However, furnaces will need special adaptations to handle the high volume of smoke created by the ignition of the quench oil.

Induction Hardening. Spur gears, bevel gears, splined hubs, and cams are ideal components to utilize P/M production techniques. These parts usually require hard wear-resistant surfaces in some areas, with the retention of the ductility of the sintered matrix in the remainder of the part. Induction hardening is commonly specified for these applications.

This process can be placed in an automated machining line that can reduce handling and be a cost-effective hardening treatment when high volumes of parts are being produced. Because the inductance of P/M materials is typically reduced

due to porosity, a higher power setting is normally required to reach a given depth of hardening compared to that used for a wrought material of similar composition. Furthermore, because the heat is rapidly dissipated, a rapid transfer to the quench is mandatory.

As with wrought steels, the response to hardening by induction is dependent upon combined carbon content, alloy content, and surface decarburization. This latter variable can be a major concern with P/M parts. With today's conventional belt-type sintering furnaces using an endogas atmosphere, decarburizing can occur as the parts leave the hot zone and cool slowly through the 1100 to 800 °C (2010 to 1470 °F) temperature range.

In most cases, P/M parts are quenched in a water-based solution containing some type of rust preventative to forestall internal corrosion. In those applications where induction hardening is considered, densities above 90% should be specified. With a decrease in density, the resistivity of the steel increases and permeability decreases. For this reason, integral quench coils using a high-velocity spray quench are generally used to attain maximum surface hardness in the P/M part.

Nitrocarburizing. This process is rapidly growing in popularity as a treatment for P/M parts. Here, nitrogen is diffused into the surfaces of the steel in sufficiently high concentration to form a thin layer of ε iron nitride on the surface of the part. This is done at temperatures ranging from 570 to 600 °C (1060 to 1110 °F). At these temperatures no austenite transformation occurs, thereby significantly reducing the dimensional changes and distortion.

The process uses conventional integral quench atmosphere furnaces. The atmosphere usually consists of a 50/50 mixture of endothermic gas and anhydrous ammonia. Control of the nitrided layer thickness, as with the other treatments, is dependent on density. If the nitrided layer is allowed to form on the internal pore surfaces to any significant extent, a volume expansion can occur. For this reason, density of the P/M part should be above 90% of theoretical. This nitrided layer, when properly applied, can reduce the coefficient of friction at the surface of the part and provide improved wear resistance compared to conventional hardening to martensite. This process is best applied to applications where sliding wear and fretting are involved.

Because the hard nitrided layer is relatively thin, this process should not be applied where high indentation or impact loading is involved. The ε nitride layer that is formed can attain a file hardness in excess of HRC 60, depending on the alloy content of the steel. Indentation hardness testing is not recommended when evaluating this process. Since no transformation occurs, the P/M parts can be air cooled without loss of surface hardness. Also, no oil absorption occurs, which leaves the porosity open for impregnation if desired.

Nitrocarburizing also provides improved strength and reduced notch sensitivity in P/M parts. Figure 3 shows the fatigue improvement of two low-carbon P/M steels after nitrocarburizing. A typical nitrocarburized microstructure of an iron-copper-carbon P/M steel is shown in Fig. 4.

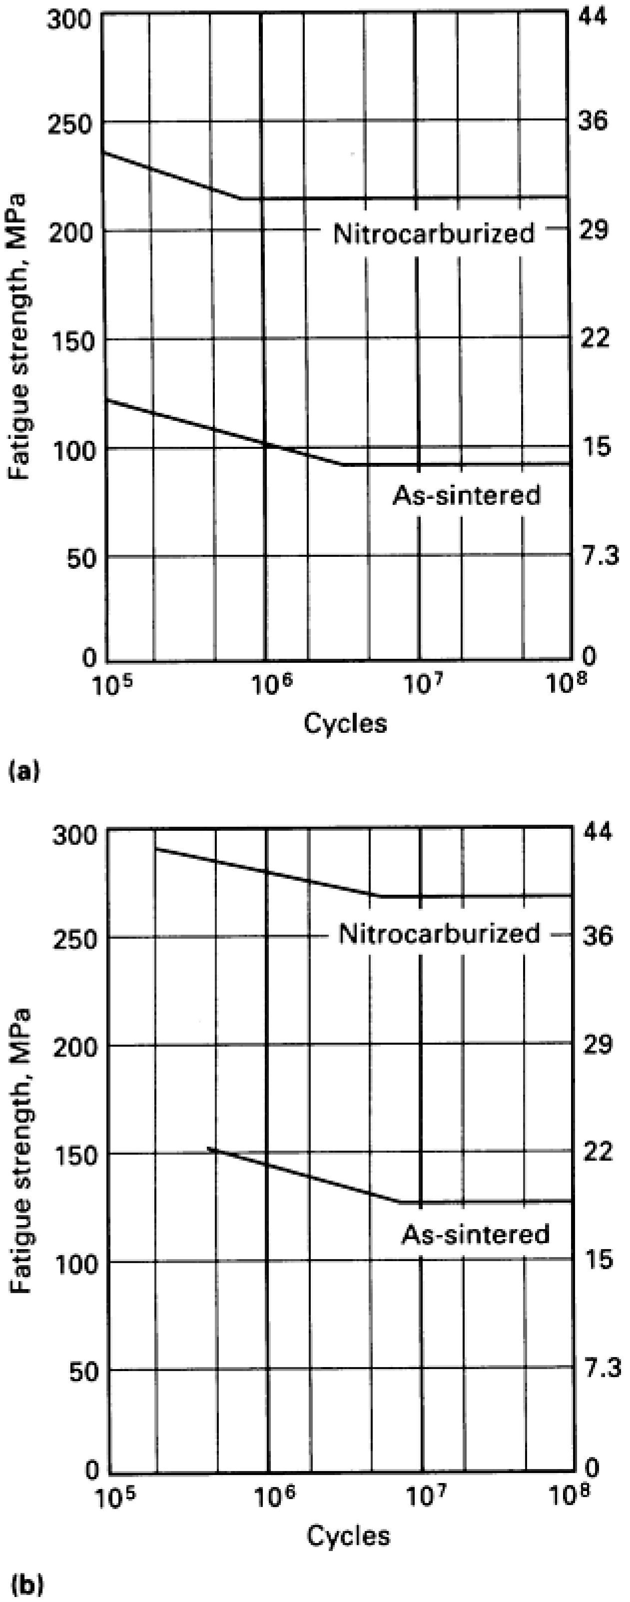

Fig. 3 Increase in the notched axial fatigue strength of sintered low-carbon P/M steels after nitrocarburizing for 2 h at 570 °C (1060 °F). (a) F-0000 carbon steel. (b) FC-0205 copper-carbon steel. Metal powder density was 7.1 g/cm^3 (0.256 lb/in.^{3}). Source: Ref 5

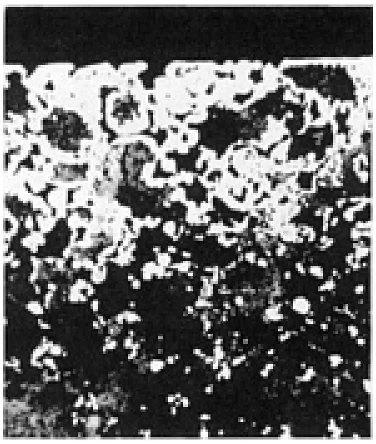

Fig. 4 Typical microstructure in a sintered ferritic nitrocarburized iron-copper-carbon P/M steel. 100×. Source: Ref 5

Plasma nitrocarburizing is in essence a variant of the now well-established glow-discharge plasma (ion) nitriding method (see the discussion that follows on ion nitriding). A technical argument against the use of plasma nitrocarburizing has been the effect of retained lubricant on the character and stability of the glow-discharge plasma, thus effecting the reliability of the plasma technology when applied to sintered parts. Lubricants are added to powdered products in order to achieve optimum pressing conditions. A method by which the lubricant can be satisfactorily removed prior to the P/M parts entering the vacuum chamber of the plasma unit is described in Ref 7. Using this method, it is now routinely possible to plasma nitrocarburize in one batch up to 4500 components, such as chain gear wheels, that have been manufactured by P/M. The microstructure of such a plasma nitrocarburized component is shown in Fig. 5. It is interesting to note that detailed examination shows that pores within the material, but close to the surface, also show the presence of the compound layer. The extent of the depth of such nitrocarburized pores is a function of the degree of interconnected porosity of the component, which is, in turn, a function of the pressing conditions.

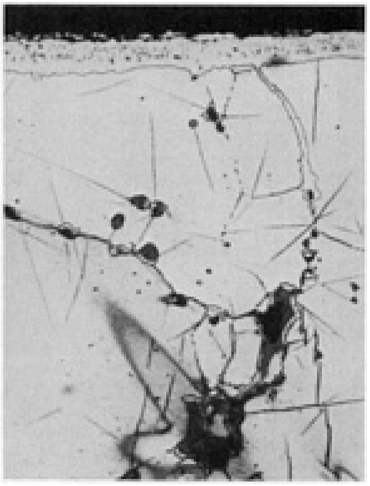

Fig. 5 Microstructure of a plasma nitrocarburized P/M steel with a compound surface layer thickness of 10 μm. Source: Ref 7

Ion Nitriding. The hardness, wear resistance, and fatigue strength can also be improved by plasma, or ion, nitriding. This is a method of surface hardening using glow discharge technology to introduce nascent (elemental) nitrogen to the surface of a metal part for subsequent diffusion into the material. In a vacuum, high-voltage electrical energy is used to form a plasma, through which nitrogen ions are accelerated to impinge on the workpiece. This ion bombardment heats the

workpiece, cleans the surface, and provides active nitrogen. Ion nitriding provides better control of case chemistry and uniformity and has other advantages, such as lower part distortion than conventional gas nitriding.

When ion nitriding of P/M steels, precleaning is more critical than with wrought alloys because of the porosity characteristic. A baking operation should precede the ion nitriding of P/M parts in order to break down or release agents and/or to evaporate any cleaning solvents.

Tool Steels

A tool steel is any steel used to make tools for cutting, forming, or otherwise shaping a material into a final part or component. These complex alloy steels, which contain relatively large amounts of tungsten, molybdenum, vanadium, manganese, and/or chromium, make it possible to meet increasingly severe service demands. In service, most tools are subjected to extremely high loads that are applied rapidly. The tools must withstand these loads a great number of times without breaking and without undergoing excessive wear or deformation. In many applications, tool steels must provide this capability under conditions that develop high temperatures in the tool. Most tool steels are wrought products, but precision castings can be used in some applications. The powder metallurgy process is also used in making tool steels. It provides, first, a more uniform carbide size and distribution in large sections and, second, special compositions that are difficult or impossible to produce in wrought or cast alloys.

Tool Steel Classifications

Tool steels are classified according to their composition, applications, or method of quenching. Each group is identified by a capital letter; individual tool steel types are assigned code numbers. Table 2 gives composition limits for the tool steels most commonly used. More detailed information on tool steels, including their processing, properties, and applications, can be found in Ref 8 and 9.

Table 2 Composition limits of principal types of tool steels

(a) All steels except group W contain 0.25 max Cu, 0.03 max P, and 0.03 max S; group W steels contain 0.20 max P, and 0.025 max S. Where specified, sulfur may be increased to 0.06 to 0.15% to improve machinability of group H, M, and T steels.

(b) Available in several carbon ranges.

(c) Contains free graphite in the microstructure.

(d) Optional.

(e) Specified carbon ranges are designated by suffix numbers.

High-speed steels are tool materials developed largely for use in high-speed metal cutting applications. There are two classifications of high-speed steels; molybdenum high-speed steels, or group M, which contain from 0.75 to 1.52% C and 4.50 to 11.0% Mo, and tungsten high-speed steels, or group T, which have similar carbon contents but high (11.75 to 21.00%) tungsten contents. Group M steels constitute more than 95% of all high-speed steel produced in the United States.

Hot-work steels (group H) have been developed to withstand the combinations of heat, pressure, and abrasion associated with punching, shearing, or forming of metals at high temperatures. Group H steels usually have medium carbon contents (0.35 to 0.45%) and combined chromium, tungsten, molybdenum, and vanadium contents of 6 to 25%. H steels are divided into chromium hot-work steels, tungsten hot-work steels, and molybdenum hot-work steels.

Cold-work steels are restricted in application to those uses that do not involve prolonged or repeated heating above 205 to 260 °C (400 to 500 °F). There are three categories of cold-work steels: air-hardening steels, or group A; high-carbon, high-chromium steels, or group D; and oil-hardening steels, or group O.

Shock-resisting, or group S, steels contain manganese, silicon, chromium, tungsten, and molybdenum, in various combinations; carbon content is about 1.50%. Group S steels are used primarily for chisels, rivet sets, punches, and other applications requiring high toughness and resistance to shock loading.

The low-alloy special purpose, or group L, tool steels contain small amounts of chromium, vanadium, nickel, and molybdenum. Group L steels are generally used for machine parts and other special applications requiring good strength and toughness.

Mold steels, or group P, contain chromium and nickel as principal alloying elements. Because of their low resistance to softening at elevated temperatures, group P steels are used almost exclusively in low-temperature die casting dies and in molds for injection or compression molding of plastics.

Water-hardening, or group W, tool steels contain carbon as the principal alloying element (0.70 to 1.50% C). Group W steels, which also have low resistance to softening at elevated temperatures, are suitable for cold heading, coining, and embossing tools, woodworking tools, metal-cutting tools, and wear-resistant machine tool components.

Surface Treatments for Tool Steels (Ref 10)

Most surface treatments are employed to increase surface hardness and/or wear resistance, minimize adhesion (reduce friction), or improve the corrosion resistance of the tool steel base. The processes discussed below are described in greater detail elsewhere in this Volume or in *Heat Treating*, Volume 4 of the *ASM Handbook*.

Carburizing. The processes of case hardening and carburizing are of limited use in tool steel applications, because of the relatively high carbon contents of the tool steels. Carburizing can be accomplished in many ways, and essentially consists of heating the final machined tool into the austenite region in the presence of carbonaceous solids, liquids, or gases.

Low-carbon plastic mold steels (P type) are often carburized after hubbing or machining of the cavity in the mold. In this application, the tool steel is intentionally lean in carbon content to improve hubbing or machining, and must be carburized in order to have sufficient surface hardness for the end use.

Nitriding is a frequently used surface treatment that increases surface hardness, adds to the corrosion resistance of the tool, and reduces friction. Basically, the process involves heating the finished tool in the presence of a nitrogen-containing liquid or gas and allowing nitrogen to diffuse into the tool. Gas nitriding is usually accomplished at a lower temperature (about 527 °C, or 980 °F) and longer time (10 to 90 h) than liquid nitriding, which occurs at temperatures ranging from 538 to 552 °C (1000 to 1025 °F) for 2 to 4 h. A nitrided depth that ranges from 13 to 76 μm (0.0005 to 0.003 in.) is desired.

Because of decreased wear and die pickup, cold-extrusion punches experience a two to three-fold improvement in life. Nitriding is often used whenever mold wash is a problem in the die casting of zinc or aluminum alloys. Galling of sheet metal working dies can be alleviated by nitriding these dies before use.

Steels that will be nitrided should contain one or more of the nitride-forming elements (chromium, vanadium, or aluminum) in order to prevent the easy spalling and chipping that results when iron nitride is formed. Commonly nitrided tool steels include H11, H12, H13, A2, O2, and the high-speed tool steels.

Ion or plasma nitriding has many of the same characteristics of liquid or gas nitriding. This process relies on a nitrogen gas being ionized by glow discharge conditions between the tool (carbide) and the furnace wall or shield (anode).

The primary advantages are the reductions in time and temperature, which save money and reduce the distortion and softening of prehardened tools. Usually, treatment times vary between 0.5 and 36 h.

Boriding. In this process, boron atoms from a solid, liquid, gas, or plasma atmosphere surrounding the finished part are diffused into the surface, creating a hard, water-resistant iron boride layer. Metal-to-metal wear testing demonstrated a three-fold improvement in wear resistance of borided O1 and O2 tool steels and over a two-fold increase in A2 tool steel (Ref 11). Borided A2 tool steel showed twice the life of uncoated O2 tool steel in a deep-drawing operation in which low-carbon steel cups were manufactured (Ref 11). An H13 roller designed to flange milk cans was borided and produced three times as many cans before it wore out (Ref 12).

Boriding takes place at temperatures as low as 600 °C (1100 °F), but usual practice involves a period from 1 to 6 h at temperatures from 800 to 900 °C (1470 to 1650 °F) (Ref 11, 12). The resultant layer is between 13 and 130 μm (0.0005 and 0.005 in.), and tends to be dull because of the microroughness of the surface. This high process temperature requires that the boron treatment act as the austenitization step, or else the process must be followed by reaustenitization. This necessarily limits the process to applications where tolerances of about 25 μm (0.001 in.) can be tolerated.

Carbide Coating by Toyota Diffusion Process. Good surface covering and strongly bonding carbide coatings, such as VC, NbC, and Cr_7C_3, can be formed on die steel surfaces by a coating method developed at Toyota Central Research and Development Laboratory, Inc. of Japan.

In the Toyota Diffusion (TD) process, metal dies to be treated are degreased, immersed in a carbide salt bath for a specific time period, quenched for core hardening, tempered, and washed in hot water for the removal of any residual salt. The borax salt bath contains compounds (usually ferroalloys) with carbide-forming elements such as vanadium, niobium, and chromium. The bath temperature is selected to conform to the hardening temperature of the die steel. For example, the borax bath temperature would be between 1000 and 1050 °C (1830 and 1920 °F) for H13 die steel.

The carbide layer is formed on the die surface through a chemical reaction between carbide-forming elements dissolved in the fused borax and carbon in the substrate. The carbide layer thickens due to reaction between the carbide-forming element atoms in the salt bath and the carbon atoms diffusing into the outside surface layer from the interior of the substrate.

The thickness of the carbide layer is varied by controlling the bath temperature and immersion time. An immersion time of 4 to 8 h is needed for H13 steel to produce carbide layers with satisfactory thickness (5 to 10 μm) for die-casting applications. Dies are then removed from the bath and cooled in oil and salt or air for core hardening followed by tempering.

Coated tool steels, such as H12 and H13 steels, exhibit high hardness and excellent resistance to wear, seizure, corrosion, and oxidation. In addition, resistance to cracking, flaking, and heat checking is claimed. Hardness of the coating depends on layer composition: 3500 HV for vanadium carbide, 2800 HV for niobium carbide, and 1700 HV for chromium carbide.

Oxidation is a well-established process used for high-speed steel cutting tools. Increases in tool life of up to 100% are mostly due to a decrease in friction, because of the hard oxide coating and the ability of the porous oxide to entrap lubricant and draw it to the tool-workpiece interface. Steam oxidation of a finished tool is accomplished either by exposure to steam at a temperature of about 566 °C (1050 °F) or by treating in liquid sodium hydroxide and sodium nitrate salts at approximately 140 °C (285 °F) for periods of time ranging from 5 to 20 min. These treatments result in a black oxidized layer that is less than 5 μm (0.0002 in.) thick and will not peel, chip, nor crack, even when the tool is bent or cut. Tool life improvements due to steam oxidation are listed in Tables 3 and 4.

Table 3 Machining tool life improvements due to steam oxidation

Tool	Application	Tool life	
		Before steam treating	After steam treating
M2 broachers	Cutting AISI 1010 latch	20 h per grind	70 h per grind

M2 drills	Drilling Bakelite plastic insulating blocks	10 holes	25 holes
	Phenolic terminal plates	1700 holes per grind	8500 holes per grind
	Drilling AISI 4030 steel 25 mm (1 in.) thick	17 holes	81 holes
M7 end mill tools	Cutting 8740 steel forgings	30 pieces	200 pieces
A6 hobs	Cutting teeth on AISI 3140 forged gear	. . .	62.2% increased life
M2 milling cutters	Two slots in 1020 steel	150 cuts per grind	306 cuts per grind
	Slotting 1020 steel bars	2000 per grind	7000 per grind
M2 saw blades	Cutting 75 mm (3 in.) rods, austenitic steel	100% endurance at 0.52 m/s (102 sfm)	120% endurance at 0.57 m/s (112 sfm)
M2 taps	Cutting SAE 52100 steel	1800 pieces	3000 pieces

Table 4 Effect of steam oxidation on tool life in forming various carbon steel nuts and bolts

Tool	**Application**	**Tool life**	
		Before steam treating[(a)]	**After steam treating**[(b)]
M2 4th station punch	Castle nut 1030 material	21,000 nuts	42,000 nuts
M2 4th station punch	Slotted insert nut 1030 material	22,000 nuts	38,000 nuts
M2 4th station punch	Castle nut 1030 material	29,000 nuts	80,000 nuts
M2 3rd station punch	Castle nut 1110 material	20,000 nuts	35,000 nuts
M2 4th station punch	Castle nut 1110 material	15,000 nuts	35,000 nuts
M2 trim die	Bolt head 1335 material	7,000 bolts	16,000 bolts

(a) Hardened and triple tempered.

(b) Hardened, triple tempered and steam treated.

Bright Finish. Most high-speed cutting tools are finished with a ground or mechanically polished surface that would be categorized as a bright finish. Bright finished tools are often preferred to tools with an oxide finish for machining nonferrous work material. The smooth or bright finish tends to resist galling, a type of welding or buildup associated with many nonferrous alloys. However, work materials of ferrous alloys tend to adhere to similar, iron-base tools having a bright finish. This buildup on the cutting edges leads to increased frictional heat, poor surface finish, and increased load at the cutting edge.

Plating. Three different kinds of plating are used on tool steels. Cadmium plating is used for appearance purposes and to reduce corrosion of the tool. It also has some usefulness in preventing adhesion. Nickel plating is commonly used for appearance purposes and to prevent corrosion.

The most commonly practiced tool steel plating process is hard chromium plating. Plating thickness varies between 2 and 13 μm (0.0001 and 0.0005 in.) and, because it is very hard, it prolongs life by increasing abrasive wear resistance. More important than plating hardness is its very low friction coefficient, which effectively prevents adhesive wear.

However, hard chromium plating is not without problems. Tool steels may be hydrogen embrittled when plated, and the plating has a tendency to spall and flake. These wear debris can actually accelerate abrasive wear.

Chemical vapor deposition (CVD), a process conducted in a vacuum chamber, relies on a deposition from reacted gas onto the tool steel surface. Many different materials can be used as coatings. Chromium, Al_2O_3, TiC, CrC, Fe_4N, and TiN are commonly used, and other materials are being studied. This process utilizes high temperatures, usually above 800 °C (1472 °F), which means that tool steels must be tempered after the CVD coating is applied. The most popular wear-resistant coatings are TiC and TiN, which are used to coat high-speed, cold-work die and hot-work die tool steels. These coatings commonly range in thickness from 2 to 20 μm (0.0001 to 0.001 in.). Using CVD coating with TiC and TiN, the primary mechanism of wear reduction is the extremely high hardness, which leads to excellent abrasion resistance, although some decrease in friction coefficient can often be realized. The chlorine content of the coating must carefully be maintained at a level below 5% to avoid degradation of the wear resistance (Ref 14).

Tool steels that can be successfully CVD coated include the AISI A, S, D, H, M, and T steel types. The lower-alloyed S type and all of the W and O types are either very difficult or impossible to properly coat, because of their low austenitization temperatures.

Physical vapor deposition (PVD), which is also conducted in a vacuum chamber, can be accomplished in several different ways. The process relies on plasma-aided precipitation of either TiC or TiN onto tool steel at temperatures ranging from 200 to 550 °C (400 to 1025 °F) (Ref 14). This temperature range is much more suitable for the coating of high-speed tool steels than the temperatures required for CVD.

Tool steel wear is reduced in about the same proportions (2 to 6 times less wear), whether the TiC or TiN is applied by CVD or PVD. TiN coatings on H13 pins reduced the friction coefficient in pin-on-disk tests from 0.7 to less than 0.2 (Ref 15). Modified ASTM G65-10 abrasive wear testing of D3 steel showed that wear of the TiN-coated samples was between 4 and 23% of the uncoated samples, depending on their initial surface roughness (Ref 15). This result led Sundquist et al. to propose that increases in tool life that are due to TiN coating can only be expected when the surface roughness is less than the coating thickness (Ref 15). Specific examples of the use of PVD coatings for improving the life of high-speed steel tools are listed in Table 5.

Table 5 Increased tool life attained with PVD coated cutting tools

Cutting tool	Coating	Workpiece material	Workpieces machined before resharpening

Type	High-speed tool steel, AISI type			Uncoated	Coated
End mill	M7	TiN	1022 steel, 35 HRC	325	1200
End mill	M7	TiN	6061-T6 aluminum alloy	166	1500
End mill	M3	TiN	7075T aluminum alloy	9	53
Gear hob	M2	TiN	8620 steel	40	80
Broach insert	M3	TiN	Type 303 stainless steel	100,000	300,000
Broach	M2	TiN	48% nickel alloy	200	3400
Broach	M2	TiN	Type 410 stainless steel	10,000-12,000	31,000
Pipe tap	M2	TiN	Gray iron	3000	9000
Tap	M2	TiN	1050 steel, 30-33 HRC	60-70	750-800
Form tool	T15	TiC	1045 steel	5000	23,000
Form tool	T15	TiN	Type 303 stainless steel	1840	5890
Cutoff tool	M2	TiC-TiN	Low-carbon steel	150	1000
Drill	M7	TiN	Low-carbon steel	1000	4000
Drill	M7	TiN	Titanium alloy 662 layered with D6AC tool steel, 48-50 HRC	9	86

Ion implantation is a process by which atoms of virtually any element can be injected into the near-surface region of any solid. The implantation process involves forming a beam of charged ions of the desired element and then accelerating them at high energies towards the surface of the solid, which is held under high vacuum. The atoms penetrate into the solid to a depth of 0.25 to 25 nm (2.5 to 250 Å). This process differs from coating processes in that it does not produce a discrete coating; rather, it alters the chemical composition near the surface of the solid. The most common element implanted in tool steels in order to improve tribological properties, specifically adhesive and sliding wear, is nitrogen.

Examples of ion implantation in metal forming and cutting applications are listed in Table 6. Ion implantation of titanium and carbon has also improved the service life of stamping and cutting tools.

Table 6 Examples of ion implantation in metalforming and cutting applications

Part	Part material	Process	Work material	Ion	Energy, keV	Benefit
Tool inserts	TiN-coated tool steel	Machining	4140	N	80	3× life
Taps	HSS	Tapping	4140	N	80	3× life
	HSS	Tapping	4130	N	80	5× life
	HSS	Tapping	4140	N	50	10× life
	M35	Tapping	. . .	N_2	200	4× life
	M7	Tapping	. . .	N	100	2× life
Cutting blade	M2	Cutting	1050	N	100	2× life
	M2	Cutting	SAE 950	N	100	4× life
Dies	D2	Forming	321 SS	N	80	2× life
	M2	Forming	Steel	N	100	2-12× life
	M2	Forming	1020	N	100	Negligible effect
	D6	Forming	TiO_2 and rubber	N	100	6× life
Molds	D2	Forming	Polymers	N	50	5× life
Rollers	H13	Rolling	Steel	N	100	5× life

Note: HSS, high-speed steel; SS, stainless steel.

Laser surface processing methods, such as laser melting, have also been applied to tool steels. Hsu and Molian (Ref 18) reported that the tool life of laser-melted M2 steel tool bits was from 200 to 500% higher than if they were conventionally hardened using catastrophic failure criterion (Fig. 6). For laser-melted M35 steel tool bits, the tool life was from 20 to 125% higher than if they were conventionally hardened using flank wear failure criterion (Fig. 6). High-alloy martensite, fine austenite grain size, and finely dispersed carbides all contributed to high hardness, good toughness, and low coefficient of friction.

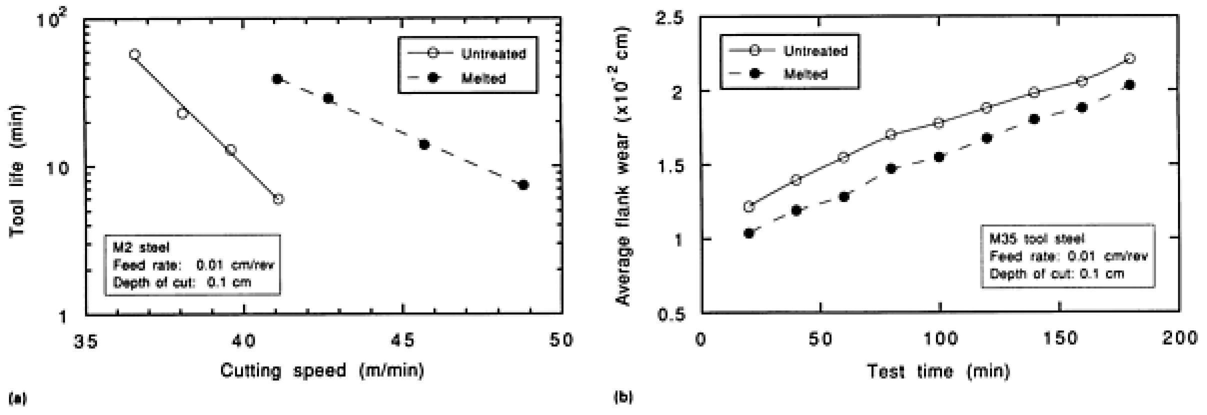

Fig. 6 Tool life of conventionally heat-treated and laser-melted tool bits. (a) M2 tool steel. (b) M35 tool steel. Source: Ref 18

Maraging Steels (Ref 19)

Maraging steels comprise a special class of high-strength steels that differ from conventional steels in that they are hardened by a metallurgical reaction that does not involve carbon. Instead, these steels are strengthened by the precipitation of intermetallic compounds at temperatures of about 480 °C (900 °F). The term maraging is derived from martensite age hardening and denotes the age hardening of low-carbon, iron-nickel lath martensite matrix. The physical metallurgy and properties of maraging steels are described in Ref 19.

Commercial maraging steels are designed to provide specific levels of yield strength from 1030 to 2420 MPa (150 to 350 ksi). Some experimental maraging steels have yield strengths as high as 3450 MPa (500 ksi). These steels typically have very high nickel, cobalt, and molybdenum contents and very low carbon contents. Carbon, in fact, is an impurity in these steels and is kept as low as commercially feasible in order to minimize the formation of titanium carbide (TiC), which can adversely affect strength, ductility, and toughness.

Table 7 lists the chemical compositions of the more common grades of maraging steel. The nomenclature that has become established for these steels is nominal yield strength (ksi units) in parentheses. Thus, for example, 18Ni (200) steel is normally age hardened to a yield strength of 1380 MPa (200 ksi). The first three steels in Table 7--18Ni (200), 18Ni (250), and 18Ni (300)--are the most widely used and most commonly available grades. The 18Ni (350) grade is an ultrahigh-strength variety made in limited quantities for special applications. Two 18Ni (350) compositions have been produced (see the footnote in Table 7). The 18Ni (Cast) grade was developed specifically as a cast composition.

Table 7 Nominal compositions of commercial maraging steels

Grade	Composition, %[(a)]					
	Ni	**Mo**	**Co**	**Ti**	**Al**	**Nb**
Standard grades						
18Ni(200)	18	3.3	8.5	0.2	0.1	. . .
18Ni(250)	18	5.0	8.5	0.4	0.1	. . .
18Ni(300)	18	5.0	9.0	0.7	0.1	. . .
18Ni(350)	18	4.2[(b)]	12.5	1.6	0.1	. . .
18Ni(Cast)	17	4.6	10.0	0.3	0.1	. . .
12-5-3(180)[(c)]	12	3	. . .	0.2	0.3	. . .
Cobalt-free and low-cobalt bearing grades						
Cobalt-free 18Ni(200)	18.5	3.0	. . .	0.7	0.1	. . .
Cobalt-free 18Ni(250)	18.5	3.0	. . .	1.4	0.1	. . .
Low-cobalt 18Ni(250)	18.5	2.6	2.0	1.2	0.1	0.1

(a) All grades contain no more than 0.03% C.

(b) Some producers use a combination of 4.8% Mo and 1.4% Ti, nominal.

(c) Contains 5% Cr

A number of cobalt-free maraging steels and a low-cobalt bearing maraging steel have recently been developed. The driving force for the development of these particular alloys was the cobalt shortage and resultant price escalation of cobalt during the late 1970s and early 1980s. The nominal compositions for these alloys are also listed in Table 7.

Surface Treatments for Maraging Steels (Ref 19)

Cleaning. Grit blasting is the most efficient technique for removing oxide films formed by heat treatment. Maraging steels can be chemically cleaned by pickling in sulfuric acid or by duplex pickling in hydrochloric acid and then in nitric acid plus hydrofluoric acid (see Tables 7 and 11 in the article "Surface Engineering of Stainless Steels" in this Volume). As with conventional steels, care must be taken to avoid overpickling. The sodium hydride cleaning of maraging steels should be avoided to minimize problems with crack formation. Grease and oils can be removed by cleaning in trichloroethane-type solutions.

Nickel Plating. Maraging steels can be nickel plated in chloride baths provided that proper surface-activation steps are followed. Heavy chromium deposits can be plated on top of nickel electrodeposits. Maraging steels are less susceptible to hydrogen embrittlement during plating than conventional quenched and tempered steels of comparable hardness. They are not immune to hydrogen, however, and baking after plating is recommended. Baking should be done at temperatures of about 150 to 205 °C (300 to 400 °F) for periods of 3 to 10 h, depending on size and baking temperature. Baking cannot be combined with age hardening, because considerable hydrogen remains in the steel after heat treating at the higher temperatures.

Nitriding. Considerable surface hardening can be achieved by nitriding maraging steels in dissociated ammonia. Hardness levels equivalent to 65 to 70 HRC can be achieved at depths of up to 0.15 mm (0.006 in.) after nitriding for 24 to 48 h at 455 °C (850 °F). Nitriding at this temperature allows age hardening to occur during nitriding; therefore, the two processes can be accomplished simultaneously. Salt bath nitriding for 90 min at 540 °C (1000 °F) has been done successfully. Such treatment must be very carefully controlled to avoid excessive overaging. Both the fatigue strength and the wear resistance (Fig. 7) of maraging steels are improved by nitriding.

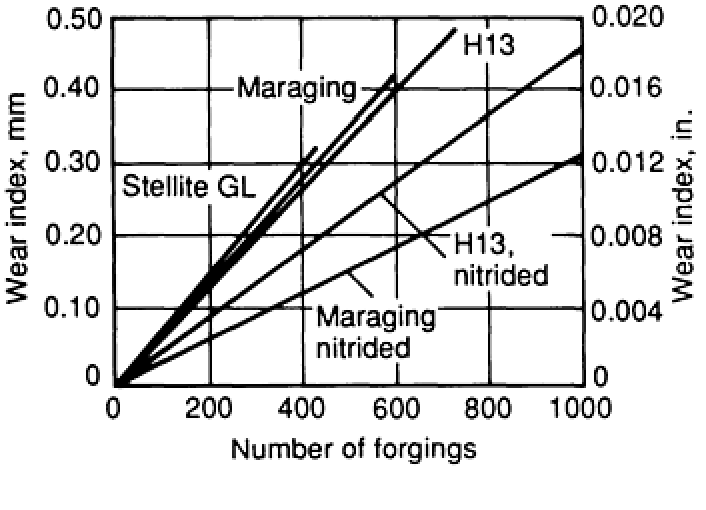

Fig. 7 Relative wear rates of nitrided and non-nitrided tool steels and maraging steels used in extrusion forging

Maraging steels can also be surface hardened by ion nitriding. Ozbaysal and Inal (Ref 20) have demonstrated that the surface hardening of maraging steels without a reduction in core hardness is possible using the ion nitriding process. Their studies on 18Ni(250), 18Ni(300), and 18Ni(350) showed that the highest surface hardness and the highest core hardness for all three grades were achieved by nitriding at approximately 440 °C (825 °F). Figure 8 shows the surface and core hardness as functions of ion nitriding time and temperature for 300-grade maraging alloy.

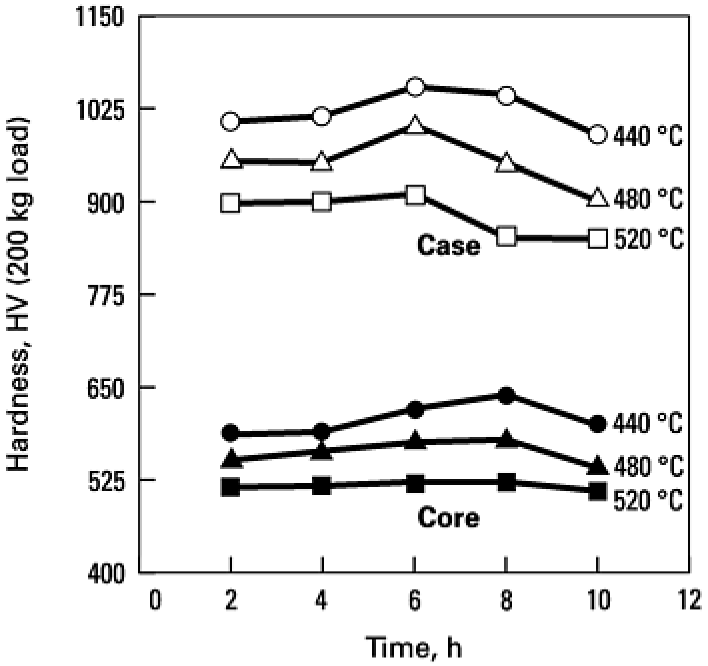

Fig. 8 Surface (case) and core hardness as functions of ion nitriding time and temperature for 18Ni (300) maraging steel. Source: Ref 20

Electrical Steels (Ref 21)

Electrical steels are flat-rolled silicon-containing alloys used for soft magnetic applications such as components (magnetic cores) for motors, generators, and transformers. The beneficial effects of silicon additions to iron include:

- Increase of electrical resistivity
- Suppression of the γ loop enabling desirable grain growth
- Development of preferred orientation grain structure

The addition of silicon also reduces magnetocrystalline anisotropy energy, and at ~6.5% Si content reduces the magnetostriction constants to nearly zero. High-permeability and low hysteresis losses can therefore be attained at the 6.5Si-Fe composition. On the negative side, the addition of silicon to iron lowers magnetic saturation, lowers Curie temperature, and seriously decreases mechanical ductility. At silicon levels above ~4%, the alloy becomes brittle and difficult to process by cold-rolling methods; thus, few commercial steels contain more than ~3.5% Si.

The commercial grades of silicon steel in common use are made mostly in electric or basic oxygen furnaces. Continuous casting and/or vacuum degassing (V-D) may be employed. Flat-rolled silicon-iron sheet and strip has low sulfur content, typically below 0.25%, with better grades below 0.01%. Carbon contents are frequently less than 0.04%. Manganese may be present up to approximately 0.70%. Residual elements such as chromium, molybdenum, nickel, copper, and phosphorus may also be present. The major alloying addition is silicon plus up to 0.6% Al (optional). These alloys are not generally sold on the basis of their composition, but rather are sold based upon controlled magnetic properties, particularly ac core losses.

Electrical sheet grades are divided into two general classifications, (1) oriented steels and (2) nonoriented steels. The oriented steels are given mill treatments designed to yield exceptionally good magnetic properties in the rolling, or lengthwise, direction of the steel. Nonoriented grades are made with a mill treatment that yields a grain structure, or texture, of a random nature and, therefore, the magnetic properties in the rolling direction of the steel are not significantly better than those in the transverse direction. Subdivisions of these steels include semiprocessed grades and the fully processed grades. The former must be given a heat treatment by the purchaser. Fully processed grades are process annealed by the manufacturer.

Table 8 gives examples of properties specified by ASTM and American Iron and Steel Institute (AISI) for standard grades of nonoriented and oriented electrical steel. The AISI designations were adopted in 1946 to eliminate the wide variety in nomenclature formerly used. When originally adopted, the AISI designation number approximated ten times the maximum core loss,* in watts per pound, exhibited by 29 gage (0.36 mm, or 0.014 in.) samples when tested at a flux density of 1.5 T (15 kG) and a magnetic circuit frequency of 60 Hz. Note that fully processed M-36 tested as 0.36 mm (0.14 in.) strip now has a maximum allowable core loss of 4.2 W/kg (1.9 W/lb), not an approximate level of 7.9 W/kg (3.6 W/lb). Low core loss is obtained with higher silicon contents, larger grain size optimization, lower impurity levels, thinner gages, and insulating coatings.

Table 8 Properties of selected electrical steels

AISI type (approximate equivalent)	Nominal (Si + Al) content, %	Thickness		ASTM designation	Maximum core loss at 60 Hz and B = 1.5 T (15 kG)	
		mm	in.		W/kg	W/lb
Nonoriented						
Semiprocessed (ASTM A 683)[(a)]

(b) Refer to ASTM A 677-84 and companion specification A 677M-83 (metric) for detailed information.

(c) Refer to ASTM A 876-87 and companion specification A 876M-87 for detailed information.

(d) *B* (magnetic induction) = 1.7 T (17 kG).

The AISI designations are still in common use, but the newer ASTM designations provide more specific information regarding the grade identified. A typical ASTM designation is 47S200. The first two digits of the ASTM designation indicate the thickness in mm (×100). Following these digits is a letter (C, D, F, S, G, H, or P) that indicates the material type and the respective magnetic test conditions. The last three digits provide an indication of the maximum allowable core loss in units of either (watts/kg) × 100, or (watts/lb) × 100. If the core-loss value is expressed in watts/kg, the grade designation takes the suffix M, indicating an ASTM metric standard. Several ASTM flat-rolled products specifications are written in English and metric versions, such as A 677-84 and its companion metric specification A 677M-83.

Surface Treatments for Electrical Steels

The purpose of the core metal in a motor, generator, or transformer is to offer the best path for the magnetic lines of flux, and its success in this respect is measured by its permeability. Cores are usually composed of a larger number of thin metal laminations that are fabricated by punching from thin sheets of metal, and which are subsequently assembled to form a core.

Interlaminar insulation is necessary for high electrical efficiency in the magnetic core, whether the application is static or rotating. For small cores used in fractional-horsepower motors, an oxide surface on the laminations may insulate the core adequately. Insulations of AISI types C-1, C-2, C-3, C-4, and C-5 are used for more rigorous requirements. Table 9 describes the characteristics of these various core coatings.

Table 9 Types of core plate coatings used for lowering core losses in electrical steels

Core plate, designation	**Description**
C-1	An organic enamel or varnish coating sometimes used for cores not immersed in oil. It enhances punchability and is resistant to ordinary operating temperatures. It will not withstand stress-relief annealing.
C-2	An inorganic insulation consisting of a glass-like film formed during the high-temperature annealing of electrical steel, particularly grain-oriented electrical steel, as the result of the reaction of an applied coating of MgO and silicates in the surface of the steel. This insulation is intended for air-cooled or oil-immersed cores. It will withstand stress-relief annealing and has sufficient interlamination resistance for wound cores of narrow-width strip such as in distribution transformers. It is not intended for stamped lamination because it is abrasive to dies.
C-3	An enamel or varnish coating intended for air-cooled or oil-immersed cores. C-3 enhances punchability and is resistant to normal operating temperatures. It will not withstand stress-relief annealing.
C-4	Consists of a chemically treated or phosphated surface useful for air-cooled or oil-immersed cores. It will withstand stress-relief annealing in relatively neutral atmospheres.
C-5	An inorganic insulation similar to C-4 but with ceramic fillers (such as colloidal silica) added to increase the electrical insulation properties. C-5 can be used in air-cooled or oil-immersed cores and will endure stress-relief annealing.

Source: ASTM A 345

Organic-Type Insulation. Types C-1 and C-3 are organic and cannot be successfully applied to laminations before annealing. They are unsuitable for electrical equipment operated at high temperatures or for power transformers with certain types of coolants. However, they improve the punchability of the sheet steel.

Inorganic-Type Insulation. Inorganic types C-4 and C-5 are used when insulation requirements are severe and when annealing temperatures up to 790 °C (1450 °F) must be withstood. Typical values of interlaminar resistance for these two types are between 3 and 100 Ω· cm/lamination under a pressure of 2070 kPa (300 psi). These coatings also can be made to impart residual tensile stresses in the steel substrate, which can improve magnetic properties.

Core insulation must be sufficiently thin and uniform so as to have no more than 2.0% effect on the lamination factor (solidity of the core). To calculate the required insulation for most operations at power frequency, the square of the resistivity, in ohm-centimeters per lamination, should at least equal the square of the width of the magnetic path, in inches. This usually ensures a negligible interlaminar loss that is less than 1.0% of the core loss.

Ceramic Films. Japanese electrical steel producers have reported significant improvement in core loss as a result of ion plating of TiN and CrN ceramic coatings (Ref 22). Application of these ceramic films on chemically polished grain-oriented electrical steel sheet increased the magnetic flux density by 0.004 to 0.015 T (0.04 to 0.15 kG) and lowered the core loss by 0.12 to 0.20 W/kg (0.05 to 0.09 W/lb). By laser domain refining (see discussion below), it was possible to further improve the core loss by 0.04 to 0.09 W/kg (0.02 to 0.04 W/lb). Using this dual ceramic film/laser treatment, electrical steels with original core losses of 0.88 W/kg (0.4 W/lb) were improved to an ultralow core loss of 0.55 W/kg (0.25 W/lb), which corresponds to an improvement of about 40% (Ref 22).

Laser Magnetic Domain Refinement. Core loss improvements of 2 to 14% can be achieved by rapid scanning (typically 100 m/s, or 325 ft/s) a high-powered focused laser beam across the surface (transverse to the rolling direction) of grain-oriented glass-coated (Si-Mg-P-Al glass) 3% silicon-irons (Ref 23). There is no flame, spark, or smoke generated during this process, which is also referred to as laser scribing, and the material/coating shows no visible surface change. The improvement in core loss is due to a thermal shock imparted to the microstructure which causes slip plane dislocations to form, thereby producing new magnetic domain wall boundaries (Ref 23). By adjusting the spacing of the scanned laser lines, the energy lost due to moving domain walls back and forth under the action of the applied ac field in the transformer is minimized. The laser lines restrict the length of the domains and also act to control the width of the domains. Thus by adjusting the spacing of the laser lines, the domain sizes can be controlled, i.e., refined. Figure 9 illustrates the improvement in core loss as a function of applied field strength for a 0.26 mm (0.0104 in.) thick silicon steel sheet.

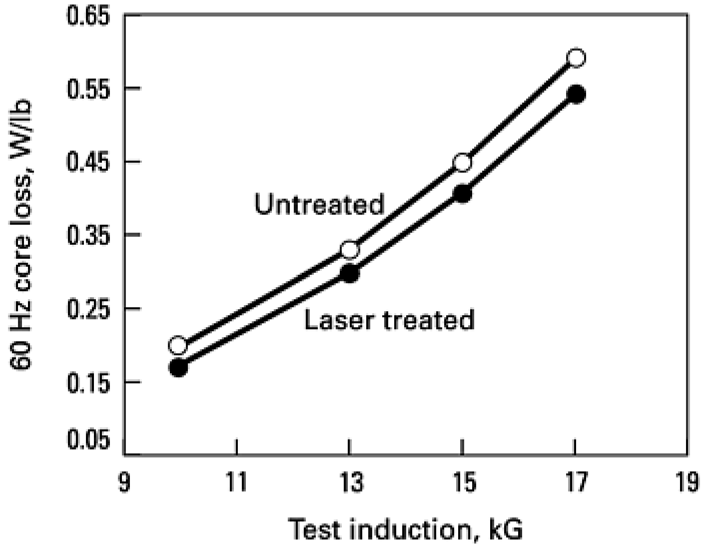

Fig. 9 Effect of laser scribing on the core loss of a high-permeability grain-oriented electrical steel. Source: Ref 23

* The term *core loss,* as applied to electrical steel, is a quantitative measure of the rate at which electrical energy is converted to thermal energy during 50 or 60 cycle ac magnetization. Core loss is separated into two components: hysteresis loss and eddy current loss.

Surface Engineering of Heat-Resistant Alloys

Revised by F.S. Pettit, University of Pittsburgh

Introduction

HEAT-RESISTANT ALLOYS (solid-solution-strengthened or precipitation-hardened nickel-, iron-, or cobalt-base alloys) are often referred to as superalloys, because of their strength, oxidation resistance, and corrosion resistance at elevated service temperatures (650 to 1205 °C, or 1200 to 2200 °F). The surfaces of parts made from these alloys must be cleaned of contaminants, of which there are several types.

Shop soils, such as oil, grease, and cutting fluids, must be removed by solvents or soaps. The article "Solvent Cold Cleaning and Vapor Degreasing" in the Section "Surface Cleaning" of this Volume describes those contaminants and the procedures that must be used to remove them. The Section "Environmental Protection Issues" contains articles that provide guidelines for selecting appropriate solvents or suitable alternatives.

The removal of metallic contaminants, tarnish, and scale resulting from hot-working or heat-treating operations on nickel-, cobalt-, and iron-base heat-resistant alloys is described in this article; a brief description of applicable finishing and coating processes is also provided. For additional information on heat-resistant alloys, see Volume 1 of the *ASM Handbook.*

Metallic Contaminant Removal

Parts made from heat-resistant alloys can accumulate traces of other metals on their surfaces after contacting cutting tools, forming dies, and heat-treating fixtures. Although metal contamination is not always harmful, its presence can be highly deleterious in certain cases. For example, Inconel X-750 may be unaffected by traces of zinc from drawing dies, but even the smallest particle of aluminum will readily alloy with the Inconel at elevated temperatures and degrade the corrosion resistance and mechanical integrity of the affected areas. Copper is another example of a metal that may affect some nickel-base alloys when they are subsequently exposed to high temperatures. Therefore, all surface contaminants should be removed from heat-resistant alloys before they are heat treated or subjected to service at elevated temperatures.

In operations such as cutting and forming, the use of lubricants can either prevent or sharply reduce metal contamination. This is the preferred practice, because lubricants can be removed easily and cheaply, if they have not been baked or fired.

When contamination is unavoidable, testing is recommended to determine the seriousness of the contamination. After heat-treating operations, metallographic examination can be conducted to detect alloy diffusion, and bend or hardness tests can be conducted to detect embrittlement. For example, lead can be detected by the yellow precipitate that forms when a test solution of chromic acid (10 wt%), sodium chlorate (1.5 wt%), and water (88.5 wt%) is applied to the suspected surface at temperatures ranging from 21 to 60 °C (70 to 140 °F).

Mechanical removal methods used for metallic contaminants include dry or wet abrasive blasting with metal-free abrasives, polishing with ceramic materials, and wet tumbling. The shape of a part, the required surface finish, the allowable loss of gage, and residual stress considerations will determine the suitability of these mechanical methods.

Chemical removal methods, however, are used more often than mechanical methods to remove metallic contaminants. A typical procedure for chemically removing iron, zinc, and thin films of lead is to first perform vapor degreasing or alkaline cleaning, and then immerse the parts in a 1:1 solution (by volume) of nitric acid (1.41 sp gr) and water for 15 to 30 min at approximately 35 °C (95 °F). Water rinsing, followed by drying, completes the process.

Another procedure that has been successful in removing brass, lead, zinc, bismuth, and tin from nickel-base and cobalt-base alloys involves vapor degreasing or alkaline cleaning, followed by soaking at room temperature in a solution of nitric acid (54 g/L, or 7.22 oz/gal), acetic acid (150 to 375 g/L, or 20 to 50 oz/gal), and hydrogen peroxide (19 to 64 g/L, or 2.5 to 8.5 oz/gal). Depending on the severity of the contamination, the soaking time can vary from 20 min to 4 h, as determined by visual observation of the reaction. After this treatment, parts must be rinsed thoroughly in water and dried. When possible, a test specimen should be immersed for the maximum time anticipated and then examined for chemical attack before the first load of parts is processed.

Nickel-base alloys should be acid etched to prepare for subsequent nondestructive inspection. The etching process removes smeared metal that may be present as a thin surface layer after machining and/or blast cleaning. The parts can be etched by immersing them in a bath containing hydrochloric acid (80%), hydrofluoric acid (13%), and nitric acid (7%) to remove the disturbed or smeared layer. This bath may leave smut that must be removed by a second bath containing iron chloride (22%), hydrochloric acid (75%), nitric acid (2%), and water. After being rinsed and dried, the parts can undergo visual and penetrant inspections. The extent of etching depends on the depth or thickness of the smeared layer. All of this layer should be removed. However, overetched parts will retain excessive amounts of penetrant.

Tarnish Removal

Tarnish, which is a thin oxide film, does not always have a harmful effect on the end use of parts made from heat-resistant alloys. In fact, it can even be useful, such as when it functions as a bond for paint, a barrier to prevent diffusion from another alloy, or a retardant to further oxidation. However, other functional requirements can necessitate the removal of tarnish from parts. Tarnish should always be removed before welding or brazing.

Abrasive cleaning methods, such as those used to remove metallic contaminants, are also used to remove tarnish. The applicability of these methods is determined by part shape, required surface finish, and allowable loss of gage or dimension.

However, abrasive cleaning can remove some metal and degrade surface finishes. Therefore, flash pickling is used more often than abrasive cleaning to remove tarnish. A typical flash-pickling formula uses nitric acid (1.41 sp gr; 23 vol%), hydrofluoric acid (1.26 sp gr; 4 vol%), and water (73 vol%). Parts are immersed in this solution for 1 to 5 min at approximately 52 °C (125 °F). Warming the parts in hot water before flash pickling speeds tarnish removal. Water rinsing and drying must follow pickling.

Oxide and Scale Removal

The most widely used methods for removing oxides or scale from heat-resistant alloys, in order of decreasing preference based on economic considerations, are acid pickling, abrasive cleaning by tumbling or blasting, and descaling in molten salt. Alkaline scale conditioning is helpful in modifying the scale to facilitate its removal by these methods. When extremely heavy oxide layers must be removed, grinding is an appropriate preliminary operation. Combinations of two or more methods are often used. Before these removal methods are discussed, the characteristics of the various products that need to be removed are described.

Oxide films will form on parts that are heated in reducing atmospheres, out of contact with air. Sometimes, these oxides can be removed by immersing the parts for 5 to 15 min in a tarnish-removing, flash-pickling bath, such as that with the formulation given above. However, most heat-resistant alloys form a tenacious coating in the presence of carbon monoxide or water because of their high content of oxide-forming metals, such as nickel, cobalt, and chromium. The resulting oxides vary widely with alloy composition and furnace atmosphere. Usually, pickling is required for their removal. Scale conditioners are useful.

Scale develops on hot-forged, hot-formed, or heat-treated parts that are processed in air. Usually, scale is tenacious and occurs in all gradations, including thick layers that result from heating in an oxidizing furnace using high-sulfur fuels. The scale that forms under such conditions has a dull, spongy appearance. Fine cracks may be present, and patches of scale

may break from the surface. The underlying metal is rough and cannot be corrected by pickling. In these extreme conditions, grinding or abrasive blasting to sound metal, followed by flash pickling, is recommended.

Scale conditioning is used to soften, modify, or reduce scale to promote easier and more uniform acid pickling, but is seldom required to remove discolorations or thin interference coatings. A scale-conditioning bath consists of a highly alkaline aqueous solution, sometimes containing complexing and chelating compounds. The main purpose of these agents is to solubilize the scale as much as possible. The performance of a particular chelating agent depends on the affinity of the compound for the metal ions present, the pH of the scale-conditioning solution, and the physical and chemical composition of the scale. Typical multicycle descaling operations, including scale conditioning, are defined in Tables 1 and 2.

Table 1 Procedure for removing scale from heat-resistant alloys

Operation	Time, min	Temperature		Solution	Concentration
		°C	°F		
Precleaning cycle					
Vapor degreasing	5-10	87-88	185-190	Stabilized trichloroethylene	. . .
Emulsion cleaning	10-20	54-66	130-150	Emulsion cleaner	20 vol%
Scale-conditioning cycle					
Alkaline chelating	15-30	125-135	260-275	Caustic solution containing alkanol amines and aliphatic hydroxy acids	. . .
Alkaline oxidizing	60-120	95-105	205-220	Potassium permanganate	5 wt%
				Sodium hydroxide	20 wt%
				Water	Remainder
Pickling cycle					
Acid pickling	5-30	49-60	120-	Hydrofluoric acid	4 wt%

Table 2 Procedure for removing scale from Inconel alloys

Operation	Time	Temperature		Solution[a]	Concentration[a]
		°C	°F		

Alkaline conditioning	1-2 h	96-105	205-220	Sodium hydroxide	20 wt%
				Potassium permanganate	5 wt%
Rinse	15-30 s	Not heated	Not heated	Water quench and water spray	. . .
Acid pickling	5-10 min	60-71	140-160	Sulfuric acid (1.83 sp gr)	7.5 vol%
				Hydrochloric acid (1.16 sp gr)	12 vol%
Rinse	15-30 s	Not heated	Not heated	Water	. . .
Acid pickling	10-20 min	60-71	140-160	Nitric acid (1.41 sp gr)	20 vol%
Rinse	15-30 s	Not heated	Not heated	Water	. . .
Acid pickling	5-60 min[b]	49-54	120-130	Hydrofluoric acid (1.26 sp gr)	3.7 vol%
				Nitric acid (1.41 sp gr)	22 vol%
Rinse	15-30 s	Not heated	Not heated	Water	. . .

(a) Undefined remainder is water.

(b) Type of oxide will determine immersion time required; until immersion time is established, inspect frequently to avoid overpickling.

Minimal scale removal occurs during treatment in the alkaline scale-conditioning bath. Further treatment in highly alkaline solutions containing a strong oxidizing material, such as potassium permanganate, is often necessary. The scale on heat-resistant alloys sometimes contains carbon and incompletely burned and polymerized residues, as well as metallic oxides. These organic components react with the oxygen that is released by the alkaline oxidizing bath.

Acid Pickling. After the scale is conditioned, it is subjected to acid pickling, during which most of the high-temperature scale either breaks away from or becomes so loosely attached to the parts that pressure rinsing with water completes the descaling. The acid pickle is usually a dilute nitric acid or a hydrofluoric-nitric acid solution. In addition to removing scale, pickling solutions that contain nitric acid will remove many surface contaminants through oxidation. However, because the acid solution attacks the base metal, it is necessary to limit the pickling time to prevent excessive metal loss or metal surface roughening.

Parts made from alloys that are high in aluminum and titanium, such as M252 and René 41, must undergo a special procedure before welding or brazing. When parts are in the solution-treated condition and descaling is required, they are treated in a scale-conditioning solution, as previously described, after which they are immersed in a solution of nitric acid (30 wt%) and hydrofluoric acid (3 wt%) for 5 to 10 min. Alloys in the aged condition are descaled anodically in an acid solution. A solution made for this procedure should contain sulfuric acid (75 wt%) and hydrofluoric acid (3 wt%). It should be operated using a current density of 215 to 430 A/mm^2 (20 to 40 A/ft^2) and graphite cathodes. The material should be immersed in the electrolytic cleaning bath for 3 to 12 min, and the operation will be complete when the amperage drops to nearly zero. Sodium sulfite (1.6 wt%) is used to reactivate the solution after a period of operation.

Alloys that contain less than approximately 12% Cr, unstabilized austenitic stainless steels, and martensitic and ferritic stainless steels can experience high metal loss or intergranular attack by acids during pickling. When the susceptibility of a material to these problems is unknown, it is safer to perform mechanical descaling than acid pickling. In one specific instance, acid descaling was proven to cause intergranular attack and a subsequent loss of ductility in aged René 41.

Weld areas typically differ, in terms of composition and structure, from the base metal and react differently to conditioning and pickling cycles. Weld areas or heat-affected zones are often susceptible to selective attack during pickling. Although inhibitors can eliminate or reduce this selective attack, it is preferable to use abrasive or other mechanical descaling methods, rather than acid pickling, to remove scale from welded parts, unless a safe pickling procedure has been found for a given application.

Hydrogen embrittlement does not occur in nickel-, cobalt-, or austenitic iron-base alloys as a result of aqueous descaling.

Abrasive blasting with dry aluminum oxide can be used to remove oxide and scale from all types of wrought and cast heat-resistant alloys. Silicon carbide is more expensive than aluminum oxide and is seldom used. Silica (silicon dioxide, or sand) has a limited application because of its lack of cutting ability. It is sometimes used to clean refractory metal forgings prior to pickling. Grit sizes as coarse as No. 30 (0.59 mm, or 0.023 in.) are recommended for cleaning forgings and castings. Finer grits, such as Nos. 90 and 100 (0.17 and 0.15 mm, or 0.0065 and 0.0059 in., respectively), are used for general blasting.

Metallic shot and grit should not be used to descale heat-resistant alloys unless their use is followed by pickling to remove metal contamination. For parts that must be welded or brazed, or that have highly tenacious scales produced by furnace atmospheres, pickling after dry abrasive cleaning is recommended, regardless of the abrasive used.

Wet abrasive blasting, also referred to as vapor honing, is also used to clean heat-resistant alloys. This process uses Nos. 200 to 1250 silica abrasive particles (0.074 to 0.010 mm, or 0.0029 to 0.0004 in.) mixed with water to produce a slurry that removes loose scale, discoloration, and soils. Metal loss is not excessive when normal pressures and exposure times are used.

When spherical beads made of high-quality optical crown glass are used as the abrasive, stock loss is minimized. Bead sizes of 0.038 to 0.074 mm (0.0015 to 0.0029 in.) are generally used, and blasting pressures are kept below 410 kPa (60 psi) to prevent the beads from fracturing.

Surfaces that have been wet blasted are usually suitable for welding, brazing, electroplating, and final inspection processes. Further cleaning is seldom necessary. Exceptions are alloys with a high titanium and aluminum content, which require the special procedure discussed in the section "Acid Pickling" in this article.

Most of the general advantages and limitations associated with the abrasive cleaning of steel will also apply to heat-resistant alloys. However, there is a risk of contamination from either metallic abrasives or abrasives that have been used to clean parts made from metals of widely different compositions. For example, heat-resistant alloys should not be blasted with abrasive material that has been used to clean low-alloy steel, aluminum, copper, or magnesium. However, abrasives used to clean titanium and corrosion-resistant steels have been used to clean heat-resistant alloys without serious contamination. The flash pickling of these alloys after abrasive cleaning provides additional assurance that no harmful surface contamination remains. Detailed information on equipment and procedures for dry and wet blasting is provided in the Section "Finishing Methods" in this Volume.

Wet tumbling by the barrel or vibratory method can be used to descale heat-resistant alloys if the shape and size of the parts are suitable. The removal of burrs and sharp edges is accomplished in the same operation. Shop soils are also removed, thus eliminating the need for preliminary degreasing.

Parts are tumbled or vibrated in a mixture of acid descaling compound and metal-free abrasives and then subjected to a neutralizing cycle. Precautions regarding metal contamination are similar to those noted above for abrasive blasting.

Pickling is required after tumbling and before resistance welding to remove residual smut, which can cause poor-quality weldments. There is less need for pickling prior to fusion welding, unless an inspection of the weldments reveals porosity or inclusions that are a result of pickup from the tumbling process.

Wire brushing is sometimes used to remove very light scale or surface discoloration. All brushes used on heat-resistant alloys must have stainless steel bristles.

Salt-bath descaling is an effective first step in removing scale from heat-resistant alloys. The process is generally more expensive than acid pickling, particularly if production is intermittent, because of the cost of maintaining the bath during idle time. The electrolytic salt bath used to descale heat-resistant alloys contains fused caustic soda, rather than sodium hydride. The parts and the tank are alternately negative and positive poles of a direct current circuit.

This fused caustic soda bath, which contains oxidizing salts such as sodium nitrate, is operated at 425 to 540 °C (800 to 1000 °F). It is slightly more effective than the sodium hydride bath on high-chromium alloys, such as type 310 stainless steel, and cobalt-chromium-nickel-base alloys, such as L-605. Processing steps are similar. Parts are immersed in the oxidizing bath for 5 to 15 min, quenched in water, soaked in a solution of 5 to 10% sulfuric acid at 70 °C (160 °F) for 1 to 5 min, and then dipped in a solution of 15 to 20% nitric acid and 2 to 4% hydrofluoric acid at 54 to 60 °C (130 to 140 °F) for 2 to 15 min.

A typical sequence for sodium hydride descaling and pickling is given in Table 3. Equipment details and other information on salt-bath descaling are provided in the Section "Surface Cleaning" in this Volume.

Table 3 Procedure for sodium hydride descaling and acid pickling of heat-resistant alloys

Operation	Time	Temperature		Solution[a]	Concentration, vol %[a]
		°C	°F		
Sodium hydride descale	1-2 h	370-390	700-730	Sodium hydroxide	. . .
Quench	15-30 s	Not heated	Not heated	Water	. . .
Neutralizing rinse	1-3 min	RT to 60	RT to 140	Sulfuric acid	2-10

Applicable Finishing and Coating Processes

Many finishing operations that are commonly used for steel and other metals are not required for the heat-resistant alloys for several reasons. First, these alloys are inherently resistant to corrosion in a wide range of environments. Second, the applications of parts made from these alloys do not typically require a polished finish.

The oxide coating that is obtained during processing is frequently of value to heat-resistant alloys that are subjected to elevated temperatures in service. Consequently, the dense, tenacious oxide that develops on formed or machined finished parts during final heat treatment is allowed to remain as protection against further oxidation.

Polishing of heat-resistant alloys is sometimes used to obtain a desired surface finish, as well as to remove light scale or oxide from parts that are to be welded or brazed. Silicon carbide in various grit sizes is commonly used to prepare surfaces for brazing.

Surfaces are usually prepared for welding by polishing with No. 90 grit aluminum oxide, set up with sodium silicate on a cloth wheel. Discoloration can be removed by polishing with No. 120 grit aluminum oxide, used with a greaseless compound and a cloth wheel. Buffing is seldom required for the finishing of heat-resistant alloys.

Electroplating. Chromium, copper, nickel, and silver are sometimes electroplated on heat-resistant alloys in order to:

- Prepare for brazing
- Deposit brazing metal
- Provide antigalling characteristics
- Repair expensive parts or correct dimensional discrepancies

Conventional nickel plating processes are often used to assist in brazing. Deposits can vary in thickness from 2.5 to 25 μm (0.1 to 1 mil). Alloys that contain titanium or aluminum will require the thicker deposits.

Silver and copper are the metals most often deposited as actual brazing materials. Some brazing alloys are deposited as separate layers of their various constituent metals on a weight-percentage basis. Plate thickness depends on the amount of metal needed for brazing.

Electrodeposited silver or nickel is used in special applications for antigalling purposes. Either nickel or chromium can be used to repair worn parts or build up dimensions. Procedures and electrolytes for plating these metals are described in the Section "Plating and Electroplating" in this Volume.

Ceramic coatings are frequently applied to heat-resistant alloys to increase the oxidation resistance of parts exposed to extremely high temperatures, such as gas turbine and missile components. Several types of ceramics are currently used, and some serve as thermal barriers, as well. The article "Ceramic Coatings and Linings" in this Volume describes the relevant procedures.

Diffusion coatings of aluminum, chromium, silicon, or combinations thereof, also are used to protect heat-resistant alloy parts from high-temperature corrosion and to prolong part life. The coating of engine exhaust valves with aluminum is a common example. Procedures for diffusion coating are described in the Section "Vacuum and Controlled-Atmosphere Coating and Surface Modification" in this Volume.

Shot peening is currently used to improve the mechanical properties of compressor blades, turbine-blade dovetails, and latter-stage turbine-blade airfoils by introducing favorable patterns of residual stress. Although all turbine-blade dovetails are peened with steel shot, glass beads are sometimes favored over metallic shot in other shot-peening applications. The advantages of glass beads are that they:

- Pose no risk of metal contamination
- Remove virtually no metal
- Are available in smaller sizes than metallic shot and can therefore be used to peen areas that are difficult to reach when using metallic shot

However, glass beads are not equivalent to metal shot for improving mechanical properties. Details on peening are given in the Section "Finishing Methods" in this Volume.

Cleaning and Finishing Problems and Solutions

The complex oxides and scale that form on heat-resistant alloys often create production problems and require the use of special procedures to obtain the desired surfaces. The examples described below, all of which are drawn from actual production experience, identify cleaning and finishing problems and the procedures used to solve them.

Example 1. After heat treatment, turbine combustion chambers made from Hastelloy X sheet exhibited irregular scale adherence, variations in surface finish, and loss of formability. An investigation disclosed that residual shop soils, such as lubricants, marking inks, and handprints, remained on the parts despite the solvent cleaning and vapor degreasing to which the parts were subjected before being heat treated. These soils were decomposing during heat treatment and causing carbon diffusion.

The substitution of electrolytic alkaline cleaning for the methods previously used eliminated the difficulty. In this procedure, parts were immersed for 5 min in a bath compounded to Federal Specification P-C-535 and operated at 82 to 93 °C (180 to 200 °F) using 6 to 8 V. Parts were anodic in the electrical circuit. The scale was easily removed by subjecting the heat-treated parts to a 5 min immersion in a room-temperature acid pickling bath composed of 70% nitric acid (20 to 30 vol%), 60% hydrofluoric acid (10 to 15 vol%), and water (55 to 70 vol%).

Example 2. The descaling of alloys A-286 and S-816 was inadequate when this procedure was used:

- Descale in an oxidizing salt bath at 480 to 495 °C (900 to 925 °F) for 25 min, and then quench in cold water
- Immerse in a solution of sulfuric acid (23 vol%) for 10 to 15 min, and then rinse with cold water
- Immerse in a solution of 25% nitric acid and 3% hydrofluoric acid for 2 min, and then rinse in cold water
- Immerse in 30% nitric acid for 5 min, rinse in cold water, rinse in hot water, and then dry

However, changing the procedure to the following proved to be successful:

- Descale in an oxidizing salt bath at 480 to 495 °C (900 to 925 °F) for 10 min, and then quench in cold water
- Immerse in 23% sulfuric acid for 5 min, and then rinse in cold water
- Immerse for 1 min in a solution of 25% nitric acid and 3% hydrofluoric acid, rinse in cold water, rinse in hot water, and then dry
- Reimmerse in oxidizing salt bath at 480 to 495 °C (900 to 925 °F) for 10 min, and then quench in cold water
- Immerse for 30 s in solution of 25% nitric acid and 3% hydrofluoric acid, and then rinse in cold water
- Immerse for 5 min in 30% nitric acid, rinse in cold water, rinse in hot water, and then dry

Example 3. Excessive zinc contamination of formed parts made from 19-9 DL alloy was traced to the contamination of drawing lubricants that had been stored too closely to zinc dies that were being finished by sanding. The zinc was removed from the parts by chemicals (see the section "Chemical Removal Methods" in this article). A recurrence of this problem was prevented by improved housekeeping and by direct instructions to personnel.

Example 4. It was not feasible to broach turbine disks made from D-979 alloy in the solution-treated and aged condition. The disks were first broached in the solution-treated condition, and then the surfaces were protected by a flash of nickel (Wood's plating) and a subsequent overlay of copper, so that they could undergo aging at temperatures higher than 730 °C (1350 °F) in a reducing gas atmosphere. After aging, the plated copper and nickel were removed from the disks by the procedures given in Tables 4 and 5.

Table 4 Procedure for stripping copper plate

Composition of bath	
Chromic oxide, g/L (oz/gal)	360 (48)
Sulfuric acid (concentrated), mL/L	39-55 (5-7)
Water	Remainder
Temperature	Room temperature
Time	Varies with thickness of plate

Table 5 Procedure for stripping nickel plate

Composition of bath	
Sodium cyanide, g/L (oz/gal)	90 (12)
Nitroaromatics, g/L (oz/gal)	60 (8)
Water	Remainder
Temperature, °C (°F)	49-66 (120-150)
Time	Varies with thickness of plate

Stripping the chemicals and using a light vapor blast to remove smut resulted in clean, dimensionally unaltered parts and had no detrimental effect on mechanical properties. The procedures defined in Tables 4 and 5 were based on the available facilities. A cheaper and faster method would be to strip the copper and nickel in a nitric acid solution (50 vol%) at room temperature.

Example 5. Conventional salt-bath descaling and pickling failed to remove all annealing scale from stampings made from 19-9 DL, Hastelloy X, Inconel 600, and Inconel X-750. The sequence of operations performed on these stampings was either to form, degrease, remove metal contamination, anneal, and descale, or to immerse in molten salt and then pickle. The difficulty was traced to the open-hearth, gas-fired annealing furnaces. It was found that the atmosphere was reducing while the burners were on, and that a thin, tight scale was produced.

A satisfactory remedy was to adjust the burners to bring the oxygen content to 3%. The resulting scale was loose and easily removed by the usual descaling and pickling procedures.

Example 6. Jet-engine combustion liners made from Hastelloy X require three in-process anneals. Forming without first removing scale required expensive carbide dies, and the resulting liners were unacceptable. The problem was solved by installing a salt-bath descaling line. The following cycle was satisfactory for descaling:

- Immerse in an oxidizing salt bath at 480 °C (900 °F) for 10 to 20 min, and then rinse, first in cold water and then in water at 82 °C (180 °F)

- Immerse in a solution of 24% hydrochloric acid for 2 to 10 min, and then rinse in cold running water
- Immerse in nitric-hydrofluoric acid for 2 to 10 min, rinse in cold running water, hose off, and then dry

Example 7. Small cracks appeared in welded 19-9 DL tubing (1.3 mm, or 0.050 in. wall) after annealing. The processing sequence was to form tubing from flat stock, degrease, perform an automatic seam weld, anneal, and descale. The tubing was formed on dies of zinc alloy, but was not dezinced before being welded. Small amounts of zinc on the surface near the weld melted during welding. This initiated zinc diffusion, and the residual stresses around the weld were sufficient to crack the embrittled material. The problem was solved by pickling the tubing in 20% nitric acid to remove the zinc before welding.

Surface Engineering of Aluminum and Aluminum Alloys

Introduction

ALUMINUM OR ALUMINUM ALLOY products often have various types of finishes applied to their surfaces to enhance appearance or improve functional properties. This article discusses the methods employed in the cleaning, finishing, and coating of aluminum.

Abrasive Blast Cleaning

One of the simplest and most effective methods for cleaning aluminum surfaces is by blasting with dry nonmetallic or metallic abrasives. Although this method is normally associated with the cleaning of aluminum castings, it is also used to prepare surfaces of other product forms for subsequent finishes, such as organic coatings. In addition to cleaning, blasting is used to produce a matte texture for decorative purposes.

Abrasive blasting is an efficient means of removing scale, sand, and mold residues from castings. Because castings typically are thick, they generally suffer no distortion from the process. Blast cleaning of parts with relatively thin sections is not recommended, because such parts are readily warped by the compressive stresses that blasting sets up in the surface; coarse abrasives can wear through thin aluminum sections. Typical conditions for dry blasting with silica abrasive are given in Table 1.

Table 1 Conditions for abrasive blast cleaning of aluminum products with silica

Grit size	Mesh	Nozzle diameter		Nozzle to work[(a)]		Air pressure	
		mm	in.	mm	in.	kPa	psi
20-60	Coarse	10-13	$\frac{3}{8}$ - $\frac{1}{2}$	300-500	12-20	205-620	30-90
40-80	Medium	10-13	$\frac{3}{8}$ - $\frac{1}{2}$	200-350	8-14	205-620	30-90

100-200	Fine	6-13	$\frac{1}{4}$ - $\frac{1}{2}$	200-350	8-14	205-515	30-75
Over 200	Very fine	13	$\frac{1}{2}$	200-300	8-12	310	45

(a) Nozzle approximately 90° to work

Washed silica sand and aluminum oxide are most commonly used for abrasive blast cleaning of aluminum alloys. Steel grit is sometimes used and, because of the fragmenting characteristics of silica, is often preferred. It also has a longer life, which lowers cleaning costs. However, when an aluminum surface is blasted with grit, steel particles become embedded, and unless they are removed by a subsequent chemical treatment, they will rust and stain the surface. It is good practice to remove particle contamination with a nitric acid pickle to prevent degradation of corrosion resistance. A 20-min soak in 50% nitric acid solution at ambient temperature will dissolve embedded or smeared iron particles, but it will not remove silica or aluminum oxide. When aluminum is blasted with No. 40 or 50 steel grit, a 9.5 mm ($\frac{3}{8}$ in.) diameter nozzle and air pressure at about 276 kPa (40 psi) are commonly used. Organic materials such as plastic pellets and crushed walnut shells also are used to blast clean aluminum, often for the removal of carbonaceous matter.

Stainless steel shot is sometimes used for cleaning aluminum surfaces. Shot blasting is used as a preliminary operation for developing a surface with a hammered texture. An attractive finish is produced when this textured surface is bright dipped and anodized. In addition, the varying degrees of matte texture that can be produced by blasting offer many decorative possibilities. Blasting is often used to produce the maximum diffuseness of the reflectivity of a surface. For example, aluminum army canteens are blasted as a final finish to reduce glare. Glass bead blasting offers another approach to cleaning and producing diffuse surfaces.

Sandblasting with a fine abrasive produces a fine-grain matte finish on wrought or cast aluminum products. For plaques, spandrels, and related decorative architectural applications, sandblasting the background and polishing or buffing the raised portions of the surface produces an effect known as highlighting.

The matte finish produced by abrasive blasting is highly susceptible to scratching and to staining from fingerprints. Therefore, matte-finish surfaces usually are protected by an anodic coating or clear lacquer. Anodizing is the more popular protective treatment, because it does not alter the original texture of a surface. Clear lacquers smooth out roughened surfaces and produce various degrees of gloss, which may be undesirable. Anodizing of a blasted aluminum surface results in a gray color because of embedded abrasive particles in the surface. This color frequently is nonuniform because of variations in blasting conditions, such as nozzle-to-work distance, direction or movement of the nozzle, and air pressure.

Blasting conditions can be closely controlled by the use of specially designed equipment. Uniform movement of the work on conveyors, established nozzle movement, constant velocity of the abrasive, and controlled size of grit contribute to better color uniformity of subsequently anodized surfaces.

The nonuniform appearance that results from blasting can be corrected by bleaching prior to anodizing. Bleaching is done by deep etching in a solution of 5% sodium hydroxide at 40 to 65 °C (100 to 150 °F) to remove metal that contains embedded abrasive. Some trial and error may be necessary to determine etching time for specific conditions. If the surface is not etched enough, a mottled appearance may result. Embedded abrasive can also be removed with a solution of nitric acid and fluoride used at room temperature.

Care should be exercised when selecting the aluminum or aluminum alloy to be sandblasted. For example, alloy 1100, which contains 99% Al, provides a transparent anodic finish; alloys rich in manganese, silicon, and copper, on the other hand, are colored when anodized. Alloy segregation can occur in high-magnesium alloys, and pitting will result unless special pretreatments are used. Table 2 lists several typical applications for abrasive blast cleaning of aluminum products, indicating the type and size of abrasive used and typical production rates.

Table 2 Applications for abrasive blast cleaning of aluminum products

Automatic rotary equipment with five nozzles was used for blasting of all parts except the cake pan, for which a hand-operated single-nozzle setup was used.

Product	Size		Abrasive		Pieces, h
	mm	in.	Type	Mesh size	
Blasting to prepare for organic coating					
Cake pan	280 by 380 by 51	11 by 15 by 2	Alumina	100	60
Frying pan	250 mm diam	10 in. diam	Alumina	100	260
Griddle	6775 mm^2	10.5 $in.^2$	Alumina	100	225
Sauté pan	200 mm diam	8 in. diam	Alumina	100	250
Blasting for appearance produced

Cocktail-shaker body[(b)]	100 mm diam by 180	4 in. diam by 7	Steel	80	375

(a) 1 qt army canteen blasted for reduction of light reflectivity.

(b) Blasted for decorative effect

Wet blasting mixes a fine abrasive with water to form a slurry that is forced through nozzles directed at the part. Abrasive grits from 100 to 5000 mesh may be used. Wet blasting is generally employed when a fine-grain matte finish is desired for decorative purposes.

An attractive two-tone finish on appliance trim can be obtained by contrasting a buffed finish with a wet-blasted finish. Aluminum firearm components and eyeglass parts such as frames and temples often are wet-blasted to produce fine matte finishes. In these applications, anodic coatings, either plain or colored, are used to protect without distorting the intended surface texture.

Typical wet blasting procedures are listed in Table 3. Wet blasting is also used to prepare surfaces for organic or electroplated coatings. Ultrafine glass bead blasting is an alternative to wet blasting.

Table 3 Conditions for wet blasting of aluminum-base materials

At a nozzle-to-work distance of 75 to 100 mm (3 to 4 in.) and an operating pressure of 550 kPa (80 psi)

Operation	Abrasive	
	Type	Mesh size
Deburr and clean	Alumina	220
Blend and grind	Silica flour	325
Lap and hone	Glass	1000
	Diatomite	625-5000

Barrel Finishing

Barrel finishing is a low-cost method of smoothing sharp edges, imparting a matte finish, and preparing surfaces for anodizing, painting, or plating. Many small aluminum stampings, castings, and machined parts are cleaned, deburred, and burnished by barrel finishing. In most instances, the main objective is deburring and/or burnishing, with cleaning being an accidental benefit of the treatment. Deburring sometimes is the final barrel operation, but more often it is followed by burnishing to obtain a smoother finish or one that is better suited to anodizing or plating. Parts that have only been deburred are often painted. Burnished parts are frequently anodized for protection.

Small aluminum parts are sometimes tumbled dry in media such as pumice and hardwood pegs, hardwood sawdust, or crushed walnut shells to remove burrs and improve the finish. However, this method is relatively inefficient compared to the more widely used wet process.

All aluminum alloys can be safely finished by wet barrel methods. Limitations imposed by workpiece size and shape are essentially the same as for steel and other metals. There are two general areas in which wet barrel finishing of aluminum parts is more critical than in processing similar parts made of steel. First, there is danger of surface contamination by ferrous metals, caused by the use of either a steel barrel or a steel medium. Second, the pH of the compounds is more critical when processing aluminum, because the metal is susceptible to etching by both acids and alkalis, and because gas generated during chemical attack can build up pressure in the barrel and cause serious accidents. Barrels must be vented when processing aluminum. Compounds that are nearly neutral (pH of about 8) are recommended, although some alloys can be safely processed in compounds having a pH as high as 9.

Barrels used for aluminum are basically the same as those used for processing steel. However, barrels made of steel or cast iron should be lined with rubber or similar material to prevent contamination. A preferred practice is to use specific barrels exclusively for processing aluminum.

Deburring is done by tumbling the work in a nonlubricating compound that contains abrasives. In most instances, media also are used to cushion the workpieces and increase the abrasive action. Synthetic detergents mixed with granite fines or limestone chips are usually preferred as the compound for deburring aluminum; aluminum oxide and silicon carbide are not desirable because they leave a smudge that is difficult to remove. High water levels, completely covering the mass, are used during deburring to assist in maintaining fluidity of the mass and to help prevent the medium from becoming glazed and losing cutting action. Deburring can also be accomplished by using vibratory units with synthetic abrasives.

Barrel burnishing is used to produce a smooth, mirrorlike finish on aluminum parts. Bright dipping immediately prior to burnishing aids in producing desired results. Other preliminary treatments also are helpful in specific instances, particularly for cast aluminum parts. One of these pretreatments entails etching the castings for 20 s in an alkaline solution at 80 °C (180 °F) and then dipping them for 2 to 3 s in a solution consisting of 3 parts by volume nitric acid (36° Bé) and 1 part hydrofluoric acid at 20 to 25 °C (70 to 75 °F).

The principle of barrel burnishing is to cause surface metal to flow, rather than to remove metal from the surface. Burnishing compounds must have lubricating qualities; soaps made especially for burnishing are usually used and are readily obtainable. Many of them have a pH of about 8, although more acidic materials can be used.

When burnishing aluminum, the pH of the burnishing compound must be closely controlled. This is accomplished by frequent titration of the compound, followed by the addition of small amounts of borax or boric acid as needed. Steel balls and shapes are the most commonly used burnishing media. Several examples of conditions used in barrel finishing applications are detailed in Table 4. Note that deburring and burnishing are sometimes accomplished in a single operation.

Table 4 Conditions for wet barrel finishing of aluminum products

Product	**No. of pieces per**		**No. of pieces per load**	**Cycle time, min**	**Barrel speed, rev/min**
	kg	**lb**			
Clean, deburr and brighten[(a)]					
Percolator spout	60	130	630	20	33

Deburr and brighten[(b)]					
Die cast handles	11	25	600	120	15
Burnish to high gloss[(c)]					

(a) Rubber-lined steel, single-compartment drum, 560 mm (22 in.) diam, 760 mm (30 in.) long. Processing cycle: load drum with medium (20 kg or 50 lb of 3-mm or $\frac{1}{8}$-in. steel balls per load), parts, and compound (154 g or 5.5 oz of burnishing soap per load); cover load with water (66 °C or 150 °F); rotate drum for specified time; unload, rinse, separate parts from medium; tumble-dry parts in sawdust for 4 min.

(b) Rubber-lined steel, double-compartment drum; each component 740 mm (29 in.) long, 915 mm (36 in.) in diameter. Processing cycle: load deburring compartment with parts, compound (2 kg or 5 lb of burnishing soap), and medium (365 kg or 800 lb of No. 4 granite chips), using hoist; cover load with cold tap water; rotate drum for 1 h; unload, and rinse with cold water; separate parts and medium, and transfer parts to burnishing compartment; add burnishing compound (0.9 kg or 2 lb of burnishing soap) and medium (680 kg or 1500 lb of 3-mm or $\frac{1}{8}$-in. steel

balls); cover load with water (71 °C or 160 °F) and rotate drum for 1 h; separate parts and medium, and rinse parts in hot water and then in cold water; spin dry in a centrifugal hot-air dryer.

(c) Single-compartment drum, 1.5 m (5 ft) long, 1.2 m (4 ft) in diameter. Processing cycle: load drum with parts (parts are fixtured, to prevent scratching), medium (2040 to 2270 kg or 4500 to 5000 lb of steel balls 3, 6, and 8 mm or $\frac{1}{8}$, $\frac{1}{4}$, and $\frac{5}{16}$ in. in diameter, and 2 and 3 mm or $\frac{1}{16}$ and $\frac{1}{8}$ in. steel diagonals), and compound (5 kg or 12 lb of alkaline burnishing soap. pH 10); cover load with cold tap water; rotate drum for 22 $\frac{1}{2}$ min in one direction, then 22 $\frac{1}{2}$ min in reverse direction; rinse and unload; dip-rinse parts, and hand wipe

Self-tumbling is an effective means of cleaning, deburring, or burnishing small aluminum parts. Procedures for self-tumbling are basically the same as those for other methods of barrel finishing, except that the parts themselves serve as the medium. Compounds for self-tumbling of aluminum should be of nearly neutral pH, and oxides should be removed from the aluminum parts before tumbling. The size and shape of the parts usually determine whether self-tumbling is suitable. Interior surfaces receive little or no action during self-tumbling.

Vibratory finishing is a newer method used for deburring and burnishing metal parts. When applied to aluminum parts, compounds and media are subject to the same restrictions as discussed previously for conventional barrel finishing.

Polishing and Buffing

Because aluminum is more easily worked than many other metals, few aluminum parts require polishing prior to buffing for final finish. In some instances, polishing may be required for the removal of burrs, flash, or surface imperfections. Usually, buffing with a sisal wheel prior to final buffing is sufficient.

Polishing. Most polishing operations can be performed using either belts or setup wheels. Setup wheels may be superior to belts for rough polishing when canvas wheels in a relatively crude setup can be used. For fine polishing work, a specially contoured wheel may be more satisfactory than a belt. Setup wheels have two main disadvantages in comparison with belts: wheels may be costly; and time, skill, and equipment are necessary for setting up wheels. (The actual time required may be as short as 10 min, but this time is spread over several hours because of intermediate drying steps.) Inventory thus becomes an important factor when several wheels with different types of abrasives or grit sizes are needed. Considerable operator skill is required for wheel polishing, whereas unskilled labor can be used for belt polishing. Flap wheels have been used to replace setup wheels for many applications. The use of flap wheels tends to overcome the above-mentioned disadvantages. Typical conditions for polishing aluminum parts are discussed in the following examples.

The conditions for wheel polishing die cast aluminum soleplates for steam irons are as follows:

Type of polishing wheel	Felt
Setup time	10 min
Wheel speed	180-2000 rev/min
Lubricant	Tallow grease stick

The medium-hard felt polishing wheel is 350 to 400 mm (14 to 16 in.) in diameter, with a 125 mm (5 in.) face. The surface of the wheel is double coated with 240-mesh alumina abrasive bonded with hide glue. Setup time, spread out over several hours of operation, totals 10 min. The polishing wheel can cover 34 to 43 m/s (6600 to 8400 sfm).

The soleplates are made of alloy 380.0 and the sides are polished to remove holes or other surface defects. Buffing follows to produce the required mirror finish. The polishing conditions given in the list above are based on a production rate of 115 pieces/h per wheel. Each wheel has a service life of 5000 to 6000 pieces.

Table 5 gives the conditions and sequence of operations for belt polishing of die-cast steam-iron soleplates made of aluminum alloy 380.0. Ten polishing heads are used to produce a bright finish on the soleplate sides and bottom.

Table 5 Conditions of belt polishing for bright finishing aluminum die-cast soleplates

Operation	Area polished	Polishing head, No.	Type	Contact wheel			Belt[(a)]			
				Size		Hardness, durometer	Size		Abrasive mesh size	Life, pieces
				mm	in.		mm	in.		
1	Side	1, 2	Plain face	50 by 380	2 by 15	60	50 by 3050	2 by 120	280[(b)]	600
2	Side	3, 4	Plain face	50 by 380	2 by 15	60	50 by 3050	2 by 120	320[(b)]	600
3	Bottom	5	Serrated[(c)]	150 by 380	6 by 15	45	150 by 3050	6 by 120	120[(b)]	1200

7	Bottom	9	Plain face	150 by 380	6 by 15	60	150 by 3050	6 by 120	320[(b)]	2000

(a) Belt speed for all operations was 35 m/s (6900 sfm). All belts were cloth; bond, resin over glue.

(b) Aluminum oxide abrasive.

(c) 45° serration, 13 mm ($\frac{1}{2}$ in.) land, 10 mm ($\frac{3}{8}$ in.) groove.

(d) Silicon carbide abrasive

Buffing. Selection of a buffing procedure depends mainly on cost, because it is usually possible to obtain the desired results by any one of several different methods. For example, depending on the application, hand buffing might call for the use of equipment ranging from simple, light-duty machines to heavy-duty, variable-speed, double-control units. These machines represent a wide range in capital investment.

Automatic buffing requires custom-made machinery or special fixtures on standard machinery. The size and complexity of the machinery are determined by the required production rates and by the size or shape of the workpieces. High production requires more stations, heavier equipment, and more power. The configuration of the part may be so simple that one buff covers the total area to be finished, or it may be so complex as to require the use of many buffs set at angles and advanced toward the workpiece by cam action.

For cut and color work, buffs are bias types with a thread count of 86/93. For severe cut-down, treated cloth is used with the same thread count. The final color work is accomplished using a buff with very little pucker and a low thread count of 64/64 (see Table 6). A number of procedures that have proved successful for high-luster buffing of specific aluminum parts are summarized in Table 6; others are described in the following examples.

Table 6 Equipment and operating conditions for high-luster buffing of aluminum products

Product	Size		Type of buffing machine	Type	Buffing wheel										Production, pieces per hour
					Diameter						Thread count	Wheel speed		Type of compound	
					Overall		Center		Ply

(a) Five-spindle machine; four buffing heads, one load-unload station.

(b) Each of the four wheels used had one 330 mm (13 in.) and three 360 mm (14 in.) sections.

(c) For 330 mm (13 in.) section, 45 m/s (8850 sfm); for 360 mm (14 in.), 49 m/s (9550 sfm).

(d) Two machines, run by one operator.

(e) Buff made up of 360 mm (14 in.), 381 mm (15 in.), and 410 mm (16 in.) sections.

(f) 42 m/s (8250 sfm) for 360 mm (14 in.) sections, 45 m/s (8800 sfm) for 380 mm (15 in.) sections, and 48 m/s (9400 sfm) for 410 mm (16 in.) sections.

(g) Eight-spindle machine

Table 7 gives the conditions and sequence of operations for automatic buffing of wrought aluminum frying-pan covers. A specular finish was required. In another case, the sides of die-cast aluminum frying pans made from alloy 360 were buffed to a bright finish by an automatic machine with four buffing heads. The buffing wheel of each head consisted of a 14-ply, 16-spoke sewed bias buff with a 430 mm (17 in.) outside diameter, a 230 mm (9 in.) inside diameter, and a 44 mm ($13\frac{3}{4}$ in.) diameter arbor hole. Wheel speed was 1745 rev/min, equal to 39 m/s (7700 sfm). Each buff was made up of four sections. A liquid buffing compound was applied by one gun per wheel at the rate of 3 g per shot (0.1 oz per shot) for the first wheel, 2.5 g per shot (0.09 oz per shot) for the second and third wheels, and 1 g per shot (0.04 oz per shot) for the fourth wheel. The gun was on for 0.1 s and off for 5 s. The service life of each buffing wheel was 1600 to 2100 pieces.

Table 7 Sequence and conditions of automatic buffing operations for obtaining specular finish on aluminum frying-pan covers

(a) Liquid tripoli compound applied to buffing heads No. 1 through 29; stainless steel buffing compound applied to heads No. 30 through 33.

(b) Each head buffs two sides.

(c) Domet flannel sections interleaved with 180 mm (7 in.) diam disks of Kraft paper.

(d) Inapplicable to flannel buff

Die-cast aluminum soleplates for steam irons (Table 8) were buffed to a bright finish on an automatic machine with eight buffing heads. The soleplates were made of alloy 380.0 and were prepolished with 320-mesh grit. A liquid buffing compound was applied by one gun per wheel for the first four heads and by two guns per wheel for the last four heads. The guns were on for 0.12 s and off for 13 s. The service life was 72,000 pieces for each buff of the first four heads, and 24,000 pieces for each buff of the last four heads.

Table 8 Automatic bright-finish buffing of aluminum soleplates

Operation	Area buffed	Buffing head No.	Buffing wheel										Application of compound[b]

(a) All wheels had 180 mm (7 in.) diam centers.

(b) Proprietary liquid compound was used. Cycle time: 0.12 s on, 13.0 s off

Satin Finishing

Mechanical satin finishing is an established method for obtaining an attractive surface texture on aluminum hardware items such as knobs, hinges, rosettes, and drawer pulls. Satin finishes are also used for architectural, appliance, and automotive trim. The satin finish results from small, nearly parallel scratches in the metal surface, which give the surface a soft, smooth sheen of lower reflectivity than that of polished or buffed surfaces.

Satin finishes can be applied by fine wire brushing. Other methods use a greaseless abrasive compound in conjunction with a conventional buffing head, tampico brush, cord brush, string buff, or brush-backed sander head. Abrasive-impregnated nylon disks mounted like buffs are also used, as are abrasive cloth sections mounted on a rotating hub. All of these methods produce about the same type of finish; the use of any particular one depends on the surface contour of the workpiece.

Surfaces of workpieces to be satin-finished should be free of grease and oil, and low contact pressures should be used. Wire brushes must be kept free of oxide and accumulations of aluminum metal. This is accomplished by frequently bringing a pumice stone or soft brick in contact with the rotating brush. A common wire brushing setup consists of a 250 mm (10 in.) diameter wheel having a surface speed of about 8.0 m/s (1600 sfm) and wires 0.4 mm (0.015 in.) in diameter. Undue pressure on a rotating wire wheel will bend the wires and cause excessive tearing of the aluminum surface.

Stainless steel wires are recommended, because other metals such as brass or steel may become embedded in the aluminum surface, producing discoloration or corrosion. If brass or steel wire wheels are used, the embedded particles can be removed by immersing the work in a nitric acid solution (1 part water to 1 part acid by volume) at room temperature.

The satin finish processes in which a greaseless abrasive compound is used are essentially dry. Water is required to soften the binder in the abrasive compound so that it will adhere to the surface of the buff. After the binder dries, the buff is ready for operation. At this stage a lubricant, such as a buffing compound or tallow, may be used to produce a higher reflection.

Table 9 describes the equipment and techniques employed in mechanical satin finishing processes. If the satin-finished parts are to be anodized, etching or bright dipping should not precede anodizing, because the satin appearance will be lost. Cleaning treatments that do not etch or that only slightly etch the metal should be used before anodizing.

Table 9 Methods, equipment, and conditions for mechanical satin finishing of aluminum

Method	Suitable equipment			Speed		Lubricant
	Buffing lathe	Portable power head	Power required	m/s	sfm	
Wire brushing[a]	Yes	Yes	[b]	6-11	1200-2250	None
Sanding with brush-backed head[c]	Yes	No	[d]	900-1800 rev/min	900-1800 rev/min	Optional
Tampico or string brushing[e]	Yes	No	[b]	15-31	3000-6000	Pumice[f]
Finishing with abrasive-coated cloth[g]	Yes	Yes	[d]	31-36	6000-7000	Optional
Finishing with nylon disks[h]	Yes	Yes	[i]	23-33	4500-6500	Optional

Buffing with compounds[j]	Yes	Yes	[b]	15-26	3000-5000	[k]

(a) 305 mm (12 in.) diam brush of stainless steel wire 0.125 mm (0.005 in.) in diameter.

(b) 1 hp per 25 mm (1 in.) of brush width.

(c) Using 60- to 600-mesh abrasive cloth loadings.

(d) 1 hp per head.

(e) 300 mm. (12 in.) diam brush.

(f) With oil or water; emery cake also may be used.

(g) Cloth is mounted radially on rotating hubs; coated with 50- to 320-mesh emery abrasive.

(h) Disks impregnated with silicon carbide abrasive, coarse to ultrafine.

(i) $\frac{1}{4}$ hp per 25 mm (1 in.) of disk width.

(j) Greaseless satin-finishing compounds containing aluminum oxide abrasive (200 or 240 mesh) used with unstitched or loosely stitched buffs (360 mm or 14 in.) or with string brush.

(k) Dry, or with buffing compound or grease stick

Chemical Cleaning

The cleanliness requirements for an aluminum surface are governed by the subsequent finishing operations. For example, plating or the application of chromate or another mild-reaction conversion coating requires cleaning procedures that are somewhat more stringent than for anodizing.

When establishing a cleaning cycle or when testing different cleaners or cleaning conditions, it is desirable to test the cleanliness of the processed surface. Wetting an aluminum surface with water, known as the water break test, does not always provide an indication of cleanliness if oxides are of concern, because oxide-coated surfaces free of oil or grease can be wetted uniformly. Also, a surface that has been processed with a detergent containing a wetting agent can be wetted even though not thoroughly clean, because the film of wetting agent remains on the unclean surface. Two other methods of testing aluminum for cleanliness are to:

- Spray or coat the work surface with, or dip a test panel into, an unheated aqueous solution containing 30 g/L (4 oz/gal) of cupric chloride and 29 mL/L (3.8 fluid oz/gal) of concentrated hydrochloric acid. Uniform gassing or a deposit of copper indicates that the surface is chemically clean.
- Spray or coat the work surface with, or dip a test panel into, an unheated chromate conversion coating bath of the acid type until an orange-colored film is formed. A uniform orange film indicates a

chemically clean surface.

Solvent Cleaning. The primary function of solvent cleaners is to remove oil and grease compounds. Organic solvents alone rarely provide sufficient cleaning to permit final finishing operations; solvents usually are used to remove large amounts of organic contaminants to minimize overloading of subsequently used alkaline cleaners.

Greases and oils vary as to solubility in specific solvents. Fish oils are more difficult to remove than other types of oils. In the dried condition, some oxidizing oils, such as linseed oil, form a leathery film that is difficult to remove with any solvent.

Polishing and buffing compounds are readily removed by most solvents when cleaning is performed immediately after buffing. If the compounds are permitted to harden, they may be difficult to remove. Heated solutions, agitation, or mechanical action (ultrasonics or physical force) may be required for satisfactory cleaning. To remove compounds burned in the surface, the parts must be soaked in a liquid using an organic degreaser. such as trichlorethylene or methylene dichloride (rather than vapor degreasing), or in an inhibited alkaline cleaner.

If polishing and buffing compounds cannot be removed immediately after buffing, the application of a neutral mineral oil over the buffed surface will maintain the compounds in a more soluble condition for subsequent removal by a solvent. The sequence of operations usually required for buffed aluminum surfaces is: solvent cleaning, rinsing, removal of surface oxides, rinsing, and finally the application of the desired finish. Some of these steps may be omitted, depending on the type and quality of the buffing compound, the quality of workmanship in buffing, and the quality of solvents and cleaners used.

Emulsifiable solvents also are used to clean aluminum. These are organic solvents, such as kerosene, Stoddard solvent, and mineral spirits, to which small amounts of emulsifiers and surfactants are added. In use, this type of cleaner emulsifies the oil or grease on the surface. The soil and cleaner are removed with water, preferably applied by spraying.

This type of degreasing is satisfactory prior to anodizing, etching, removal of surface oxides, chemical conversion coating, plating, or painting. In some instances, intermediate treatments are required, such as the removal of surface oxides before etching.

The emulsifiable solvent should have a pH of 8 or less; otherwise, it will stain or corrode the aluminum if permitted to remain on the surface prior to rinsing or additional cleaning. However, emulsifiable solvents with higher pH are more efficient cleaners, and they can be used if the surfaces are rinsed or are cleaned by additional methods within 2 or 3 min after degreasing.

A lower-cost cleaning solution can be obtained by adding water to the emulsifiable solvent. This less-efficient type of solution is limited to the removal of light oil and grease. It is now common practice to use alkaline cleaners to remove oil and grease instead of solvents, the use of which is under increasing scrutiny by the Environmental Protection Agency (EPA).

Alkaline cleaning is the most widely used method for cleaning aluminum and aluminum alloys. This method is easy to apply in production operations, and equipment costs are low. Aluminum is readily attacked by alkaline solutions. Most solutions are maintained at a pH between 9 and 11, and they are often inhibited to some degree to minimize or prevent attack on the metal. The most frequently used alkaline cleaner is the mildly inhibited type.

Cleaners of either the etching or nonetching type have some ability to emulsify vegetable and animal oils or greases, but not mineral oils or greases. Therefore, they can sometimes remove fresh buffing compounds and the lard oils used in spinning operations.

Nonetching cleaners can be classified as either silicated or nonsilicated. The silicated cleaners are based on aqueous solutions of sodium carbonate, trisodium phosphate, or other alkalis, to which small amounts of sodium silicate are added to inhibit etching. The main disadvantage of the silicated types, aside from their inability to emulsify and remove mineral oils, is that the silicate may react with the aluminum to form an insoluble aluminum silicate, especially when the temperature of the bath exceeds 80 °C (180 °F). However, lower operating temperatures decrease the efficiency of the solution for the removal of certain soils. Silicated alkaline cleaners are available that are used at 50 to 60 °C (120 to 140 °F) to reduce energy consumption.

Nonsilicated cleaners are often based on the use of relatively large concentrations of surfactants. High operating temperatures are required, but some cleaners used above 70 °C (160 °F) etch the aluminum surface. Cleaners containing a large quantity of surfactants, particularly those types that resist complete rinsing, must not be carried into baths used for bright dipping, anodizing, or chemical conversion coating.

Neither silicated nor nonsilicated cleaners remove aluminum oxide uniformly. Because oxide removal is essential for the application of decorative or functional finishes, the best procedure is to clean, remove oxide with an acid solution, and then proceed with finishing.

Nonetching cleaners may be used after solvent cleaning to produce water-wettable surfaces, or they may be used alone when soils are light and easily removed. The surfaces should be treated to remove oxides afterward. When sodium orthosilicate or sodium metasilicate is used, the concentration of carbonates must be kept at a minimum to minimize the formation of floc, which may redeposit on the work. Unlike sodium hydroxide, the alkali silicates have good wetting, emulsifying, and rinsing properties. The ratio of silicon dioxide to sodium oxide in the compound determines the effectiveness of the alkali silicates. Sodium orthosilicate has good detergency and is effective in the cleaner at a ratio of 1 to 2, whereas the ratio of sodium metasilicate should be 1 to 1.

Agitation of the cleaner increases the cleaning action and is best created by pumps, propellers, or movement of the work. Air agitation, although easier to install and convenient to operate, has the following disadvantages:

- Air can reduce the solution temperature.
- The additional oxygen may cause staining and tarnishing on some alloys.
- Air agitation introduces carbon dioxide, which may increase the carbonate content.

The work should be rinsed immediately after removal from the alkaline bath to prevent dry-on. Warm water is preferred; if low-temperature cleaners are used, then rinsing with cold water is satisfactory.

Aluminum surfaces sometimes contain areas of localized corrosion, referred to as atmospheric etch, caused by contaminants in the air during storage. The corroded areas are more visible after alkaline cleaning or etching than before. When corrosion spots are present, the work may be dipped in a sodium bisulfate solution of 45 g/L (6 oz/gal), or in a cold 70% nitric acid solution, to minimize the effect of the subsequent alkaline cleaning.

During alkaline cleaning, especially if etching occurs, some alloys containing copper, iron, manganese, or silicon develop a black smut on the surface. Compositions and operating conditions of common alkaline cleaners are given in Table 10.

Table 10 Alkaline cleaners used to clean aluminum surfaces

Constituent or condition	**Amount or value**
Etching cleaners	
Sodium hydroxide	22-75 g (3-10 oz)
Sodium phosphate	0.8-4 g (0.1-0.5 oz)
Water, to make	4 L (1 gal)
Temperature of bath	60-80 °C (140-180 °F)

Immersion time	30 s-10 min
Sodium hydroxide	2-6 g (0.25-0.75 oz)
Sodium phosphate	8-60 g (1-8 oz)
Sodium carbonate	8-60 g (1-8 oz)
Water, to make	4 L (1 gal)
Temperature of bath	60-80 °C (140-180 °F)
Immersion time	2-5 min
Nonetching cleaners	
Sodium pyrophosphate and sodium metasilicate	Total of 15-75 g (2-10 oz)
Water, to make	4 L (1 gal)
Temperature of bath	60-70 °C (140-160 °F)
Immersion time	2-5 min
Trisodium phosphate and sodium metasilicate	Total of 15-75 g (2-10 oz)
Water, to make	4 L (1 gal)
Temperature of bath	60-70 °C (140-160 °F)
Immersion time	2-5 min
Sodium carbonate	4-8 g (0.5-1 oz)
Sodium metasilicate	4-8 g (0.5-1 oz)
Water, to make	4 L (1 gal)
Temperature of bath	6-70 °C (140-160 °F)
Immersion time	2-5 min

Borax	22-38 g (3-5 oz)
Sodium pyrophosphate	4-8 g (0.5-1 oz)
Water, to make	4 L (1 gal)
Temperature of bath	60-70 °C (140-160 °F)
Immersion time	2-5 min

Electrocleaning is seldom used for cleaning aluminum and aluminum alloys, because it offers no advantage over an etching cleaner. However, a few processes are used in production operations. These use low voltage, usually in the range of 6 to 12 V. Cathodic cleaning, in which the work is the cathode, is more common than anodic cleaning. Common practice is to reverse the current during the last 5 to 10 s of the cleaning operation.

After removal from the cleaner, the work is rinsed in warm or hot water, dipped in acid to neutralize any residual alkali, and finally rinsed in cold water. The work can then be finished as desired. The composition of two solutions that are recommended for electrocleaning are:

Constituents	**Composition, %**
Solution A	
Sodium orthosilicate	85
Sodium carbonate (anhydrous)	10
Sodium resinate	5
Solution B	
Sodium carbonate (anhydrous)	46
Trisodium phosphate	32
Sodium hydroxide	16
Rosin	6

Note: For typical operating conditions, see text.

Acid Cleaning. Acid cleaners may be used alone or in conjunction with other acid, alkaline, or solvent cleaning systems. Vapor degreasing and alkaline cleaning may be required for the removal of heavy oils and grease from workpieces before they are immersed in an acid bath. One of the main functions of an acid cleaner is to remove surface oxides prior to resistance welding, painting, conversion coating, bright dipping, etching, or anodizing.

A mixture of chromic and sulfuric acids is commonly used to remove surface oxides, burnt-in oil, water stains, or other films, such as the iridescent or colored films formed during heat treating. This acid mixture cleans and imparts a slightly etched appearance to the surface, preparing it for painting, caustic etching, conversion coating, or anodizing. Nonpolluting, proprietary products free of chromic acid are available for acid cleaning and deoxidizing.

Oxide films must be thoroughly removed before spot welding. A mixture of phosphoric and chromic acids is another solution that can be used for this purpose. Because of the corrosive nature of the chlorides and fluorides in welding fluxes, the fluxes should be removed as soon as possible after welding. Mixtures of nitric and hydrofluoric acids are best for removing fluxes. Most fluxes can also be satisfactorily removed by a dilute (5 to 20 vol%) nitric acid solution.

Proprietary nonetching acid cleaners are available for cleaning aluminum and aluminum alloys. Operating temperatures of these solutions range from 55 to 80 °C (130 to 180 °F), and pH usually ranges from 4.0 to 5.7. Compositions and operating conditions for typical acid cleaning solutions are given in Table 11.

Table 11 Acid cleaners used to clean aluminum surfaces

Constituent or condition	Amount or value
Solution 1	
Chromic acid	45-90 g (6-12 oz)
Sulfuric acid (66° Bé)	150-190 mL (19-24 fluid oz)
Water, to make	4 L (1 gal)
Temperature of bath	45-80 °C (110-180 °F)
Immersion time	up to 20 min
Solution 2	
Nitric acid (42° Bé)	500-750 mL (64-96 fluid oz)
Hydrofluoric acid (48%)	25-190 mL (3-24 oz)
Water, to make	4 L (1 gal)
Temperature of bath	Room temperature
Immersion time	1-5 min

Solution 3	
Sulfuric acid (66° Bé)	100 mL (13 fluid oz)
Hydrofluoric acid (48%)	25 mL (3 fluid oz)
Chromic acid	40 g (5 oz)
Water, to make	4 L (1 gal)
Temperature of bath	65-70 °C (150-160 °F)
Immersion time	2-5 min
Solution 4	
Nitric acid (42° Bé)	38-125 mL (5-16 fluid oz)
Sodium sulfate (hydrate)	60-120 g (8-16 oz)
Water, to make	4 L (1 gal)
Temperature of bath	75-80 °C (170-175 °F)
Immersion time	4-8 min
Solution 5	
Phosphoric acid	70 mL (9 fluid oz)
Chromic acid	20 g (2.75 oz)
Water, to make	4 L (1 gal)
Temperature of bath	45-65 °C (110-150 °F)
Immersion time	1-5 min

Aluminum parts should be insulated from ferrous metal baskets or supports when immersed in acid cleaning solutions, because contact of these two metals can produce a galvanic action that causes corrosion. Materials such as vinyl plastisols, epoxy, polyethylene, and polypropylene may be used for insulation. When practical, baskets or rods should be of the same or similar material as the workpieces.

Chemical Brightening (Polishing)

Chemical brightening, also known as bright dipping and chemical polishing, smoothens and brightens aluminum products by making use of the solution potential of the aluminum surface in the various baths employed and of the local differences in potential on the aluminum surface.

In general, chemical brightening baths can be concentrated or dilute acid solutions that contain oxidizing agents. The acids commonly used are sulfuric, nitric, phosphoric, acetic, and, to a lesser extent, chromic and hydrofluoric. Ammonium bifluoride is used when it is desirable to avoid the hazards that attend the use of hydrofluoric acid. Fluoboric and fluosilicic acids may also be used as alternates to hydrofluoric acid. An alkaline bath, such as Alupol, can also be used for chemical etching. This bath consists of 20 kg (44 lb) sodium nitrate, 15 kg (33 lb) sodium nitrite, 25 kg (55 lb) sodium hydroxide, and 20 kg (44 lb) water. An aluminum part is immersed for 1 to 5 min at a bath temperature of 90 to 140 °C (195 to 285 °F). Protrusions, valleys, and scratches are eliminated, and reflectance is increased.

Phosphoric-Nitric Acid Baths. Among the various types of concentrated baths, the phosphoric-nitric acid baths are the most widely used in the United States. Compositions and operating conditions for two commercial baths of this type are given below:

Constituent or condition	Range
Phosphoric-nitric[(a)]	
Phosphoric acid (85%)	45-98 wt%[(b)]
Nitric acid (60%)	0.5-50 wt%[(b)]
Water	2 to 35 wt%
Temperature	85-110 °C (190-230 °F)
Immersion time	30 s to 5 min
Phosphoric-acetic-nitric[(c)]	
Phosphoric acid (85%)	80 vol%
Acetic acid (glacial, 99.5%)	15 vol%
Nitric acid (60%)	5 vol%
Temperature	85-110 °C (190-230 °F)
Immersion time	30 s to 5 min

(a) U.S. Patent 2,729,551 (1956).

(b) Recommended volumetric make-up consists of 93.5 parts of 85% phosphoric acid and 6.5 parts of 60% nitric acid.

(c) U.S. Patent 2,650,157 (1953)

Additionally, certain proprietary chemical bright dips can be operated at 75 to 80 °C (170 to 180 °F), which is significantly lower than the normal 85 to 110 °C (190 to 230 °F) for conventional baths. The low-temperature baths, however, are limited in allowable water drag-in from prior rinse operations. Excessive water drag-in results in poor brightening.

Alkali nitrates may be used as substitutes for nitric acid. Acetic acid, copper salts, and other additives are used in some phosphoric-nitric acid baths. As additive content increases, solution control becomes more complex.

For economy, some phosphoric-nitric acid baths are operated with an aluminum phosphate content near the tolerable maximum of 10 to 12%, with a dissolved aluminum content of about 40 g/L (5 oz/gal). This is close to the saturation point, at which precipitation of this compound on the work produces etch patterns.

The addition of surfactants increases the amount of metal removed under a given set of operating conditions. Surfactants help to enhance the chemical polishing as well as to suppress the evolution of fumes. Acetic and sulfuric acids alter the physical property/composition relationship in the concentrated acid baths and also complicate control problems. Acetic acid volatilizes rapidly from the bath.

Small concentrations of heavy metals in the bath enhance the brightening effect, particularly on alloys with negligible copper content. Copper can be introduced into the bath by one of three methods: the direct dissolution of a small amount of copper; the addition of a small amount of a copper compound, such as 0.01 to 0.02% cupric nitrate; or the use of racks made of aluminum-copper alloys. Copper is added to the bath when brightening aluminum alloys such as 2024 and 7075, which contain high percentages of copper. Excess copper can plate out of the bath. In some baths, however, excess copper causes etching, and sometimes nickel or zinc is used instead.

Phosphoric-nitric acid baths are not recommended for brightening alloys that contain silicon. Excessive dissolution causes dispersion of undissolved silicon, which deposits on the work surfaces and is difficult to remove by rinsing. When high-silicon alloys are used, the addition of 1 to 2% hydrofluoric acid to the bath is recommended. The gradual buildup of other metals in the bath from the aluminum alloys processed usually causes no difficulty unless the amount of aluminum dissolved exceeds the solubility limit. When this occurs, excess aluminum precipitates and causes coprecipitation of trace elements, which may be difficult to remove from the work.

Contamination of the bath by more than trace amounts of buffing or polishing compounds and other soils should be avoided. These compounds may cause the bath to foam excessively and may interfere with its polishing action. Food-grade or National Formulary phosphoric acid should be used. Lower grades contain fluorides, arsenic, and other impurities that are harmful to the process.

Close control of the nitric acid and water contents, necessary for optimum chemical brightening, is difficult because of the rapid volatilization of these liquids and because of the time required for chemical analysis of the bath. A control method based on an electronic device that monitors the nitric acid content and on the physical measurement of specific gravity and viscosity has been developed.

Drag-out is a major factor in the cost of chemical brightening. The amount of solution and the weight of chemicals lost by drag-out are related to the specific gravity and viscosity of the solution. Drag-out can be minimized by operating the bath at higher temperatures, but this condition may increase the amount of transfer etch while moving to the rinse tank, as well as the rate of aluminum dissolution and the rate of evaporation of nitric acid and water. However, transfer etch can be avoided by rapid transfer into the rinse, and the rate of aluminum dissolution can be minimized by a shorter period of immersion. In general, an operating temperature in the range of 85 to 100 °C (190 to 212 °F) is satisfactory, provided an

optimum bath composition, including additives, is maintained. Also, evaporation of nitric acid and water is not excessive at this temperature. Acetic acid also reduces transfer etch, but this acid volatilizes rapidly from the bath.

Surfactants are employed in some baths to suppress the evolution of fumes; however, they may cause foaming and increase the amount of drag-out. Surfactants also increase the rate of workpiece dissolution. The generation of heat accompanying high dissolution rates must be considered when providing for the control of bath temperatures within the specified range.

Agitation is useful for maintaining a uniform temperature and composition throughout the bath, and for fast removal of reaction products and replenishment of reactants at the surfaces of the work. The most satisfactory method is mechanical agitation and movement of the work in an elliptical pattern. Air agitation is commonly used, but it must be properly controlled. Small air bubbles cause excessive loss of volatile acids by evaporation and an excess of nitrous oxide fumes. Large air bubbles sufficient to create uniform bath temperature provide satisfactory agitation. Excessive solution agitation can cause pitting and streaking on work, so the agitation should always be moderate.

The bath must be well vented to remove the noxious fumes; an exhaust of about 90 m^3/min per square meter (300 ft^3/min per square foot) of bath surface is recommended. Fumes evolved during transfer of the parts to the first rinse tank should likewise be vented, and it is good practice also to vent the first rinse tank, for which an exhaust of about 60 m^3/min per square meter (200 ft^3/min per square foot) of water surface is satisfactory. Water should be warm and air-agitated.

The fumes can be exhausted by fan or steam jet. Fume separators are required when the fumes cannot be exhausted into the atmosphere. Dilute caustic soda solutions are used to scrub the fumes and neutralize the acid.

Phosphoric and Phosphoric-Sulfuric Acid Baths. Concentrated solutions of phosphoric acid at operating temperatures above 80 °C (175 °F) were the first baths used for brightening aluminum. A more effective bath, which combines some smoothening or polishing with brightening action, is one containing 75 vol% phosphoric acid and 25 vol% sulfuric acid. This bath, which is operated at 90 to 110 °C (195 to 230 °F) for 30 s to 2 min, produces a diffuse but bright finish.

Under some conditions of composition and bath temperature, a white film of phosphate salts remains on the metal after treatment in either of these baths. The film must be removed by using a hot (60 to 70 °C, or 140 to 160 °F) aqueous solution of chromic and sulfuric acids. The composition of this acid solution is not critical and may range from 2 to 4% CrO_3 and 10 to 15% H_2SO_4 by weight.

Electrolytic Brightening (Electropolishing)

Electrolytic brightening, also known as electrobrightening and electropolishing, produces smooth and bright surfaces similar to those that result from chemical brightening. After pretreatment (which consists of buffing, cleaning in an inhibited alkaline soak cleaner, and thorough rinsing) the work is immersed in the electrobrightening bath, through which direct current is passed. The work is the anode.

Solution compositions and operating conditions for three commercial electrolytic brightening processes, as well as for suitable post-treatments, are given in Table 12. Operating conditions for electrolytes used in electrobrightening are selected to produce the desired selective dissolution and may vary for optimum results on different aluminum alloys.

Table 12 Electrolytic brightening and polishing solutions and processes for use on aluminum and aluminum alloys

Bath	Percentage	Temperature		Duration, min	Voltage, V	Current density		Film thickness		Appearance properties	Remarks
		°C	°F			A/dm^2	A/ft^2	μm	mils		
Seignette salt brightener (alkaline process)											

Sodium potassium tartrate	15 wt%	38-42	100-108	2-15	10	3-5	30-50	. . .	. . .	High luster, mirror-like reflectivity	For pure aluminum, Raffinal, Reflektal, and for jewelry and reflectors

Sulfuric acid	10-20 wt%	18-22	64-72	10	12	1	10	4	0.1	Colorless, transparent film	Without anodizing good results; best results with anodizing
Water	90-80 wt%										
Sodium bisulfate	20 wt%	33-37	91-98	10	10	0.5	5	2	0.08	Colorless, transparent film	Without anodizing good results; best results with anodizing
Water	80 wt%										

Fluoboric acid electrobrightening operating conditions and suitable post-treatments are given in Table 13. This process can be used for specular and diffuse reflectors, products made of super-purity aluminum (99.99%) in combination with up to 2% Mg, and products made of high-purity aluminum (99.7 to 99.9%).

Table 13 Fluoboric acid electrobrightening of aluminum and aluminum alloys

Constituent or condition	Amount or value
Electrobrightening[(a)]	
Fluoboric acid	2.5 wt%
Temperature of bath	30 °C (85 °F)
Current density	1-2 A/dm^2 (10-20 A/ft^2)
Voltage	15-30 V
Immersion time	5-10 min
Agitation	None
Smut removal	

Phosphoric acid	1.0 wt%
Chromic acid	0.5 wt%
Temperature of bath	90-95 °C (190-200 °F)
Immersion time	30 s
Anodizing	
Sulfuric acid	7-15 wt%
Current density	1.3 A/dm^2 (12 A/ft^2)
Temperature of bath	20 °C (70 °F)
Immersion time	10 min
Sealing	
Distilled water	100%
Temperature of bath	95-100 °C (200-212 °F)
Immersion time	10 min

(a) U.S. Patent 2,108,603 (1938)

Sodium carbonate electrobrightening can be used for specular reflectors, automotive trim, decorative ware, and jewelry. It can also be used for products made of super-purity aluminum in combination with up to 2% Mg, products made of high-purity aluminum, and products made of the following commercial alloys (in approximate order of decreasing quality of finish): 5457, 5357, 6463, 6063, 5052, 1100, 5005, 3003, and 6061. Sodium carbonate electrobrightening operating conditions and suitable post-treatments are given in Table 14.

Table 14 Sodium carbonate electrobrightening of aluminum and aluminum alloys

Constituent or condition	Amount or value
Electrobrightening	
Sodium carbonate (anhydrous)	15 wt%

Trisodium phosphate	5 wt%
pH	10.5
Temperature of bath	80-82 °C (175-180 °F)
Current density	2-3 A/dm^2 (20-30 A/ft^2)
Voltage	9-12 V
Initial immersion without current	20 s
Immersion time with current	5 min
Agitation	Work rod only
Anodizing[(b)]	
Sodium bisulfate	20 wt%
Temperature of bath	35 °C (95 °F)
Current density	0.5 A/dm^2 (5 A/ft^2)
Voltage	10 V
Immersion time	15 min
Smut removal[(a)]	
Sulfuric acid	10 vol%
Temperature of bath	20-25 °C (70-80 °F)
Immersion time	15-30 s
Sealing	
Distilled water	100%
Temperature of bath	85 °C (185 °F)

Immersion time	20 min

(a) Smut may also be removed mechanically.

(b) The anodizing treatment in the preceding list may be used as an alternative.

Sulfuric-phosphoric-chromic acid electrobrightening operating conditions and suitable post-treatments are given in Table 15. This process is used primarily for macrosmoothening to replace mechanical polishing wholly or in part. Other applications include architectural trim, decorative ware, jewelry, and products made of commercial alloys.

Table 15 Sulfuric-phosphoric-chromic acid electrobrightening of aluminum and aluminum alloys

Constituent or condition	**Amount or value**
Electrobrightening[(a)]	
Sulfuric acid	4-45 wt%
Phosphoric acid	40-80 wt%
Chromic acid	0.2-9.0 wt%
Trivalent metals	6 wt% max
Temperature of bath	70-95 °C (160-200 °F)
Viscosity of bath at 82 °C (180 °F)	9-13 cP
Current density	2.5-95 A/dm^2 (25-950 A/ft^2)
Voltage	7-15 V
Agitation	Mechanical
Smut removal

Temperature of bath	95-100 °C (200-212 °F)
Immersion time	10 min

(a) U.S. Patent 2,550,544 (1951)

Selection of Chemical and Electrolytic Brightening Processes

Chemical and electrolytic brightening are essentially selective-dissolution processes, in which the high points of a rough surface are attacked more rapidly than the depressions. An important feature of these processes is their ability to remove a surface skin of metal that is contaminated with oxides and with traces of residual polishing and buffing compounds, or other inclusions, while at the same time brightening the surface.

Metallurgical Factors. The composition, orientation, and size of the individual grains within a workpiece have a direct effect on the uniformity of dissolution during brightening. Fine-grain material is the most desirable for chemical or electrolytic brightening. Best results are obtained with alloys that are of uniform chemical composition and that do not precipitate constituents of different potential from the matrix during any necessary heating or heat treatment. Also, the alloys should be such that forming operations cause only relatively minor detrimental effects.

Mill operations must be controlled to produce material that can be brightened satisfactorily. It is important that the material be fine-grain and that surfaces be free of imperfections, such as segregation, oxide inclusions, laps, die marks, and stains.

Optical Factors. In general, the highest total and specular reflectance of a brightened surface is obtained on pure aluminum having a fine grain structure. Reflectance, both total and specular, decreases as alloy content increases; however, at a given alloy content the decrease will vary with the process. Magnesium has a very small effect on reflectance. The effect of alloying elements varies greatly with different brightening processes.

In a few applications, chemically or electrolytically brightened surfaces are protected by a clear organic coating. However, most surfaces brightened by these methods are anodized to produce a clear, colorless, protective oxide coating. For many decorative uses, the anodic coating is subsequently dyed.

Applications of chemical and electrolytic brightening processes are functional and decorative. They include jewelry, razor parts, automotive trim, fountain pens, searchlight reflectors, natural-finish or brightly colored giftware, architectural trim, household appliances, and thermal reflectors for components of space vehicles.

Chemical and electrolytic brightening may be used before or after buffing, as an intermediate operation, or to replace buffing either completely or partly. In processes where brightening is used to replace buffing completely, aluminum is dissolved at relatively rapid rates, and 25 μm (1 mil) or more of metal is removed. In processes where brightening is used as the final operation of the finishing sequence, metal is dissolved more slowly, and total metal removal usually ranges from about 3 to 13 μm (0.1 to 0.5 mil). Such procedures are used primarily on super-purity aluminum with up to 2% Mg and on high-purity aluminum.

Chemical versus Electrolytic Brightening. Because of improvements in chemical brightening processes, brightening results are equivalent to those obtained by the electrolytic processes, with the exception of reflector-type finishes on super-purity and high-purity aluminum.

Initial and operating costs for equipment are lower for chemical brightening than for electrolytic brightening, because electrical power and associated equipment are not required. Chemical brightening can be used on a variety of alloys.

Electrobrightening processes can have low chemical costs, because the chemicals used are less expensive and because baths operate well at high levels of dissolved aluminum. Other advantages of some baths used in electrobrightening are chemical stability of the solution and the ability of the bath to operate continuously for long periods at optimum efficiency with relatively simple control.

Advantages over Buffing. In performance and economy, chemical and electrolytic polishing processes offer the following advantages over buffing:

Performance

- Contaminants are not introduced into the metal surface. Chemical or electrolytic processes remove trace amounts of contaminants initially present in the surface skin or embedded in the metal during prior operations. Surfaces brightened by these processes have better total and specular reflectance.
- Anodized and dyed surfaces that have been chemically or electrolytically brightened have a brilliance, clarity, and depth not attainable with buffed surfaces. Anodizing reduces the reflectance values of chemically or electrolytically brightened surfaces less than it reduces the reflectance of buffed surfaces.
- Chemical or electrolytic brightening of aluminum prior to electroplating provides better adhesion and continuity of the plated deposits. This improves corrosion resistance and serviceability.

Economy

- Labor costs are lower than for buffing.
- Processes are readily adaptable to high-production parts that, because of their shape, cannot be finished on automatic buffing machines, and to parts that require buffing of a large percentage of the total surface area. Modification of automatic buffing machines to accommodate parts of different shapes may be more expensive than changes in racking for chemical or electrolytic brightening of these parts.
- Incorporation of processes into an automatic anodizing or electroplating line can result in economies in terms of space, equipment, and operations, and it may eliminate one or more cleaning or pickling operations in the pretreatment cycle. Deburring can sometimes be completely eliminated because of the high rate of metal removal on edges and corners.

Chemical Etching

Chemical etching, using either alkaline or acid solutions, produces a matte finish on aluminum products. The process may be used for final finishing, but it is more often used as an intermediate step prior to lacquering, conversion coating, anodizing, or other finishing treatments. Chemical etching also is used extensively in conjunction with buffing or chemical brightening.

The advantages of etching with alkaline or acid solution prior to anodizing are that it removes oxide films and embedded surface contaminants that otherwise would discolor the anodic coating; roughens the surface slightly, to produce a less glossy anodized surface and to minimize slight differences in the mill finish of different production lots; and minimizes

color-matching differences, which are more apparent with glossy or specular surfaces. Matte finishes are readily produced by chemical etching on the following wrought and cast aluminum alloys:

Wrought alloys

- *Sheet and plate:* 1100, 2014, 2024, 3003, 5005, 5052, 5457, 6061, 7075
- *Extrusions:* 2014, 2024, 6061, 6063, 6463, 7075

Casting alloys

- 242, 295, 514, A514, B514, F514, 518, 510

Cleaning prior to etching is recommended for attainment of the highest-quality finish. The need for prior cleaning, however, is determined by the amount and type of soil present on the surface of work being processed. In many instances, the etching solution serves as both a cleaner and a finishing medium.

Post-Treatments. Subsequent treatments, such as anodizing or chromate conversion coating, are required for protection against corrosion and against mechanical damage to the soft, easily marred surface. Clear lacquer may be applied to protect the matte finish produced by the etching process. Before being lacquered, the work must be cleaned of etching smut, thoroughly rinsed in clean cold water, and dried in warm air. Lacquering or painting should be done as soon as possible in a clean atmosphere.

Alkaline Etching

Alkaline etching reduces or eliminates surface scratches, nicks, extrusion die lines, and other imperfections. However, some surface contaminants, if not removed before the work enters the etching solution, may accentuate these imperfections during etching. Oxides, rolled-in dirt, and many other surface contaminants can sometimes be eliminated by deoxidizing the work with a 2 to 4 wt% chromic acid/10 to 15 wt% sulfuric acid etchant at 60 to 70 °C (140 to 160 °F) prior to alkaline etching. This treatment removes stains resulting from heat treatment and other causes without removing much metal.

Solution Makeup and Control. A hot (50 to 80 °C, or 120 to 180 °F) solution of sodium hydroxide, potassium hydroxide, trisodium phosphate, or sodium carbonate is used for alkaline etching. The solution may contain more than one alkali. The use of uninhibited alkaline solutions (such as sodium hydroxide solutions) is not recommended for high-strength 7*xxx* and 2*xxx* aluminum alloys in certain artificially aged tempers because of the danger of intergranular attack.

Sequestrants, such as gluconic acid, sodium gluconate, the glucamines, and sorbitol, are added to alkaline solutions to prevent the formation of hydrated alumina. If permitted to form, this compound coats tank walls and heating coils with a difficult-to-remove scale. Sequestrants increase the life of the bath by preventing the formation of scale and by reducing the accumulation of sludge in the tank. They are added in concentrations of 1 to 5%.

Sodium hydroxide is the alkali most commonly used. Its reaction with aluminum is exothermic, produces hydrogen gas and sodium aluminate, and may increase the temperature of the bath, depending on the relationship between rate of metal removal and tank volume. Uniform finishes may thus be more difficult to obtain with large loads or rapid dissolution rates in small tanks, because the increase in temperature causes faster etching and more rapid depletion of the chemical constituents in the bath.

The concentration of sodium hydroxide in the etching solution usually ranges from 15 to 60 g/L (2 to 8 oz/gal). For most applications, a concentration of 30 to 45 g/L (4 to 6 oz/gal) is adequate. The choice of concentration is influenced by the finish desired, the operating temperature of the bath, the quality of water, the transfer time between the etchant and rinse, and the amount of drag-out.

Solution control is guided by regular titration of samples to determine free sodium hydroxide and sodium aluminate (aluminum). In a common method of operation, the concentration of free sodium hydroxide is not permitted to fall below

26 or 30 g/L (3.5 or 4 oz/gal) when a uniform, medium-deep etch is required. The normal working concentration of aluminum is about 30 g/L (4 oz/gal), or about 2.5 wt%. When the aluminum content of the solution approaches 55 to 75 g/L (7 to 10 oz/gal) and the free sodium hydroxide content about 40 g/L (5 oz/gal), the finish may become brighter and more reflective, indicating that the solution is nearly exhausted and should be partly or completely replaced.

Determination of specific gravity also is useful in solution control. A solution that has a specific gravity of 1.15 to 1.18 while maintaining a free sodium hydroxide content of 30 to 38 g/L (4 to 5 oz/gal) is considered to be approaching exhaustion. When this condition is reached, the finish being produced should be carefully observed for nonuniform etching and shiny appearance. As the aluminum content of the solution increases, the solution becomes more viscous, which may result in poor rinsing and greater drag-out. Special proprietary rinse additives are available that help to reduce the drag-out and streaking problems caused by high viscosity of the etchant.

Environmental regulations have led to the development of waste recovery technology for used caustic etching solutions. These baths can be operated without any chelating agents, such as sodium gluconate. Recovery processes depend on a controlled precipitation of dissolved aluminum with an accompanying regeneration of free sodium hydroxide. Closed-loop recovery systems of this type also reduce chemical costs and provide more uniform etching. Because of the high capital investment required, these recovery processes are most feasible for large installations.

Equipment and Operating Procedures. Tanks and heating coils for alkaline etching may be made of low-carbon steel. Ventilation is required for the etching tanks, because the mistlike fumes generated are a health hazard to personnel, and because alkali-contaminated air can corrode or etch unprotected aluminum in the work area, especially during periods of high humidity. Efficient venting should be provided to exhaust the fumes and spray generated during the transfer of the parts to the first rinse tank.

Sometimes a blanket of foam on the solution is used to reduce the amount of mist. Foam is usually created by the addition of surface-active, or wetting, agents to the bath. A layer of 25 or 50 mm (1 or 2 in.) of foam on the surface of the bath is usually adequate.

Work to be processed may be placed on appropriate racks or loaded in baskets for immersion in the etching solution. Dipping is the method most often used for etching, although in some instances spray etching has been used. Workpieces to be bulk-processed in baskets must be positioned to prevent the formation of air or gas pockets. For best results, it is desirable to agitate the solution by air or by movement of the work.

Racks and baskets are usually used when etching is followed by subsequent treatments, such as chemical brightening or conversion coating. Stainless steel is a suitable material for bulk-etching baskets, because it withstands the corrosive conditions of the various solutions used in the cleaning and finishing processes. Baskets for bulk etching cannot be used for anodizing because an electrical contact cannot be made. Bulk parts must be transferred to specially designed containers with a pressure contact prior to anodizing.

In general, bath temperatures range from 50 to 80 °C (120 to 180 °F). Specific operating temperature is determined by the final finish desired, the time cycle, available equipment, and the concentration of the bath constituents.

After etching, the work should be rinsed immediately. A high etching temperature and a long transfer time from the etching tank may cause dry-on of the etchant. This condition produces a nonuniform finish characterized by cloudy, pitted, or stained areas.

An air-agitated rinse is beneficial, as is a double rinse in cold water flowing in a countercurrent. The latter method uses smaller tanks, uses less water, and produces better rinsing than the use of warm water or only one rinse tank. Warm water may cause staining as a result of postetching, especially when only one rinse tank is used. The work should not remain too long in the first rinse tank following etching, because the tank usually contains sufficient residual sodium hydroxide to cause staining or a cloudy finish.

Spot welds, riveted areas, and folded edges may contain small cracks or crevices that entrap the alkaline solution. Rinsing may not remove the entrapped solution; the alkaline solution will subsequently bleed out and leave a residue of white powder after the finishing process is completed. Bleed-out also can occur after anodizing. Bleed-out is unattractive and can cause failure of organic films, such as lacquers and paints, applied for added protection.

Dimensional Changes. Etching in alkaline solutions can remove a considerable amount of metal. Figure 1 shows the dimensional changes that occurred when sheet materials of various aluminum-base alloys were etched for 1, 2, or 3 min in air-agitated sodium hydroxide solution (5 wt% NaOH) operated at 70 ± 5 °C (160 ± 5 °F). When clad materials are being treated, the etching cycle must be carefully controlled to prevent loss of the cladding.

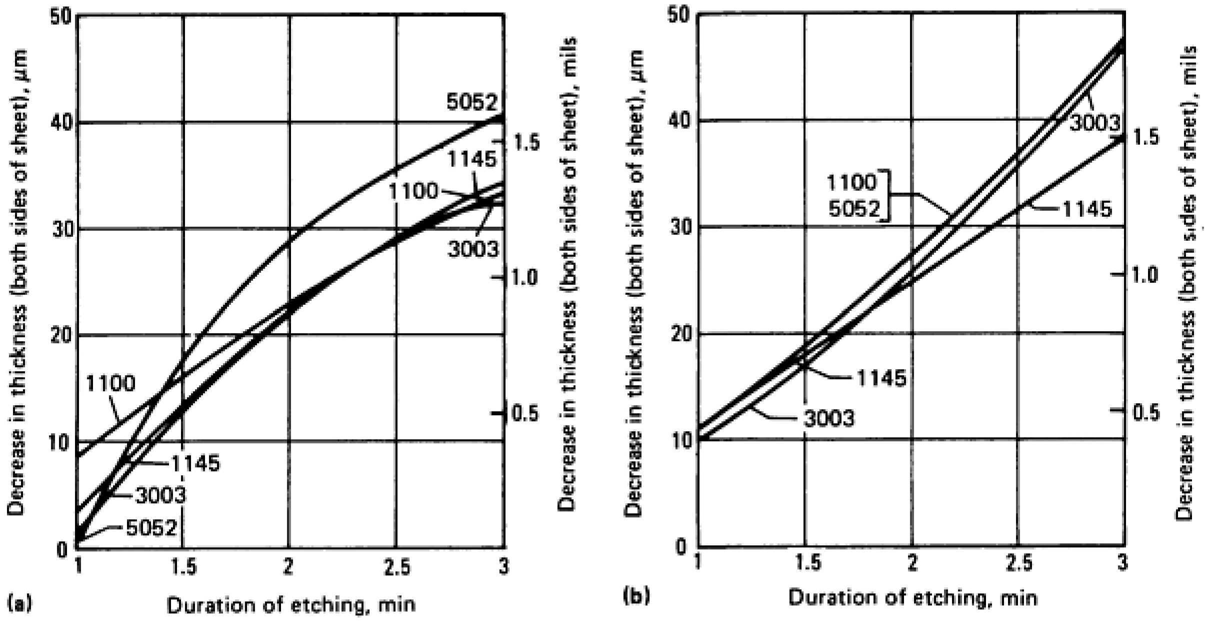

Fig. 1 Effect of time on the amount of metal removed from aluminum alloys during alkaline etching. (a) By micrometer measurement. (b) Calculated from loss in weight. Both solutions contain 5 wt% NaOH at 70 ± 5 °C (160 ± 5 °F).

Desmutting. During the cleaning and etching operation, smut (a gray-to-black residual film) is deposited on the surface of the work. This deposit usually consists of iron, silicon, copper, or other alloying constituents (in an aluminum-base material) that are insoluble in sodium hydroxide. When etching is to be followed by anodizing, the smut can sometimes be removed by the anodizing solution (current flowing); however, this practice generally cannot be controlled to produce a finish of uniform appearance. Copper and iron smuts dissolved in the anodizing electrolyte can accumulate until they make necessary premature disposal of the electrolyte. The recommended procedure is to remove the smut in a solution prepared specifically for this purpose.

A nitric acid solution (10 to 15 vol% HNO_3 or more) will remove smut. A solution containing 0.5 to 1 wt% chromic acid plus 4 to 6 wt% sodium bisulfate is similarly effective. Solutions of proprietary compounds that are nonchromated and hence nonpolluting are also used. Fluorides are usually added to solutions to aid the removal of smut from high-silicon aluminum alloys and aluminum die castings. Good results have been obtained with a room-temperature solution of 3 parts nitric acid and 1 part hydrofluoric acid.

The following example describes the solution to a problem encountered in the desmutting of die castings of a high-silicon alloy that was etched in a sodium hydroxide solution.

Because of the high silicon content of alloy 380.0 (7.5 to 9.5% Si), desmutting to obtain an attractive, uniform finish on the die castings was difficult. A chromate-type desmutting solution had been used after etching in sodium hydroxide, but it had not been entirely effective. The addition of an acid fluoride etch provided the desired finish. The sequence of operations used was as follows:

1. Soak in nonetching aluminum cleaner at 60 to 65 °C (140 to 150 °F) for 5 to 10 min.
2. Rinse in cold water.
3. Etch for 60 to 90 s in a sodium hydroxide etching solution at 60 to 65 °C (140 to 150 °F).
4. Rinse in cold water.

5. Remove part of the smut by immersing in an air-agitated, chromate-type desmutting solution at room temperature.
6. Rinse in cold water.
7. Immerse in a room-temperature acid etching solution containing fluoride and nitric acid for 30 to 60 s to remove the remaining smut.
8. Rinse in cold water.

After being prepared in this manner, the castings were chromate-conversion coated and dipped in lacquer.

Proprietary chromic-sulfuric acid desmutting solutions generally require a tank made of type 302 or 304 stainless steel, although some solutions may require type 316 or 347. They are usually operated at room temperature and normally do not require ventilation. This is an advantage over nitric acid solutions. A disadvantage of some proprietary solutions is the need for treatment of the wastes to remove the harmful effects of chromium salts before the wastes are discharged from the plant. EPA regulations and local ordinances regulate the disposition of waste solutions.

Hexavalent chromium compounds and nitric acid are especially undesirable from an EPA environmental viewpoint. As a result, these traditionally effective oxidizing agents are frequently replaced with such compounds as ferric salts, persulfates, and peroxides. (Additional information is available in the article "Chromium Elimination" in this Volume.)

Acid Etching

Acid solutions are commonly used for finished castings, especially those made of high-silicon alloys. Acid etching can be done without heavy smut problems, particularly on aluminum die castings. Hydrochloric, hydrofluoric, nitric, phosphoric, chromic, and sulfuric acids are used in acid etching.

Combinations of these acids and mixtures of acids and salts are often used for specific applications. Sulfuric-chromic acid solutions remove heat-treating stains with little etching of the metal; dilute hydrofluoric-nitric acid solutions produce bright, slightly matte-textured surfaces; and hydrochloric acid containing sodium chloride and ferric chloride is used for deep etching of designs. Additions of cobalt and nickel salts to the hydrochloric acid solution accelerate etching, but they do not affect the ability of the solution to produce a sufficiently smooth surface. Alloys containing silicon, such as sand castings, should be acid-etched with a 2 to 5% aqueous solution of hydrofluoric acid prior to anodizing.

Compositions and operating conditions for three acid etching solutions are:

Solution 1	
Nitric acid	3 parts by vol
Hydrofluoric acid	1 part by vol
Temperature of bath	20 °C (70 °F) max
Immersion time	15 s to 1 min
Solution 2	

Chromic acid	80 g (10.5 oz)
Sulfuric acid	675 mL (22.4 fluid oz)
Water, to make	4 L (1 gal)
Temperature of bath	60-70 °C (140-160 °F)
Immersion time	30 s to 2 min
Solution 3	
Chromic acid	175 g (23.5 oz)
Sulfuric acid	75 mL (2.5 fluid oz)
Water, to make	4 L (1 gal)
Temperature of bath	60-70 °C (140-160 °F)
Immersion time	30 s to 2 min

Figure 2 is a flow chart of the operations used in acid etching.

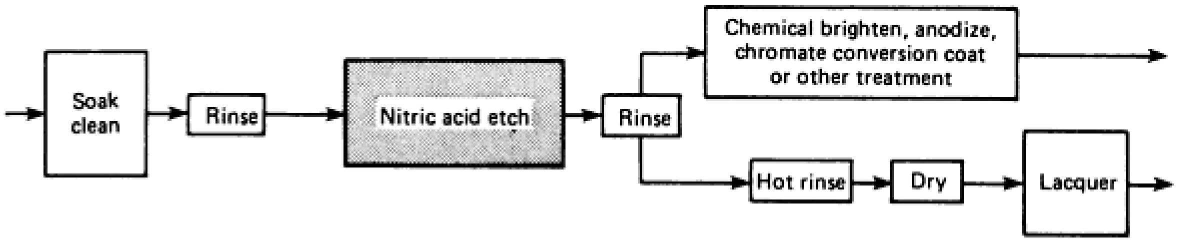

Fig. 2 Operations used in etching of aluminum and aluminum alloys

Fumes from most acid etching solutions are corrosive, and the mist or spray carried up by the gases generated constitutes a health hazard. Ventilation is required, even for solutions operated at room temperature. Tanks are made of stainless steel or plastic, or are plastic lined; plastic or plastic-lined tanks are used with solutions containing hydrochloric or hydrofluoric acid. Cooling coils may be required, because etching generates heat. Heating coils are required for solutions operated at elevated temperatures.

Acid etching is often used alone, but sometimes it may either precede or follow alkaline etching. It is usually used before alkaline etching when oxides are to be removed and after alkaline etching when smut removal is a problem. Acid etching solutions, especially those containing fluorides, are excellent smut and scale removers. After acid etching and thorough rinsing, the work is ready for further processing (Fig. 2).

Anodizing

The basic reaction in all anodizing processes is the conversion of the aluminum surface to aluminum oxide while the part is the anode in an electrolytic cell. Aluminum surfaces are anodized for a number of reasons, including to:

- Increase corrosion resistance
- Increase paint adhesion
- Prepare the surface for subsequent plating
- Improve adhesive bonding
- Improve decorative appearance
- Provide electrical insulation
- Permit application of photographic and lithographic emulsions
- Increase emissivity
- Increase abrasion resistance
- Permit detection of surface flaws

The three principal types of anodizing processes are:

- *Chromic anodizing,* in which the agent is chromic acid
- *Sulfuric anodizing,* in which the active agent is sulfuric acid
- *Hard anodizing,* in which the agent is sulfuric acid, alone or in combination with additives

Other processes, used less frequently or for special purposes, employ sulfuric-oxalic, phosphoric, oxalic, boric, sulfosalicylic, or sulfophthalic acid solutions. Except for those produced by hard anodizing processes, most anodic coatings range in thickness from 5 to 18 μm (0.2 to 0.7 mil). The succession of operations typically employed in anodizing is illustrated in Fig. 3.

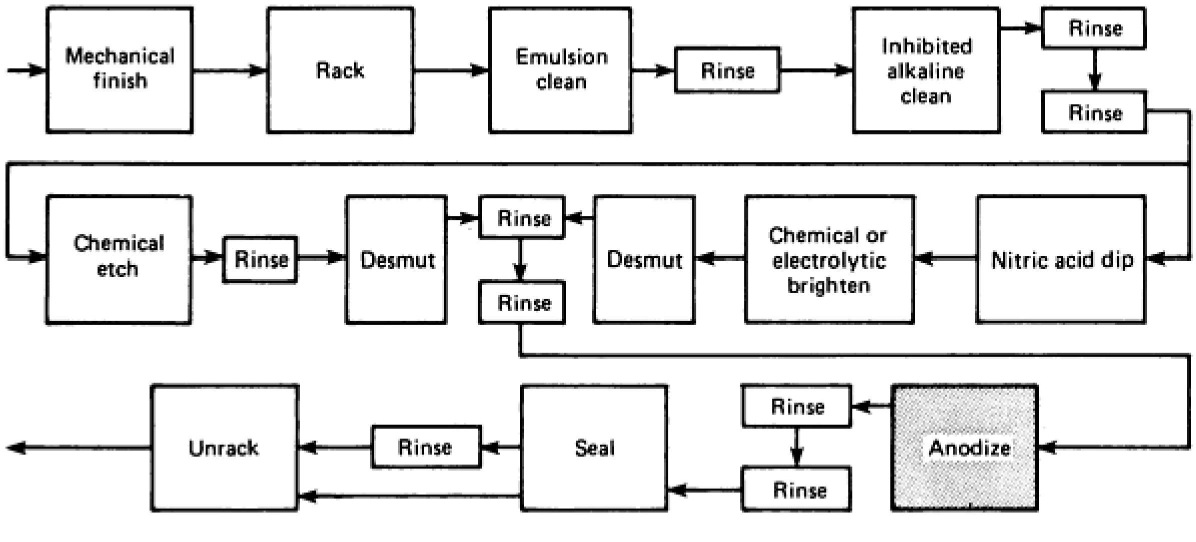

Fig. 3 Typical sequence of operations for anodizing aluminum alloys

The three major anodizing processes, as well as anodizing equipment, applications, troubleshooting, and coating evaluation, are described in detail in the article "Anodizing" in this Volume.

Chemical Conversion Coating

Chemical conversion coatings are adherent surface layers of low-solubility oxide, phosphate, or chromate compounds produced by the reaction of suitable reagents with the metallic surface. These coatings affect the appearance, electrochemical potential, electrical resistivity, surface hardness, absorption, and other surface properties of the material. They differ from anodic coatings in that conversion coatings are formed by a chemical oxidation-reduction reaction at the surface of the aluminum, whereas anodic coatings are formed by an electrochemical reaction. The reaction that takes place in chemical conversion coating involves the removal of 0.3 to 2.5 μm (0.01 to 0.1 mil) of the material being treated.

Conversion coatings are excellent for:

- Corrosion retardation under supplementary organic finishes or films of oil or wax
- Improved adhesion for organic finishes
- Mild wear resistance
- Enhanced drawing or forming characteristics
- Corrosion retardation without materially changing electrical resistivity
- Decorative purposes, when colored or dyed

Conversion coatings are used interchangeably with anodic coatings in organic finishing schedules. One use of conversion coating is as a spot treatment for the repair of damaged areas in anodic coatings. Because of their low strength, conversion coatings should not be used on surfaces to which adhesives will be applied. Anodic coatings are stronger than conversion coatings for adhesive bonding applications.

The simplicity of the basic process, together with the fact that solutions may be applied by immersion, spraying, brushing, wiping, or any other wetting method, makes conversion coating convenient for production operations. Some applications using chemical conversion coatings on various aluminum alloys are given in Table 16. In most installations, conversion coating offers a cost advantage over electrolytic methods. Moreover, unlike some anodic coatings, chemical conversion coatings do not lower the fatigue resistance of the metal treated.

Table 16 Applications of aluminum using chemical conversion coatings

Application	Aluminum alloy	Subsequent coating
Oxide conversion coatings		
Baking pans[(a)]	1100, 3003, 3004, 5005, 5052	Silicone resin
Phosphate conversion coatings		
Screen cloth	5056	Clear varnish
Storm doors	6063	Acrylic paint[(b)]
Cans	3004	Sanitary lacquer
Fencing	6061	None applied
Chromate conversion coatings		

Aircraft fuselage skins	7075 clad with 7072	Zinc chromate primer
Electronic chassis	6061-T4	None applied
Cast missile bulkhead	356-T6	None applied
Screen	5056 clad with 6253	Clear varnish
Extruded doubler	6061-T6	Clear lacquer

(a) Baking pans of these alloys may alternatively be chromate conversion coated prior to the application of silicone resin.

(b) Thermosetting

Procedure. The sequence of operations for applying a satisfactory conversion coating to aluminum-base materials is as follows:

- Removal of organic contaminants
- Removal of oxide or corrosion products
- Conditioning of the clean surface to make it susceptible to coating
- Conversion coating
- Rinsing
- Acidulated rinsing (recommended if supplementary coating is to be applied)
- Drying
- Application of a supplementary coating when required

Surface preparation entails the same procedures as are used in preparation for anodizing. However, the cleaning procedure for preparing aluminum for conversion coating is much more critical than for anodizing. After cleaning, removal of the natural oxide film is accomplished in any of the standard aqueous solutions, such as chromate-sulfate, chromate, or phosphate.

Pretreatment immediately prior to the coating operation is required for the development of extremely uniform conversion coatings. Either acid or alkaline solutions are used. Subsequent to the above operations, the work is subjected to the conversion coating solution. The addition of a wetting agent, such as sodium alkyl aryl sulfonate, to the solution helps to produce a uniform and continuous coating. After coating, the work is thoroughly rinsed and dried. The final rinse is usually hot (60 to 80 °C, or 140 to 180 °F) to aid drying. Drying is important in order to prevent staining. Drying at temperatures higher than 65 °C (150 °F) usually dehydrates the coatings and thus increases hardness and abrasion resistance.

Supplementary coatings of oil, wax, paint, or other hard organic coatings frequently are applied. If the conversion coating is intended to improve subsequent forming or drawing, the final supplementary coating may be soap or a similar dry-film lubricant.

Oxide Coating Processes. The modified Bauer-Vogel (MBV), Erftwerk (EW), and Alrok processes are the principal methods for applying oxide-type conversion coatings. Nominal compositions of the solutions used and typical operating conditions are given in Table 17. The MBV process is used on pure aluminum as well as on aluminum-magnesium, aluminum-manganese, and aluminum-silicon alloys. The coating produced varies from a lustrous light gray to a dark gray-black color. The EW process is used for alloys containing copper. The film produced is usually very light gray. The

Alrok process is for general-purpose use with all alloys, and it is often the final treatment for aluminum products. Coatings vary in color from gray to green and are sealed in a hot dichromate solution.

Table 17 Process conditions for oxide conversion coating of aluminum

Process	Bath composition	Amount		Temperature		Duration, min	Uses
		g/L	oz/gal	°C	°F		
I MBV	Sodium chromate	15	1.7	96	205	5-10 or 20-30	Corrosion protection or foundation for varnishes or lacquers
	Sodium carbonate	50	5.7				
II MBV	Sodium chromate	15	1.7	65	150	15-30	In situ treatment of large objects with paint brush or spray. When 8 g/L (0.9 oz/gal) sodium hydroxide is added, MBV oxidation may be carried out at 35 °C (95 °F) for 30 min
	Sodium chromate	50	5.7				
	Sodium hydroxide	4	0.5				
EW	Sodium carbonate	56	6.4	88-100	190-212	8-10	For copper-containing alloys
	Sodium chromate	19	2.2				
	Sodium silicate	0.75-4.5	0.09-0.5				
Alrok	Sodium carbonate	20	2.3	88-100	190-212	20	Final treatment for aluminum products
	Potassium dichromate	5	0.6				

Phosphate Coating Process. The range of operating conditions and a formula for a standard solution for phosphate coating are given below:

Specific formulations

Ammonium dihydrogen phosphate ($NH_4H_2PO_4$)	61.7%
Ammonium bifluoride (NH_4HF_2)	22.9%
Potassium dichromate ($Kr_2Cr_2O_7$)	15.4%
Operating temperature	45-50 °C (110-120 °F)
Treatment time	1-5 min
Desired operating range	
Phosphate ion	20-100 g/L (2.6-13.2 oz/gal)
Fluoride ion	2-6 g/L (0.26-0.80 oz/gal)
Dichromate ion	6-20 g/L (0.80-2.6 oz/gal)
Operating temperature	18-50 °C (65-120 °F)
Treatment time	1.5-5 min

Each liter (gallon) of solution contains 75 to 150 g (10 to 20 oz) of a mixture consisting of the above formulations (U.S. Patent 2,494,910, 1950).

Phosphate coatings vary in color from light bluish-green to olive green, depending on the composition of the aluminum-base material and the operating conditions of the bath. The phosphate-chromate conversion coatings are used extensively on aluminum parts or assemblies to provide galvanic protection from components of different kinds of materials, such as bushings or inserts made of steel.

Chromate Coating Process. Solution compositions and operating conditions for two chromate conversion coating processes are given in Table 18. Chromate coatings vary from clear and iridescent to light yellow or brown, depending on the composition of the aluminum-base material and the thickness of the film. Chromate coatings are used when maximum resistance to corrosion is desired.

Table 18 Process conditions for chromate conversion coating of aluminum

Process	Solution composition	Amount		pH	Temperature		Treatment time
		g/L	oz/gal		°C	°F	
Process A[a]	CrO_3	6[b]	0.80[b]	1.2-2.2	16-55	60-130	5 s-8 min
	NH_4HF_2	3	0.40				

	$SnCl_4$	4	0.6				
Process B[c]	$Na_2Cr_2O_7 \cdot 2H_2O$	7[b]	1[b]	1.2-2.2	16-55	60-130	5 s-8 min
	NaF	1	0.1				
	$K_3Fe(CN)_6$	5	0.7				
	HNO_3 (48° Bé)	[d]	[d]				
Process C[e]	H_3PO_4	64	8.5	1.2-2.2	40-80	105-175	1-10 min
	NaF	5	0.6				
	CrO_3	10	1.3				

(a) U.S. Patents 2,507,959 (1950) and 2,851,385 (1958).

(b) Desired range of hexavalent chromium ion, 1 to 7 g/L (0.13 to 0.90 oz/gal).

(c) U.S. Patent 2,796,370 (1957).

(d) 3 mL (0.1 fluid oz).

(e) Process for Alodine, Alochrome, and Bonderite

Chromate coatings exhibit low electrical resistivity. At a contact pressure of 1380 kPa (200 psi), in a direct-current circuit, the resistivity of a normal chromate film varies from 0.30 to 3.0 $\mu\Omega/mm^2$ (200 to 2000 $\mu\Omega/in.^2$). This resistivity is low enough so that a chromate-coated article can be used as an electrical ground. The conductivity of the films at radio frequencies is extremely high. This permits the use of a chromate film on electrical shields and wave guides. Thus, chromate conversion coating is widely used for treatment of aluminum articles for the electronics industry.

Processing equipment for conversion coating solutions must be made from acid-resistant materials. Tanks may be made of type 316 stainless steel or of low-carbon steel if lined with polyvinyl chloride or another suitably protective material. Tanks for solutions that do not contain fluorides can be constructed of acid-resistant brick or chemical stoneware. Racks can be made of low-carbon steel but must be coated with an acid-resistant compound. Heating coils or electrical immersion heaters should be made of stainless steel or stainless-clad material.

Some conversion coating solutions cause a sludge to form in the bottom of the tank. To prevent contact between the sludge and the workpieces, the tank may be equipped with a false bottom through which sludge can fall.

Adequate ventilation must be provided to remove vapors. The inhalation of fluoride vapors is dangerous. Solutions should not contact the skin; if they do, the affected area should be washed immediately with running water and then be treated by a physician. Respirators, goggles, and gloves should be worn when handling all chemicals used to make up solutions. Brushes used to apply solutions should have natural bristles; synthetic bristles are attacked by solutions.

Control of Solution. Most users of conversion coating solutions purchase prepared formulations for makeup and solution adjustment. In general, the solutions require control of both pH and the concentration of the critical elements. Direct measurement of pH is made with a glass-cell electric pH meter. The percentage concentration of active ion is obtained by direct titration with a suitable base.

Solution control becomes more critical as the size of the bath decreases with respect to the amount of work treated. Experienced operators of a conversion coating process can detect changes in the composition of the solution by observing the color and appearance of the treated work. A skilled operator often can control the bath by this method alone.

During use, coating solutions are depleted by drag-in, drag-out, and consumption of the basic chemicals. In one plant, drag-in of alkaline cleaner into the conversion coating bath adversely affected the appearance of the conversion coating. Details of this problem and the method adopted for correcting it are given in the following example.

Aluminum screen cloth made from wires of alloy 5056 clad with alloy 6253 had a rejection rate as high as 3% because of the presence of sparklers on the product after chemical conversion coating. Sparklers, also known as shiners, are areas that have higher metallic reflectance than the rest of the conversion-coated surface; they are merely an appearance defect and do not affect the adherence of organic coatings. The following processing cycle was being used:

1. Alkaline cleaning for 1 min in an inhibited solution at 70 °C (160 °F)
2. Rinsing for 30 s in overflowing cold water
3. Conversion coating for $2\frac{1}{2}$ min in a phosphate-chromate solution at 40 to 45 °C (100 to 115 °F)
4. Rinsing for 30 s in overflowing cold water
5. Second rinsing for 30 s in overflowing cold water
6. Drying
7. Application of a clear varnish (baked at 135 °C, or 275 °F for $1\frac{1}{2}$ to 2 min) or of a gray pigmented paint. (For material to be painted, conversion coating required only $1\frac{1}{2}$ min.)

The coating defects were found to be caused by contamination (and neutralization) of the acid conversion coating solution by drag-in from the alkaline cleaner. The use of a rotating beater to shake droplets of cleaning solution out of the screen openings had reduced drag-out from that bath, but it had not eliminated it.

To prevent neutralization of the acid conversion coating solution by contamination with alkali from step 1, the slightly acid overflow from the rinse in step 4 was piped back into the rinse tank in step 2, thus keeping it slightly acid. Rejects were eliminated. This procedure also reduced the amount of overflow rinse water needed to operate the line.

Control of Coating Quality. A properly applied coating should be uniform in color and luster and should show no evidence of a loose or powdery surface. Poor luster or powder surfaces are caused by low pH, improper cleaning and rinsing, excessive treatment temperature or treatment time, a contaminated bath, or insufficient agitation. Light and barely visible coatings are caused by high pH, low operating temperatures, insufficient treatment times, or high ion concentrations. Usually, the quality of a conversion coating is established on the basis of its appearance, corrosion resistance, hardness, and adherence. These qualities may be determined by the ASTM test methods described in the standards listed below:

Corrosion resistance

- Salt spray: B 117
- Copper-accelerated acetic acid salt spray (fog): B 368
- Evaluation of painted or coated specimens subjected to corrosive exposure: D 1654

Resistance to blistering

- Evaluation of blistering of paints: D 714

Adherence

- Elongation of attached organic coatings with conical mandrel apparatus: D 522

Hexavalent chromium compounds are especially effective components of solutions that form conversion coatings on aluminum. However, environmental regulations often make the handling of chromate-containing rinses a high-cost operation. Two types of technology address this problem. One is a dried-in-place chromate coating system, which eliminates the need for subsequent rinsing. The second involves the use of chromium-free treatments that form oxide films containing selected metal ions. The use of either of these processes, when possible, eliminates the need for expensive chrome destruction.

Electroplating

Aluminum-base materials are more difficult to electroplate than the common heavier metals because aluminum has a high affinity for oxygen, which results in a rapidly formed, impervious oxide film, and because most metals used in electroplating are cathodic to aluminum, so that voids in the coating lead to localized galvanic corrosion. Following are comparisons between the electrolytic potentials of several common metals and those of pure aluminum:

Metal	**Potential, mV[(a)]**
Magnesium	-850
Zinc	-350
Cadmium	-20 to 0
Aluminum (pure)	0
Aluminum-magnesium alloys	+100
Aluminum-copper alloys	+150
Iron, low-carbon steel	+50 to 150
Tin	+300
Brass	+500
Nickel	+500

Copper	+550
Silver	+700
Stainless steel	+400 to 700
Gold	+950

Note: Metals above aluminum in this list will protect it; those below cause aluminum to corrode preferentially. Cathode and anode polarization, however, can cause a reversal of these relationships.

(a) In a 6% sodium chloride solution.

Electrodeposits of chromium, nickel, cadmium, copper, tin, zinc, gold, or silver are used for various decorative and functional applications. For example, automotive aluminum bumpers get a zincate treatment, copper strike, and a plating of copper, nickel, and chromium. A copper strike coated with cadmium and chromate or by flowed tin enables the soft soldering of electrical terminals to an aluminum chassis. Brass enhances the bonding of rubber to aluminum. Silver, gold, and rhodium provide specific electrical and electronic surface properties. Examples of applications of plated aluminum with typical finishing sequences are given in Table 19.

Table 19 Applications using electroplated coatings on aluminum products

Product	**Form**	**Preplating treatment**	**Electroplating system**	**Thickness**		**Reason for plating**
				µm	**mils**	
Automotive applications						
Bearings	Sheet	None	Pb-Sn-Cu alloy	6-32	0.25-1.25	Prevent seizing

Effect of Substrate Characteristics on Plating Results. Each aluminum alloy, according to its metallurgical structure, behaves differently from others during electroplating. Alloying elements may be in solid solution in the aluminum, or they may be present in discrete particles or as intermetallic compounds. These microconstituents have different chemical or electrochemical reactivities, and their surfaces do not respond uniformly to treatment. Variations in response also occur between different lots or product forms of the same alloy.

Surface Preparation Methods. The three established methods for surface preparation prior to electroplating are surface roughening, anodizing, and immersion coating in zinc or tin solutions.

Surface roughening, which is accomplished either by mechanical abrasion or by chemical etching, assists in mechanically bonding the electrodeposits to the aluminum surface. Surface roughening is sometimes used in preparation for the application of hard chromium to aluminum engine parts, such as pistons. A water blast of fine quartz flour may be used to remove surface oxides and to abrade the surface. The adherent wet film protects the aluminum surface from further oxidation before plating. The quartz film is dislodged by the evolution of hydrogen that occurs during plating. Chemical etching produces undercut pits that provide keying action for the electrodeposited metal. In general, mechanical bonding of electrodeposits is not reliable, particularly for applications involving temperature variations. Therefore, preparation by surface roughening is not recommended.

Anodizing is sometimes used as a method of surface preparation prior to electroplating. However, the adherence of the subsequent electrodeposit is limited; plated deposits over anodic films are highly sensitive to surface discontinuities, making the time, temperature, and current density of the anodizing process critical. Phosphoric acid anodizing has been used for the aluminum alloys listed in Table 20; the sequence of operations is:

1. Vapor degreasing or solvent cleaning
2. Mild alkaline cleaning
3. Rinsing
4. Etching for 1 to 3 min in a solution containing sodium carbonate (23 g/L, or 3 oz/gal) and sodium phosphate (23 g/L, or 3 oz/gal), at 65 °C (150 °F)
5. Rinsing
6. Dipping in nitric acid solution (50% HNO_3 by volume) at room temperature
7. Rinsing
8. Phosphoric acid anodize according to the conditions given in Table 20; the anodic coating should not be sealed.
9. Rinsing

10. Electroplating in a copper pyrophosphate or nickel sulfamate bath

Table 20 Conditions for anodizing aluminum alloys prior to electroplating

Electrolyte solution of aqueous H_3PO_4

Alloy[(a)]	Specific gravity	Temperature		Voltage	Time, min
		°C	°F		
1100	1.300	30	87	22	5
3003	1.300	29	85	22	5
5052	1.300	29	85	22	10
6061	1.300	29	85	22	7

(a) With special care, phosphoric acid anodizing may be used also for aluminum-copper or aluminum-silicon alloys.

Immersion coating in a zincate solution is a traditional method of preparing aluminum surfaces for electroplating. It is simple and low in cost, but it is also critical with respect to surface pretreatment, rinsing, and the strike sequence used. The principle of zincating is one of chemical replacement, whereby aluminum ions replace zinc ions in an aqueous solution of zinc salts. Thus, a thin, adherent film of metallic zinc is deposited on the aluminum surface. Adhesion of the zinc film depends almost entirely on the metallurgical bond between the zinc and the aluminum. The quality and adhesion of subsequent electrodeposits depend on obtaining a thin, adherent, and continuous zinc film. The electrolytic Alstan strike is coming into general use as a more dependable method than the zincate process for obtaining good adhesion. It is followed by a bronze strike.

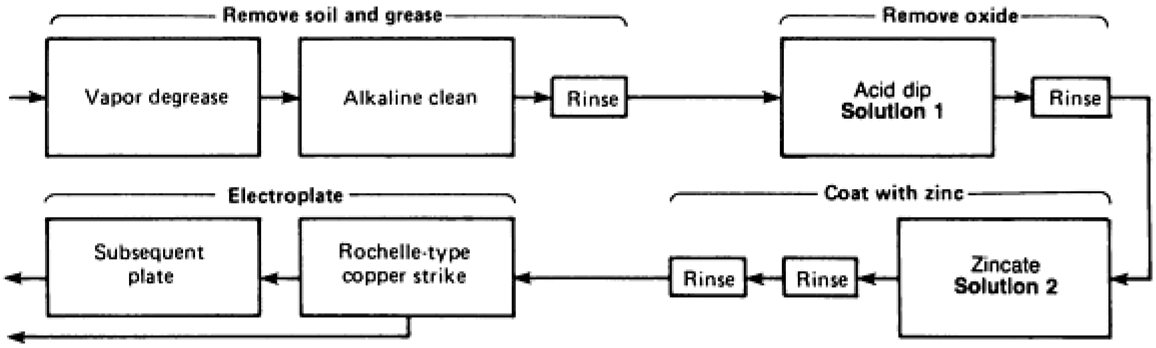
Another immersion process is based on the deposition of tin from a stannate solution. This offers improved corrosion resistance because of the more favorable electrolytic potential of tin versus zinc in chloride solutions.

Immersion Procedures. To obtain consistently good results with zinc or tin immersion procedures, it is essential that cleaning and conditioning treatments produce a surface of uniform activity for deposition. Vapor degreasing or solvent cleaning followed by alkaline cleaning is used for removing oil, grease, and other soils. The alkaline cleaner may be a mild etching solution of water containing 23 g/L (3 oz/gal) each of sodium carbonate and sodium phosphate. The solution temperature should range from 60 to 80 °C (140 to 180 °F), and the material should be immersed for 1 to 3 min and then be thoroughly rinsed. After cleaning, the material is further treated to remove the original oxide film as well as any microconstituents that may interfere with the formation of a continuous film or that may react with the subsequent plating solutions.

Castings present special problems, because their surfaces are more porous than those of wrought products. Solutions entrapped in pores are released during subsequent processing, resulting in unplated areas, staining, or poor adhesion of the electrodeposit. Sometimes the trapped solutions become evident much later, during storage or further processing (such as heating for soldering). Furthermore, even if pores are free of solution, the deposit may not bridge them, thus creating a point of attack for corrosion of the base metal. This is of particular significance in the electroplating of aluminum castings: The electrodeposited metal is electrolytically dissimilar to aluminum, and thus every opening in a casting surface will be a source of corrosion. To circumvent these problems, it is essential when preparing cast aluminum surfaces for electroplating that all processing steps be carefully controlled to avoid surfaces with excessive porosity.

In zincating, the procedures used for removal of the original oxide film and for application of a zinc film depend to a considerable degree on the aluminum alloy. Several methods are available for accomplishing this surface conditioning, and some alloys can be conditioned by more than one procedure. In such instances, the order of preference follows the order of discussion of these procedures in the following paragraph.

Wrought alloys without interfering microconstituents and casting alloys containing high silicon are prepared for electroplating according to the procedure shown by the flow chart in Fig. 4. The flow chart in Fig. 5 represents the procedure for alloys that contain interfering microconstituents; this procedure is suitable for all wrought alloys, most casting alloys, and especially aluminum-magnesium alloys. Figure 6 indicates the procedure for treating most casting alloys, wrought alloys that contain less than approximately 3% Mg, and alloys of unknown composition.



Solution No.	Type of solution	Composition	Amount	Operating temperature		Cycle time, s
				°C	°F	
Alloys 1100 and 3003						
1	Acid dip	HNO_3	50 vol%	Room	Room	15
2	Zincating	NaOH	525 g/L (70 oz/gal)	16-27	60-80	30-60
		ZnO	98 g/L (13 oz/gal)			
Alloys 413, 319, 356 and 380						
1	Acid dip	HNO_3	75 vol%	Room	Room	3-5
		HF	25 vol%			
2	Zincating	NaOH	525 g/L (70 oz/gal)	16-27	60-80	30 max
		ZnO	98 g/L (13 oz/gal)

Fig. 6 Preplating surface preparation procedures suitable for most aluminum casting alloys, for wrought aluminum alloys containing less than approximately 3% Mg (e.g., 1100, 3003, 3004, 2011, 2017, 2024, 5052, and 6061), and for aluminum alloys whose identities are not known

Table 21 gives details of three zincating solutions that may be used alternatively to the solution indicated in the tables that accompany Fig. 4, 5, and 6. The modified solution in Table 21 is recommended when double-immersion zincating (Fig. 6) is required; it is not essential for alloys 2024 and 7075. This solution produces more uniform coverage than the unmodified solution and also imparts greater corrosion resistance to the treated work. Dilute solution No. 1 in Table 21 is recommended when there are problems in rinsing and drag-out. Dilute solution No. 2 provides a greater reserve of zinc for high-production operations, but at a slight sacrifice in effectiveness of rinsing. In some special operations, triple zincate treatment is used. This involves essentially stripping the second zinc film formed in double zincate and adding a zincate from a third solution. Triple zincate provides an even more uniform and fine-grain zinc coating than double zincate.

(a) U.S. Patent 2,676,916 (1954).

(b) U.S. Patents 2,676,916 (1954) and 2,650,886 (1953)

If correct procedures are followed, the resulting zinc deposit is uniform and firmly adherent to the aluminum surface. The appearance of the surface will vary with the alloy being coated, as well as with the rate at which the coating forms. The weight of zinc deposit should be from 1.5 to 5.0 mg/dm^2 (0.1 to 0.3 mg/in.^{2}). Generally, it is desirable to limit the deposit to 3 mg/dm^2 (0.2 mg/in.^{2}).

The thinner and more uniform zinc deposits are the most suitable for plating preparation and for the service performance of plated coatings. Heavy zinc deposits usually are spongy, less adherent, and undesirable from the standpoint of corrosion resistance.

Plating Procedures. Copper is one of the easiest metals to electrodeposit on zincated aluminum surfaces. For this reason, it is used extensively as an initial strike over which other metals may be subsequently deposited. An advantage of the copper strike is that it protects the thin zinc film from attack by the plating solutions. Penetration of the zinc film and attack of the underlying aluminum surface by the plating solutions result in a poorly bonded electrodeposit.

The copper strike bath should be a Rochelle-type copper cyanide solution. The composition and operating conditions recommended for this bath are:

Copper cyanide	4 g/L (5.5 oz/gal)
Total sodium cyanide	50 g/L (6.5 oz/gal)
Free sodium cyanide	4 g/L (0.5 oz/gal) max
Sodium carbonate	30 g/L (4.0 oz/gal)
Rochelle salt	60 g/L (8.0 oz/gal)
Operating temperature	40-55 °C (100-130 °F)
pH	Varies with alloy; see Table 22

Table 22 Conditions for electroplating various metals on zincated aluminum surfaces

Zinc (direct on zincate)	12.5	0.5	10	24-35	75-95	0.5-5[(k)]	5-50[(k)]	Pyrophosphate

(a) An initial cyanide copper strike is generally used to achieve complete metal coverage of zincated aluminum parts prior to plating, because of the excellent throwing power of the copper electrolyte. A copper strike is not, however, recommended as the initial coating for alloys 5056, 214, 218, and others that contain substantial amounts of magnesium; these will achieve a better initial coverage in a brass strike. Neither copper strike nor brass strike should be used as a final finish; both should always have an electroplated top coat.

(b) The copper strike is achieved during the first 2 min while the current density of the electrolyte is maintained at 2.4 A/dm^2 (24 A/ft^2). Instead of being transferred from the strike bath to a high-speed sodium or potassium electrolyte for subsequent copper plating, the work may be allowed to remain (3 to 5 min) in the Rochelle-type electrolyte to be copper plated, provided the current density is lowered to 1.2 A/dm^2 (12 A/ft^2).

(c) Colorimetric pH of electrolyte is 12.0 for all treatable alloys except 5052, 6061, and 6063, for which pH is 10.2 to 10.5

(d) Work for which copper strike plating may be used may be left in the copper strike for copper plating, instead of being transferred to the high-speed sodium or potassium cyanide electrolyte (see footnote c).

(e) As discussed in the article on nickel plating, various electrolytes are used, depending on the specific purpose of the plated deposit. If the nickel is to be deposited directly on the zincated surface, a bath must be selected that is suitable for application over zinc (examples of such baths are fluoborate and sulfamate nickel electrolytes).

(f) The transition from low-temperature to high-temperature plating may be accomplished either by heating the electrolyte to 54 °C (130 °F) after deposition has started at 18 to 21 °C (65 to 70 °F) or by transferring the work (without rinsing) from an electrolyte at 18 to 21 °C (65 to 70 °F) to one at 54 °C (130 °F) and holding the work in the high-temperature electrolyte without current until the work reaches bath temperature. Current density is 0.07 to 0.15 A/dm^2 (0.7 to 1.5 A/in.^{2}) in the electrolyte at 18 to 21 °C (65 to 70 °F). 1935 AS/mm^2 (3 A/in.^{2}) at 54 °C (130

°F).

(g) Each bath.

(h) First strike bath contains 1 g (0.11 oz) of AgCN and 90 g (10.2 oz) of NaCN per litre (gallon); second bath, 5.3 g (0.60 oz) of AgCN and 67.5 g (7.7 oz) of NaCN per litre (gallon).

(i) Contains 5.3 g (0.60 oz) of AgCN and 67.5 g (7.7 oz) of NaCN per litre (gallon).

(j) After the aluminum material has been copper strike plated, tin may be applied also by immersion for 45 min to 1 h in a sodium stannate solution at 49 to 74 °C (120 to 165 °F). Time and temperature depend on solution used.

(k) Current is applied as work is being immersed in electrolyte.

A brass strike is sometimes used in place of copper; however, a bronze strike is frequently used on a tin immersion coating. Table 22 gives operating conditions for the electrodeposition of different metals on zincated aluminum surfaces. Environmental considerations sometimes necessitate substitution for cyanide-containing solutions. Nickel strikes, which are successful as a result of careful control of composition and operation conditions, permit this.

Immersion Plating

Immersion plating refers to processes in which another metal is deposited from solution on an aluminum surface under the influence of the potential that exists between the solution and the immersed aluminum material. An external potential is not required. Deposits produced by immersion plating are thin and of little protective value.

Zincating, the procedure used for coating aluminum surfaces with zinc prior to electroplating (see the preceding section), is an example of immersion plating. Brass deposits can be produced by adding copper compounds to the sodium zincate solutions used in zincating.

Tin can be deposited from solutions containing potassium stannate, stannous chloride, or stannous sulfate-fluoride. The lubricating qualities of these tin deposits are desirable for aluminum alloy piston and engine components. Immersion tin coatings also are used to facilitate soft soldering and as a base coating for building up electrodeposits. The composition and operating conditions of a successful immersion tin bath are given below:

Potassium stannate	100 g/L (13.40 oz/gal)
Zinc acetate	2 g/L (0.27 oz/gal)
m-Cresol sulfonic acid	35 g/L (4.40 oz/gal)
Temperature of solution	60 °C (140 °F)
Immersion time	2 min

Degreasing is the only pretreatment required. The thickness of the tin coating is about 1.3 μm (0.05 mil); solution life is about 0.75 m^2/L (30 ft^2/gal).

Electroless Plating

Electroless plating, often called chemical plating, refers to nonelectrolytic processes that involve chemical reduction, in which the metal is deposited in the presence of a reducing agent. Deposition may take place on almost any type of material, even the container of the solution. For a variety of applications in the aircraft industry, nickel is chemically plated on aluminum parts of shapes for which electroplating is not practical. However, electroless plating is too expensive to be used when conventional electroplating is feasible. The composition and operating conditions of a bath for the successful deposition of nickel are given below:

Nickel chloride	30 g/L (4 oz/gal)
Sodium hypophosphite	7.5 g/L (1 oz/gal)
Sodium citrate	72 g/L (9.60 oz/gal)
Ammonium chloride	48 g/L (6.40 oz/gal)
Ammonium hydroxide (0.880 sp gr)	13 g/L (1.75 oz/gal)
pH	10
Temperature of solution	80-90 °C (180-190 °F)
Immersion time	1 h

Deposits produced contain about 6 wt% P and usually are not considered suitable as a base for chromium plate. The immersion time given is for deposits 50 μm (2 mil) or more thick.

Silver can be plated using the electroless process on anodized aluminum-base materials. The procedure consists of degreasing the anodized surface, dipping in dilute hydrochloric acid, water rinsing, and then immersing the object in a silvering solution. A mixture of two solutions is required for silvering. The first consists of 3.33 mL (0.113 fluid oz) of a 10% solution of silver nitrate to which a 7.5 vol% solution of ammonium hydroxide is added until the precipitate first formed just redissolves, after which an excess of 40 mL (1.3 fluid oz) of ammonium hydroxide solution is added. The second solution is made by adding 80 g (3 oz) of Rochelle salt or 40 g (1.4 oz) of potassium citrate to water, to a total volume of 330 mL (11 fluid oz). Solutions are filtered and mixed immediately before use.

Additional information on electroless plating processes is available in the Section "Plating and Electroplating" in this Volume.

Painting

The difference between painting of aluminum and painting of iron or steel lies primarily in the method of surface preparation. Aluminum is an excellent substrate for organic coatings if the surface is properly cleaned and prepared. For

many applications, such as indoor decorative parts, the coating may be applied directly to a clean surface. However, a suitable prime coat, such as a wash primer or a zinc chromate primer, usually improves the performance of the finish coat.

For applications involving outdoor exposure, or for indoor applications that expose the part to impact or abrasive forces, a surface treatment such as anodizing or chemical conversion coating is required prior to the application of a primer and a finish coat. These processes were discussed above.

Anodizing in sulfuric or chromic acid electrolytes provides an excellent surface for organic coatings. Usually, only thin anodic coatings are required as a prepaint treatment. Decorative parts for home appliances generally are anodized before painting to ensure good paint adhesion over an extended period. Sulfuric acid anodic coatings are used when painting of only part of the surface is required for decorative effects; the anodic coating protects the unpainted portions of the surface.

Conversion coatings usually are less expensive than anodic coatings, provide a good base for paint, and improve the life of the paint by retarding corrosion of the aluminum substrate material. Adequate coverage of the entire surface by the conversion coating is important for good paint bonding.

The article "Painting" in this Volume contains additional information on surface preparation, paint formulations, and application procedures.

Porcelain Enameling

Porcelain enamels are glass coatings applied to products to improve appearance and protect the metal surface. Porcelain enamels are distinguished from other ceramic coatings by their predominantly vitreous nature and the types of applications for which they are used. They are distinguished from paint by their inorganic composition and the fusion of the coating matrix to the substrate metal.

Aluminum products, including tanks and vessels, architectural panels, cookware, and signs, may be finished by porcelain enameling to enhance appearance, chemical resistance, or weather resistance. The common porcelain enameling alloys for the various forms of aluminum are:

- *Sheet:* 1100, 3003, and 6061
- *Extrusions:* 6061
- *Casting alloys:* 443 and 356

Of the wrought alloys, only 6061 alloy is heat-treatable. Because of its higher strength, 6061 alloy has better handling characteristics before and during porcelain enameling, and it is stronger after porcelain enameling. The non-heat-treatable alloys are easier to form before porcelain enameling and are used for small parts for which the amount of distortion and low strength encountered after firing are acceptable. However, non-heat-treatable alloys are unsuitable for more than one coat of porcelain because of the crazing that occurs after a second firing.

Frits. The basic material of the porcelain enamel coating is frit, a special glass of small friable particles produced by quenching a molten glassy mixture. Because porcelain enamels are usually designed for specific applications, the compositions of the frits from which they are made vary widely.

Enamel frits for aluminum are usually based on lead silicate and on cadmium silicate, but they may be based on phosphate or barium. Table 23 gives the compositions of several frits used for aluminum.

Table 23 Melted-oxide compositions of frits for porcelain enameling of aluminum

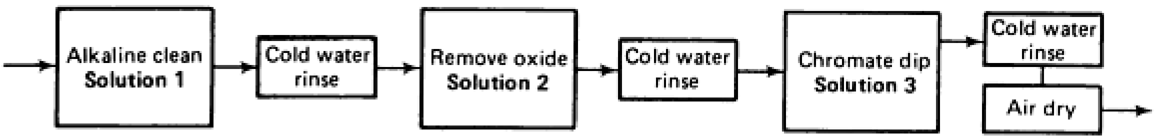
Constituent	Composition, wt%		
	Lead-base enamel	Barium enamel	Phosphate enamel

PbO	14-45	. . .	. . .
SiO_2	30-40	25	. . .
Na_2O	14-20	20	20
K_2O	7-12	25	. . .
Li_2O	2-4	. . .	4
B_2O_3	1-2	15	8
Al_2O_3	. . .	3	23
BaO	2-6	12	. . .
P_2O_5	2-4	. . .	40
F_2	. . .	. . .	5
TiO_2	15-20	(a)	(a)

(a) TiO_2, 7 to 9 wt%, added to frit during mill preparation of the enamel slip

The high-lead enamels for aluminum have a high gloss, good acid and weather resistance, and good mechanical properties. The phosphate enamels generally are not alkali-resistant or water-resistant, but they may have good acid resistance. They melt at relatively low temperatures and are useful in many applications. The barium enamels are not as low-melting as the lead or phosphate glasses, but they do have good chemical durability.

Surface Preparation. The preparation of heat-treatable aluminum alloy parts for porcelain enameling involves the removal of soil and surface oxides and the application of a chromate coating. Figure 7 shows the sequence of these surface preparation treatments and gives operating conditions. Final drying removes all surface moisture; drying must be accomplished without contaminating the cleaned surface. Parts made of non-heat-treatable aluminum alloys require only the removal of soil, which can be done by alkaline cleaning or vapor degreasing.



No.	Type	Composition of solution		Operating temperature		Cycle time, min
		Constituent	wt%	°C	°F	
1	Alkaline cleaner[a]	[b]	[b]	60-82	140-180	2-5
2	Oxide removal	Chromic acid	3.5	82	180	3-10
		Sulfuric acid	18.0			
3	Chromate dip	Chromic sulfate	0.2	Ambient		1-6
		Potassium dichromate	14.4			
		Sodium hydroxide	7.75			

(a) Vapor degreasing may be used instead of alkaline cleaning.

(b) Either inhibited or mildly etching (uninhibited) cleaners can be used

Fig. 7 Process for preparing heat-treatable aluminum alloys for porcelain enameling

Because enamel ordinarily is applied to aluminum to only about half the thickness to which it is applied to steel, freedom from surface scratches, burrs, and irregularities is doubly important for aluminum. Most shaping of aluminum is done before enameling, but the thin coating permits some bending, shearing, punching, and sawing of the enameled part.

Surfaces to be enameled should have generous inside radii of not less than 4.8 mm ($\frac{3}{16}$ in.) and outside radii of not less than 1.6 mm ($\frac{1}{16}$ in.). Attachments should be welded to the unenameled back side of enameled heavy-gage aluminum sheet or extrusions. The visible metal surfaces must not be overheated; overheating causes the aluminum to blister and alters the color and gloss of the enamel. Welding can be done before enameling, provided that the weld area is cleaned properly before coating.

Additives and Application. Porcelain enamel is usually applied to aluminum as a suspension of finely milled frit in water. Mill additions for wet process enamel frits for aluminum consist of boric acid, potassium silicate, sodium silicate, and other additives. These materials are used to control the wet suspension of the frits, and they contribute to the characteristics of the fired enamel. Titanium dioxide and ceramic pigments can also be added to produce opacity and the desired color, respectively.

Porcelain enamel slips for aluminum usually are applied by spraying, using either manual or automatic equipment with agitated pressure tanks. Slips for aluminum are not self-leveling and thus must be deposited smoothly in an even thickness and without runs or ripples.

Many aluminum parts are coated satisfactorily by the one-coat/one-fire method. Although the heat-treatable alloys can be recoated one or more times, the opacity and color of the coating will change with the thickness of the porcelain and with

repeated firing. The desirable minimum fired enamel thickness is 65 μm (2.5 mil), and the desirable maximum is 90 μm (3.5 mil).

Furnaces. Forced convection is the preferred method of heating furnaces for firing porcelain enamel on aluminum. The heat is provided by electric package heaters, quartz-tube electric heaters, or metal-sheath heaters, all specially designed for operation at high ambient air temperature. Quartz-tube and metal-sheath heaters are adapted to the furnace so that radiant heat is available in the firing zone along with forced circulation. Package heaters are placed remote from the firing zone; this is the most effective method of eliminating direct radiation and hot spots. Heat imparted to the work from the package heater is derived completely from adequate air circulation to maintain a uniform temperature throughout the furnace of ±1% of the nominal operating temperature.

Forced-convection heating is also accomplished with gas-fired radiant tubes as the heat source. The tubes are baffled from the work or firing zone so that air circulation provides the same advantages as in electric-package forced-convection heating.

Furnace construction for aluminum enameling generally requires the use of stainless steel inner liner sheets, low-density wall insulation, and plain-carbon steel exterior shell. This type of fabrication eliminates long heat-up and cool-down periods.

Firing of enamel on aluminum is accomplished between 525 and 550 °C (980 and 1020 °F); cycles are shown in Table 24. To control color and gloss of the enamel within acceptable limits, the temperature throughout the work must be held to 1.5 °C (2.5 °F).

Table 24 Cycles for firing procelain enamel on aluminum

Type of part	Section thickness, 0.025 mm (0.001 in.)	Firing time, min	Firing temperature	
			°C	°F
Any configuration	26-40	5-6 $\frac{1}{2}$	540	1000
Any configuration	51-64	7-8	540	1000
Extrusions	125	10	550	1020

Detailed information about porcelain enamel coatings is available in the article "Porcelain Enameling" in this Volume.

Shot Peening

Shot peening is a method of cold working in which compressive stresses are induced in the exposed surface layers of metallic parts by the impingement of a stream of shot, which is directed at the metal surface at high velocity under controlled conditions. It differs from blast cleaning in primary purpose and in the extent to which it is controlled to yield accurate and reproducible results. Cast steel shot is the most widely used peening medium, but glass beads often are used for peening aluminum and other metals that might be contaminated by steel shot.

Although shot peening cleans the surface being peened, this function is incidental. The major purpose of shot peening is to increase fatigue strength. For example, the fatigue strength of several aluminum alloys peened with cast steel shot can

be improved by 23 to 34%. The process has other useful applications, such as relieving tensile stresses that contribute to stress-corrosion cracking (SCC), and forming and straightening metal parts.

Peening action improves the distribution of stresses in surfaces that have been disturbed by grinding, machining, or heat treating. Shot peening is especially effective in reducing the harmful stress concentration effects of notches, fillets, forging pits, surface defects, and the heat-affected zones of weldments.

The surface tensile stresses that cause SCC can be effectively overcome by the compressive stresses induced by shot peening with either steel shot or glass beads. In one application, test bars were cut in the short transverse direction from a 7075-T6 aluminum alloy hand forging and stressed to 75% of the yield strength. During alternate immersion tests in 3.5% sodium chloride solution, unpeened specimens failed in 1, 5, 17, and 28 days. Specimens peened in the unstressed condition with cast steel shot lasted 365 and 730 days, when failure occurred in the unpeened grip outside the test area. During exposure to an industrial atmosphere, similar unpeened test bars failed in 20, 37, 120, and 161 days, whereas a peened specimen under the same conditions was uncracked when it was removed from testing after an exposure of $8\frac{1}{2}$ years.

Additional information is provided in the article "Shot Peening" in this Volume.

Designation System for Aluminum Finishes

Finishes used on aluminum are categorized as mechanical or chemical finishes or as coatings. Types of coatings that can be applied include anodic coatings, resinous and other organic coatings, and vitreous coatings. In addition, laminated, electroplated, or other metallic coatings can be used on aluminum.

In the designation system developed by the Aluminum Association, each of these categories is assigned a letter, and the various finishes in each category are designated by two-digit numerals. Specific finishes of the various types thus are designated by a letter followed by two numbers, as shown in Table 25. Two or more designations can be combined into a single designation to identify a sequence of operations covering all the important steps leading to a final complex finish.

Table 25 Designations for aluminum finishes

Designation[a]	**Finish**
Mechanical finishes--M	
As fabricated:	
M10	Unspecified
M11	Specular finish as fabricated
M12	Nonspecular finish as fabricated
M1X	Other (to be specified)
Buffed:	
M20	Unspecified

M21	Smooth specular
M22	Specular
M2X	Other (to be specified)
Directional textured:	
M30	Unspecified
M31	Fine satin
M32	Medium satin
M33	Coarse satin
M34	Hand rubbed
M35	Brushed
M3X	Other (to be specified)
Nondirectional textured:	
M40	Unspecified
M41	Extra fine matte
M42	Fine matte
M43	Medium matte
M44	Coarse matte
M45	Fine shot blast
M46	Medium shot blast
M47	Coarse shot blast

M4X	Other (to be specified)
Chemical finishes[(b)]--C	
Nonetched cleaned:	
C10	Unspecified
C11	Degreased
C12	Inhibited chemical cleaned
C1X	Other (to be specified)
Etched:	
C20	Unspecified
C21	Fine matte
C22	Medium matte
C23	Coarse matte
C2X	Other (to be specified)
Brightened:	
C30	Unspecified
C31	Highly specular
C32	Diffuse bright
C3X	Other (to be specified)
Chemical coatings:	
C40	Unspecified

C41	Acid chromate-fluoride
C42	Acid chromate-fluoride-phosphate
C43	Alkaline chromate
C44	Nonchromate
C45	Nonrinsed chromate
C4X	Other (to be specified)
Anodic coatings--A	
General:	
A10	Unspecified
A11	Preparation for other applied coatings
A12	Chromic acid coatings
A13	Hard, wear- and abrasion-resistant coatings
A1X	Other (to be specified)
Protective and decorative:	
(Less than 10 μm, or 0.4 mil)	
A21	Clear (natural)
A22	Integral color
A23	Impregnated color
A24	Electrolytically deposited color
A2X	Other (to be specified)

Architectural Class II(c):	
(10 to 18 μm, or 0.4 to 0.7 mil)	
A31	Clear
A32	Integral color
A33	Impregnated color
A34	Electrolytically deposited color
A3X	Other (to be specified)
Architectural Class I[c]:	
(18 μm, or 0.7 mil)	
A41	Clear (natural)
A42	Integral color
A43	Impregnated color
A44	Electrolytically deposited color
A4X	Other (to be specified)
Resinous and other organic coatings[d]--R	
R10	Unspecified
R1X	Other (to be specified)
Vitreous (porcelain and ceramic) coatings[d]--V	
V10	Unspecified
V1X	Other (to be specified)

Electroplated and other metal coatings[d]--E	
E10	Unspecified
E1X	Other (to be specified)
Laminated coatings[d]--L	
L10	Unspecified
L1X	Other (to be specified)

(a) All designations are preceded by the letters "AA," to identify them as Aluminum Association designations. Examples of methods of finishing are given in the Aluminum Association publication from which the presentation here is derived.

(b) Includes chemical conversion coatings, chemical or electrochemical brightening and cleaning treatments.

(c) Classification established in Aluminum Association Standards for Anodically Coated Aluminum Alloys for Architectural Applications, October 1978.

(d) These designations may be used until more complete series of designations are developed for these coatings.

When designations for chemical coatings are used alone, other processing steps normally used ahead of these finishes are at the option of the processor. Where a finish requires two or more treatments of the same class, the class letter is repeated, each time being followed by the appropriate two-digit numeral.

Designations for specific coatings have been developed only for the anodic coatings. Coatings of the four other classes may be tentatively designated by the letters respectively assigned for them; detailed designations for these four categories may be developed and added to the system later.

The examples that follow show how the designation system for aluminum finishes is used. Each designation is preceded by the letters "AA" to identify it as an Aluminum Association appellation. More detailed information can be found in the Association document titled "Designation Systems for Aluminum Finishes, 1980."

Smooth Specular Finish. A finish can be obtained by polishing aluminum with an aluminum oxide compound according to the following schedule. Begin with grits coarser than 320; follow with 320-grit and a wheel speed of 30 m/s (6000 ft/min); complete polishing by buffing with tripoli-based buffing compound at 35 to 41 m/s (7000 to 8000 ft/min). The designation for this finish is AA-M21 (Table 25).

Architectural Building Panel. A matte-anodized finish for a building, such as that produced by giving aluminum a matte finish, then chemical cleaning followed by architectural class II natural anodizing, would be designated as AA-M32C12A31:

AA	Aluminum Association
M32	Mechanical finish, directional textured, medium satin appearance
C12	Chemical treatment, inhibited alkaline cleaning
A31	Anodic coating, architectural class II (10 to 18 μm, or 0.4 to 0.7 mil thick), clear (natural)

Architectural Aluminum with Anodized Integral Color. An anodized panel with an integral color for architectural application would be designated as AA-M10C22A42:

AA	Aluminum Association
M10	Unspecified as-fabricated finish
C22	Chemically etched medium matte finish
A42	Anodic coating, architectural class I (18 μm, or 0.7 mil or thicker), integral color

Chromium-Plated Aluminum Panel. The finish for a chromium-plated aluminum panel that is first given a highly specular mechanical finish, then a nonetch chemical cleaning, followed by a thin anodic coating produced in phosphoric acid, and finally direct chromium plating, would be designated as AA-M21C12A1XE1X:

AA	Aluminum Association
M21	Mechanical finish, polished, smooth specular (see smooth specular finish, (above)
C12	Inhibited alkaline cleaned
A1X	Specify exact anodizing process
E1X	Specify exact chromium plating method

Introduction

COPPER and copper alloys constitute one of the major groups of commercial metals. They are widely used because of their excellent electrical and thermal conductivities, outstanding resistance to corrosion, ease of fabrication, and good strength and fatigue resistance. They are generally nonmagnetic. They can be readily soldered and brazed, and many coppers and copper alloys can be welded by various gas, arc, and resistance methods. For decorative parts, standard alloys having specific colors are readily available. Copper alloys can be polished and buffed to almost any desired texture and luster. They can be plated, coated with organic substances, or chemically colored to further extend the variety of available finishes.

Pure copper is used extensively for cables and wires, electrical contacts, and a wide variety of other parts that are required to pass electrical current. Coppers and certain brasses, bronzes, and cupronickels are used extensively for automobile radiators, heat exchangers, home heating systems, panels for absorbing solar energy, and various other applications requiring rapid conduction of heat across or along a metal section. Because of their outstanding ability to resist corrosion, coppers, brasses, some bronzes, and cupronickels are used for pipes, valves, and fittings in systems carrying potable water, process water, or other aqueous fluids.

The elements most commonly alloyed with copper are aluminum, nickel, silicon, tin, and zinc. Other elements and metals are alloyed in small quantities to improve certain material characteristics, such as corrosion resistance or machinability. Copper and its alloys are divided into nine major groups. These major groups are:

- *Coppers,* which contain a minimum of 99.3% Cu
- *High-copper alloys,* which contain up to 5% alloying elements
- *Copper-zinc alloys (brasses),* which contain up to 40% Zn
- *Copper-tin alloys (phosphor bronzes),* which contain up to 10% Sn and 0.2% P
- *Copper-aluminum alloys (aluminum bronzes),* which contain up to 10% Al
- *Copper-silicon alloys (silicon bronzes),* which contain up to 3% Si
- *Copper-nickel alloys,* which contain up to 30% Ni
- *Copper-zinc-nickel alloys (nickel silvers),* which contain up to 27% Zn and 18% Ni
- *Special alloys,* which contain alloying elements to enhance a specific property or characteristic, for example, machinability

Many copper alloys have common names, such as oxygen-free copper (99.95% Cu min), beryllium copper (0.2 to 2.0% Be), Muntz metal (Cu-40Zn), Naval brass (Cu-39.25Zn-0.75Sn), and commercial bronze (Cu-10Zn).

A more standardized system of identification is the unified Numbering System (UNS). In this system, wrought alloys of copper are designated by numbers 1*xxxx* to 7*xxxx*, and cast alloys are designated 8*xxxx* to 9*xxxx*; thus, the same alloy can be produced as a wrought and cast product.

Additional information about the classification, metallurgy, properties, and applications of copper and copper alloys is available in *Properties and Selection: Nonferrous Alloys and Special-Purpose Materials,* Vol 2 of *ASM Handbook.*

The selection of surface treatments for copper and copper alloys is generally based on application requirements for appearance and corrosion resistance. These treatments range from simple low-cost chemical processes that provide a uniform surface appearance, to expensive electroplates that provide maximum corrosion resistance. This article describes the cleaning, finishing, and coating processes used with copper and copper alloys.

Acknowledgements

This article was adapted from Robert M. Paine and Bob Srinivasan, Cleaning and Finishing of Copper and Copper Alloys, *Surface Cleaning, Finishing, and Coating,* Volume 5, 9th Edition, *Metals Handbook,* American Society for Metals, 1982, p 611-627. It was revised for this edition by Andrew J. Brock, Olin Corporation.

Cleaning and Finishing

Prior to subsequent processing or the application of a protective or decorative coating, the copper or copper alloy surface must be prepared by suitable cleaning procedures. The severity of these cleaning procedures will depend on the past processing history of the metal. Copper and copper alloys obtained from major materials suppliers should be received reasonably clean (free from heat treat scale or tarnish) and should only require minimal cleaning prior to further processing.

Heat treating of copper and copper alloys in air results in the formation of copper oxides; further cleaning will be necessary to remove these oxides, as discussed below. The need for such cleaning can be prevented by heat treating in reducing atmospheres, such as nitrogen with 1 to 4% H, in which the formation of copper oxides will be completely suppressed. Such atmospheres will not, however, prevent the oxidation of reactive alloying constituents such as aluminum, silicon, or zinc.

Pickling and Bright Dipping

Pickling in solutions containing 4 to 15 vol% sulfuric acid or 40 to 90 vol% hydrochloric acid is used for the removal of oxides formed on the surface of copper-base materials during mill processing and fabricating operations. The sulfuric acid solution is used to remove black copper oxide scale on brass extrusions, forgings, and machined parts; oxide on copper tubing, forgings, and machined parts; and light annealing scale or tarnish. The hydrochloric acid solution is primarily used for finishing, but is also used to remove scale and tarnish from brass forgings and machined parts, and oxide on copper forgings and machined parts. Conditions for pickling copper-base metals with sulfuric acid and hydrochloric acid are shown in Table 1. Sometimes no additional surface preparation is necessary to produce the uniformity of appearance required for further finishing of copper; however, heavily scaled material may need a bright dip or color dip after pickling.

Table 1 Pickling conditions for copper-base materials

Constituent or condition	Amount or value
Sulfuric acid bath	
Sulfuric acid[(a)]	15-20 vol%
35% hydrogen peroxide	3-5 vol%
Water	bal
Temperature of solution	Room temperature to 60 °C (140 °F)
Immersion time	15 s to 5 min
Hydrochloric acid bath	
Hydrochloric acid[(b)]	40-90 vol%
Water	bal
Temperature of solution	Room temperature

Immersion time	1-3 min

(a) 1.83 sp gr. The bath needs additives to stabilize peroxide and accelerators to maintain etch rate. Proprietary products are available from metal finishing suppliers.

(b) 1.16 sp gr

Except for bright annealed material, copper alloys must be pickled after each annealing treatment, completely descaled, and bright dipped to produce a natural surface color and luster suitable for other finishing treatments such as electroplating or painting. Scale dip and bright dip solutions are given in Table 2. Bright dips for copper-base materials consist of sulfuric and nitric acids in varying proportions with a small amount of water and hydrochloric acid. Proprietary pickle and bright dips, using sulfuric acid and stabilized hydrogen peroxide, are also available. Whereas the conventional bright dips use highly concentrated acids, this sulfuric acid-hydrogen peroxide bath is dilute and reduces worker safety hazards.

Table 2 Scale dip and bright dip conditions for copper-base metals

These solutions remove scale that is not removed by sulfuric or hydrochloric acid solutions; lower concentrations of nitric acid and higher concentrations of sulfuric acid produce a bright lustrous finish; these solutions can remove 0.0255 mm (0.001 in.) of metal and should not be used when close dimensional tolerances must be maintained. Solutions are used at room temperature.

Solution	**Sulfuric acid, vol%[(a)]**	**Nitric acid, vol%[(b)]**	**Hydrochloric acid[(c)]**		**Water, vol%**	**Immersion time,s**
			g/L	**oz/gal**		
Scale dip						
Solution A	0	50	4	$\frac{1}{2}$	50	15-60
Solution B	25-35	35-50	4	$\frac{1}{2}$	35-40	15-60

(a) 1.83 sp gr.

(b) 1.41 sp gr.

(c) 1.16 sp gr. Excess hydrochloric acid spots brass. Wood soot and activated charcoal are added to the solution to prevent this condition.

After bright dipping and thorough rinsing in cold running water, stain or tarnish may be removed by dipping in a cyanide solution. Some proprietary bright dips, incorporated with corrosion inhibitors, eliminate the use of toxic cyanides and chromates and are easy to waste treat.

When a semibright finish is satisfactory, a dichromate color dip is less expensive and more convenient to use than the conventional acid dip. Color dip should not be used if parts are to be plated or soldered. The following conditions for color dipping include a solution that removes red copper oxide and imparts a film that resists discoloration during storage and work:

Sodium dichromate	30 to 90 g/L (4 to 12 oz/gal)
Sulfuric acid, 1.83 sp gr	5 to 10 vol%
Water	bal
Immersion time	30 s
Temperature of solution	Room temperature

Extruded yellow brass rod may be pickled, usually in dilute sulfuric acid, to remove light oxide prior to drawing, forging, or machining. Yellow brass forgings are similarly treated for the removal of oxide scale and forging lubricant. Hydrochloric acid solutions may be used instead of sulfuric acid in some applications. Bright dipping follows pickling to complete the removal of all oxide. The yellow brass is then given a color dip to produce a uniform cartridge-brass color. Although brass sand castings are seldom pickled, a solution similar to that used for forgings may be used when pickling is indicated.

A typical acid treatment cycle for copper-base materials is given in the following list. The cycle may be terminated after any water rinse if the desired finish and color have been obtained:

- Pickling
- Cold water rinse
- Scale dip or bright dip
- Cold water rinse (repeat once)
- Color dip
- Cold water rinse (repeat once)
- Hot water rinse
- Air-blast dry

Aluminum bronzes form a tough, adherent aluminum oxide film during hot fabrication. This film can be removed or loosened by the following strong alkaline solution:

Sodium hydroxide	10 wt%
Water	bal

Temperature of solution	75 °C (170 °F)
Immersion time	2 to 6 min

After this treatment the material can be treated in acid solutions by some of the same cycles used for other copper-base materials.

Alloys containing silicon may form oxides of silicon that are removable only by hydrofluoric acid. Proprietary fluorine-bearing compounds are also available for this purpose. If a dull brown-to-gray appearance is not objectionable, the material may be pickled in the conventional sulfuric acid solution to remove the copper oxides. If a brighter finish is required, one of the solutions in Table 3 may be used.

Table 3 Pickling conditions for copper alloys containing silicon

Solutions are used at room temperature.

Constituent or condition	Solution A	Solution B
Sulfuric acid[(a)]	5-15 vol%	40-50 vol%
Hydrofluoric acid[(b)]	$\frac{1}{2}$-15 vol%	$\frac{1}{2}$-5 vol%
Nitric acid[(c)]	. . .	15-20 vol%
Water	bal	bal
Immersion time	$\frac{1}{2}$-10 min	5-45 s

(a) 1.83 sp gr.

(b) 52%.

(c) 1.41 sp gr

Alloys containing beryllium that have been heat treated at relatively low temperatures (below 400 °C, or 750 °F) can be pickled or bright dipped as any other copper alloy; however, alloys containing beryllium that have been heat treated at temperatures above 400 °C (750 °F) in operations such as solution annealing and those that have been bright annealed will generally possess a surface oxide that contains beryllium oxide as a major constituent. This oxide can be difficult to remove if present in a thickness greater than 0.04 to 0.05 μm (1.6 to 2.0 μin.). A 1 or 2 min soak in a solution of 50% sodium hydroxide at 130 °C (265 °F) before acid pickling facilitates removal of any beryllium oxide.

Nickel silvers and copper-nickel alloys do not respond readily to the pickling solution usually used for brasses, because nickel oxide has a limited solubility in sulfuric acid. Heavy scaling of these alloys should be avoided during annealing by using a reducing atmosphere. For example, the annealing of 18% nickel silver in a rich reducing atmosphere

results in a slight tarnish that is easily removed in the sulfuric acid pickle and dichromate solutions ordinarily used for descaling brass. Controlling the atmosphere during annealing produces a bright metal finish.

Tubing made of 30% copper-nickel may be annealed in a reducing atmosphere, but not in a brightening atmosphere, to produce a clean surface that does not require acid treatment; 18% nickel silver wire is pretreated in a proprietary hot alkaline cleaning solution and then annealed in a controlled atmosphere furnace to produce a clean and bright surface. The wire is subsequently pickled in sulfuric acid and treated in a dichromate solution to remove zinc sweat. The wire is then finish pickled in 10 to 15% sulfuric acid solution at 60 °C (140 °F).

Tarnish Removal. Tarnish, the surface discoloration formed on copper-base materials during exposure to the atmosphere or to alkaline cleaning, usually consists of a thin film of oxide or sulfide. One of the most commonly used dips for removing tarnish is an aqueous solution of 8 to 60 g/L (1 to 8 oz/gal) of sodium cyanide. The metal to be cleaned is immersed for 1 to 2 min in the cyanide solution at room temperature. Steel tanks are used to contain the solution. Thorough rinsing is required after the dip treatment.

Extreme safety precautions must be followed when cyanide solutions are being used, because cyanide is highly poisonous. To prevent the formation of ammonia, metal previously cleaned in an alkaline solution must be thoroughly rinsed before it is brought into contact with the cyanide solution. Cyanide must not come in contact with acid because lethal hydrocyanic acid is produced. Despite the strict safety precautions that are necessary, cyanide solutions are commonly used.

A solution containing 5 to 10 vol% hydrochloric or sulfuric acid may also be used to remove tarnish from copper-base materials. Immersion time is a few seconds in either of these solutions at room temperature. Thorough rinsing in water is required after the treatment. The hydrochloric acid solution may be contained in a vitrified crock, or in a rubber-lined or glass-lined tank. A vitrified crock or lead-lined tank may be used as a container for the sulfuric acid solution. Plastics such as polypropylene or polyvinyl chloride are also suitable containers for hydrochloric and sulfuric acid solutions. These materials are resistant to 50% sulfuric acid and 37% hydrochloric acid up to 65 to 70 °C (150 to 160 °F).

Another noncyanide solution sometimes used for removing tarnish consists of 10% citric acid at 70 to 80 °C (160 to 175 °F). This solution removes most tarnish stains and poses no health or ecological hazards.

Tarnish Prevention. Tarnishing of copper alloys after pickling or degreasing operations is accelerated when the metal is inadequately dried following rinsing and can be particularly rapid if the final rinse solution is contaminated with the cleaning solutions. Significant resistance to tarnishing after cleaning can be rendered by incorporating benzotriazole (BTA) or tolyltriazole (TTA) into the final rinse. Typical concentrations are 0.1 to 0.5% with the rinse water being used at 40 to 60 °C (104 to 140 °F).

Pickling Equipment. Equipment requirements for the automatic pickling of brass forgings of various sizes are given in Table 4. The automatic pickling machine is similar to automatic plating equipment. Solution conditions for automatic pickling of brass forgings are as follows:

- Hydrochloric acid solution at room temperature
- Nitric-sulfuric acid solution, 38 °C (100 °F) maximum
- Sodium dichromate solution, room temperature
- Cold water rinse, 2300 L/h (600 gal/h)
- Hot water rinse, 66 to 82 °C (150 to 180 °F), 4 L/h (1 gal/h)

Table 4 Production capacity of equipment for automatic pickling of brass forgings

Immersion time, 40 s; total cycle time, 6 min

Item or condition	Size of forgings		
	Small	Medium	Large

Number of pieces per hour	2500	500	250
Pieces per basket	250	50	25
Pounds pickled per hour	2500	2500	2500
Configuration of forgings	Irregular	Irregular[(a)]	Irregular[(a)]

(a) May contain cavities; require hand loading into baskets

Compositions of pickling tanks are determined by the type of solution used, such as:

Solution	**Tank material**
Hydrochloric acid	Plastic-lined steel
Nitric-sulfuric acid	Type 316 stainless steel
Color dip (dichromate solution)	Plastic-lined steel
Cold water rinse (four tanks)	Steel
Hot water rinse	Steel or rubber-lined steel

Work baskets require type 316 stainless steel or plastic composition with dimensions of 330 by 635 by 155 mm (13 by 25 by 6 in.) and 610 by 205 by 180 mm (24 by 8 by 7 in.). Equipment requirements for pickling brass tubes or rods and the equipment for pickling brass tubing are listed in Table 5.

Table 5 Equipment requirements for pickling brass tubes or rods

Oxide scale is removed from 25 mm (1 in.) diam brass tubing and rods that are 1.9 to 21 m (6 to 70 ft) in length; immersion time varies from 5 to 30 min; the source of heat is steam, 105,000 kJ (100,000 Btu)

Tanks[(a)]	**Material**	**Solution**	**Temperature**		**Overflow**[(b)]
			°C	**°F**	
Acid tank	Stainless steel	10% sulfuric acid	38-60	100-140	. . .
Cold water rinse tank	Wood	. . .	. . .	. . .	380 L/h (100 gal/h)

Hot water rinse tank	Wood	. . .	54-71	130-160	38 L/h (10 gal/h)

(a) All tanks measure 1.1 by 0.9 by 21 m (3.5 by 3 by 70 ft) and hold 6738 L (1780 gal) for a 0.6 m (2 ft) depth of solution.

(b) Connected to bottom of tank

Tanks for sulfuric acid may be lined with natural rubber. Tanks intended to contain nitric and hydrofluoric acids may be lined with polyvinyl chloride or polypropylene. Additional information on materials and construction of acid tanks is given in the article "Acid Cleaning" in this Volume.

Defects from Pickling. By far the most common defect encountered in pickling brass is the presence of red stain on the metal. Caused by cuprous oxide, this defect may be removed by pickling in a solution of 10% sulfuric acid containing 98 g/L (13 oz/gal) of ferric sulfate at temperatures up to 60 °C (140 °F), or in a solution of 12% sulfuric acid containing 45 g/L (6 oz/gal) of sodium dichromate at room temperature. Alternatively, sulfuric acid-hydrogen peroxide solution can be used. Red stains may result from the presence of metallic iron in the pickling solution, causing copper to plate out on the parts when the parts come in contact with iron or steel. This is because iron is anodic to copper. Care must be taken to prevent any stray pieces of iron, such as nails or tools, from entering the pickling solution. Red stains can also result from the reaction of sulfuric acid on cuprous oxide (Cu_2O), forming cupric oxide (CuO) and copper. This can be removed in any of the above oxidizing acids.

Oil and lubricants remaining on formed metal must be removed before pickling and dipping. If formed material is to be bright dipped, it should first be degreased, or the lubricant remaining will prevent the bright dip from being effective. If the work is to be annealed and pickled, it should be degreased, usually in a hot water rinse, because the oil may cause excess cuprous oxide and unwanted red staining to form during annealing. In extreme instances, the more volatile constituents of the oil burn off readily, leaving a carbonaceous deposit that must be removed mechanically.

Acid stains will appear on the metal if it is not thoroughly rinsed and cleansed of all remaining acid after pickling or dipping. At least two separate washings in water or one thorough running water wash should be used before drying. Dipping in a soap solution or a buffered salt solution will neutralize traces of acid.

The metal is etched or pitted if it is immersed for too long in a pickling solution or dip, or if the solution is too strong or too hot. The proper time, temperature, and concentration of solution may be determined quickly during trial runs.

Safety Practices. Acids, even in dilute solution, can cause serious injuries to the eyes and other portions of the body. Operators should wear face shields, rubber boots, and rubber aprons for protection. Eye fountains and showers adjacent to acid tanks, for use in the event of an accident, should be provided. Adequate ventilation and suitable hoods for the tanks are recommended.

Extreme caution should be exercised when adding acid to a water solution, especially if sulfuric acid is used. Sulfuric acid should be added slowly and only while stirring the solution.

Abrasive Blast Cleaning

Abrasive cleaning is used to remove molding, core sand, and investment material from the exterior and interior surfaces of copper-base castings. Selection of the proper kind and particle size of grit determines the type and color of the finish. The coarser grits clean faster but give a rougher finish.

Dry abrasive cleaning of beryllium copper is usually confined to castings. Steel shot is used for general cleaning to remove sand and slight surface imperfections from the casting after mold shakeout. Sands are used to blend in surface areas, to remove heat treat scale and to produce a uniform surface texture. Graded bronze chips, together with the regular commercial abrasives, are used in some applications to impart a better color and finish. Abrasive blast cleaning is seldom used to produce decorative finishes on copper alloys.

Wet blasting offers a means of cleaning previously blasted and machined surfaces without damaging the finished or threaded areas. Wet blasting produces various degrees of satin finish. The process is ideal for removing oxide film acquired during brazing, soldering, welding, or heat treating and for removing smudges, stains, and finger marks. For example, bronze castings that have been machined and brazed often are wet blasted with quartz (140-grit) for $\frac{1}{2}$ to 5 min to remove braze discoloration and shop dirt. The parts are normally degreased before wet blasting. After the castings are wet blasted, they are cleaned ultrasonically, inspected, and assembled.

Surfaces cleaned by wet blasting are uniform in appearance, although their color is not the same as original grit-blasted surfaces because of the abrasive used. Cleaning action is gentle but effective because water is the carrier.

Mass Finishing

Mass finishing is best suited for stamped, formed, or machined parts. Castings with remnants of gates and parting lines; forgings with heavy scale, flash lines, or die marks; and heavily burred, pitted, or dented parts are not well suited for mass finishing. Light burrs can sometimes be removed by a prior bright dip, after which tumbling may be used for radius blending, polishing, and burnishing. High thin burrs of soft alloys are likely to peen over. Mass finishing of soft alloys at excessive speeds with insufficient amounts of solution can result in roughened and indented surfaces. Dry tumbling is generally restricted to small parts of simple shape and maximum dimension less than 50 mm (2 in.).

Abrasives. Aluminum oxide, silicon carbide, limestone, and flintstone are the abrasive materials most often used in mass finishing of copper and copper alloys. Combinations of these abrasives may be used for specific applications. For example, a blend of aluminum oxide and silicon carbide of mesh size 46 to 150 produces a reasonably fine matter surface on parts with heavy burrs. Aluminum oxide has a cutting action, and silicon carbide has a planing action.

Preshaped abrasives of various sizes and shapes also may be used. Although more expensive than material in its natural form, preshaped abrasives permit a more constant and uniform polishing action, are more effective in holes and recesses, and retain their effective cutting shape for a longer period of use.

Compounds. Parts heavily coated with grease or oil or contaminated with dirt or chips should be degreased before mass finishing, preferably in a separate barrel, dip tank, or degreaser. A better practice is to clean parts in the barrel when progressing from rough to finishing cycles and to bright dip before burnishing. A sulfuric-nitric acid or sulfuric acid-hydrogen peroxide bright dip should be used if plating follows burnishing.

Soft water and neutral compounds are preferred for mass finishing copper and copper alloys. The use of liquid soap-free alkaline compounds for mass finishing highly leaded, free-cutting brasses prevents the formation of lead soaps that impair the effectiveness of the operation.

Compounds for mass finishing are classified according to the following categories and are purchased as proprietary materials:

- *Cleaning compounds* possess high detergency and buffering action for removing oils, greases, and residues.
- *Descaling compounds* are used to remove tarnish from copper alloys; neutralizing cycles usually follow the use of these compounds.
- *Grinding compounds* are used with abrasive mediums for softening the water, saponifying oils, and keeping chips clean; these compounds inhibit tarnish and improve the color of parts.
- *Abrasive compounds* contain grits such as aluminum oxide, silicon carbide, emery, quartz sand, or pumice.

Surface Finishes. Although mass finishing produces the final finish for many parts, it is used more extensively for cleaning prior to plating and painting or for deburring and polishing before a final finish is applied. Examples of mass finishing applications are given in Table 6.

Table 6 Operating conditions for mass finishing

Material	Medium	Size of abrasive particles		Tumbling time, h	Finish
		mm	in.		
Heavy cutting					
Brass or bronze castings	Aluminum oxide	6.4-19	0.25-0.75	6-16	Matte
Moderate cutting					
Brass stampings	Aluminum oxide	6.4-19	0.25-0.75	1-6	Light matte
Brass screw-machine parts	Aluminum oxide or granite	6.4-19	0.25-0.75	$\frac{1}{2}$-6	Light matte or bright
Light cutting[(a)]					
Brass stampings or screws[(b)]	Limestone	3.2-13	0.13-0.50	2-6	Bright

(a) Submerged tumbling is used for fragile and precision parts.

(b) Screw-machine parts

Bright rolling or water rolling in a barrel is an economical bulk method of finishing small parts. The finishes may be dull, semibright, or of high luster. This operation consists of tumbling the parts in water containing a suitable additive. The water acts as the carrier for the fine burnishing materials. Selection of additive and cycle time controls the surface roughness, stock removal, color, and reflective luster. Examples of water rolling applications are given in Table 7.

Table 7 Operating conditions for bright rolling or water rolling

Solutions are used at room temperature. Time, 20-60 min. Resulting surface has bright finish.

Parts	Weight of load		Additive[(a)]	Water		Speed, rev/min
	kg	lb		L	gal	
Blanks or buttons, copper[(b)]	363-408	800-900	Cream of tartar	95	25	32
Gripper post, nickel over brass	136	300	Proprietary[(c)]	95	25	32
Fragile tubular part, brass[(d)]	18	40	Proprietary	20	5	7

(a) 9 g/L (1 oz/gal).

(b) Removal of burrs.

(c) Additive containing sodium bicarbonate, cream of tartar, sodium acid pyrophosphate, sodium sulfite, and a wetting agent.

(d) Wall thickness is 0.150 mm (0.006 in.).

A prime consideration for successful water rolling is the cleanness of the parts. Oil, grease, scale, and dirt should be removed before rolling for luster. Basic cleaning and pickling operating conditions used before water rolling are given in Table 8.

Table 8 Operating conditions for cleaning and pickling in water rolling barrels

Barrel is made of Type 304 stainless steel. Speed of rotation, 7-32 rev/min; cycle time, 15-20 min. Parts are thoroughly rinsed in hot water after cycle is finished

Solution	Concentration	Temperature	
		°C	°F
Alkaline cleaner[a]	15-20 g/L (2-3 oz/gal)	71	160
Pickling solution[b]	1-2%	54	130

(a) Sodium hydroxide or proprietary compound.

(b) H_2SO_4

For economy, cleaning and pickling should be done in the same barrel by the same operator. For example, oily gripper parts from eyelet machines are placed in an oblique stainless steel barrel and cleaned by a suitable alkaline cleaner. After rinsing, the parts are pickled in a 1 to 2% sulfuric acid solution and rinsed. Clear water and additives, burnishing compounds, are added, and the parts are rolled until the desired finish is obtained. If the work appears to darken during water rolling, the medium should be dumped, the barrel and parts rinsed and then charged with a fresh burnishing compound. Parts suitable for water rolling to a bright finish include posts, sockets, studs, tack buttons, and zipper parts.

Vibratory finishing is particularly effective for deburring, forming radii, descaling, and removing flash from castings and molded parts. It may also be used for burnishing. Vibratory finishers deburr parts 50 to 75% faster and are more versatile than rotary tumbling barrels. There is no cascading of parts, with the attendant possibility of damage by impact. The process is adaptable to both light castings and formed parts. Vibratory finishing is also effective on internal surfaces and recesses that are not usually worked by rotary tumbling.

The mediums for vibratory finishing of copper and copper alloys are similar to those used for rotary tumbling. Dry mediums are used occasionally, but usually a liquid is added to provide lubrication, suspension of worn-off particles, and a more gentle cleaning action. The selection of medium is frequently by trial and error. Conditions for vibratory finishing are given in Table 9.

Table 9 Operating conditions for vibratory finishing

Machined part diam		Material	Medium	Parts per load	Ratio of medium to parts[(a)]	Vibrations per min	Time, min	Purpose
mm	in.							
25	1	Nickel silver	Steel pins and quartz sand	650	4 to 1	1500	40	Deburr
38	$1\frac{1}{2}$	Brass	Steel wire brads	500	2 to 1	1300	60	Deburr and form radii
75	3	Brass	Arkansas stone	150	10 to 1	1500	35	Deburr and finish

(a) 0.03 m^3 (1 ft^3) bowl

Additional information is contained in the article "Mass Finishing" in this Volume.

Polishing and Buffing

Copper alloy parts are polished after scale removal and dressing or rough cutting, but before final finishing operations, which include buffing, burnishing, or honing. Rough castings normally require two polishing operations before buffing. Forgings and stampings require one polishing operation before buffing. Pipe, tubing, and some stampings can be buffed without previous polishing. Buffing is not required when a brushed or satin finish is desired as the final finish.

Because copper-base materials are softer than steel, fewer stages of successively finer polishing are required to achieve a uniformly fine surface finish. For many parts, especially those having machined surfaces or those free of defects, a single-stage polishing operation using 180- to 200-grit abrasive on a lubricated belt or setup wheel may be all that is required before buffing. Poor-quality surfaces require preliminary rough polishing on a dry belt or wheel with 80- to 120-grit abrasive. Surfaces of intermediate quality may be given a first-stage polishing with 120- to 160-grit abrasive, either dry or lubricated. Belt polishing is generally advantageous for high-production finishing except when special shapes are processed. These are best handled by the contoured faces of setup polishing wheels.

Buffing of copper and copper alloys is usually accomplished with standard sectional cloth wheels operating at moderate speeds of 1200 to 1800 rev/min. Typical wheel speeds for various finishes are:

Finish	Wheel speed	
	m/min	ft/min
Dull[(a)]	915-1675	3000-5500
Satin	1220-1830	4000-6000

Cutting and coloring	1675-2135	5500-7000
High luster[(b)]	2135-2440	7000-8000

(a) Using 120- to 200-grit aluminum oxide.

(b) Using tripoli, lime, and silica with no-free-grease binder

When it is necessary to mush a buff to the contour of a complicated part, buffing speeds may range between 200 and 1000 rev/min.

Neutral compounds that are free of sulfur must be used to avoid staining in the plating operation when polishing and buffing precede electroplating. Excessively high temperatures during polishing and buffing may cause difficulties in subsequent cleaning and plating operations. When flawless chromium-plated surfaces are required, it is necessary both to buff and color buff the polished copper alloy surfaces before plating. Chromium reproduces all imperfections in the underlying plating or base metal, and because chromium is hard and has a high melting point, it is more resistant to flow and is not readily buffed by normal methods. A good chromium-plated surface can be obtained without the color buff operation, by only polishing and cut-down buffing. An example of offhand belt polishing and wheel buffing operations is given in Table 10.

Table 10 Offhand belt polishing and wheel buffing operations for sand cast red brass parts

Sand cast lavatory fittings made of red brass are finished in a sequence of six operations in preparation for decorative chromium plating; sequential finishing of spout with flat surfaces

Operation	**Type of contact wheel**	**Wheel speed, rev/min**	**Pieces per hour**	**Type of abrasive belt**	**Belt life, pieces**	**Polishing lubricant or buffing compound**
Rough polishing	Cloth[(a)]	2100	23	80-grit silicon carbide	29	None or light application of grease stick
Final polishing	Cloth[(a)]	2100	30	220-grit Al_2O_3	49	Grease stick
Spot polishing	Cloth[(a)]	2100	46	220-grit Al_2O_3	77	Grease stick
General buffing	Spiral-sewn, treated cloth sections with intermediate airway[(b)]	2400	32	. . .	. . .	Tripoli
Spot buffing	Spiral-sewn, treated cloth sections with intermediate airway[(b)]	2400	115	. . .	. . .	Tripoli
Color buffing	Spiral-sewn, treated cloth sections with intermediate airway[(b)]	1700	75	. . .	. . .	Silica compound

(a) 355 mm (14 in.) diam, 45 mm (1 $\frac{3}{4}$ in.) width, 90 density.

(b) 355 mm (14 in.) diam, 60.3 mm (2 $\frac{3}{8}$ in.) width, 18 ply, 86/93

Scratch brushing is used to produce a contrasting surface adjacent to a bright reflective surface; to produce an uneven surface for better paint adherence; to remove metal during final finishing of parts with intricate recesses that are inaccessible to polishing and buffing wheels; and to remove impacted soil and buffing compounds from previous finishing operations, prior to subsequent finishing in some applications.

Various types of scratching mediums are used to produce different finishes, such as butler, satin, directional, sunburst (or circular), and matte. These mediums are as follows:

- *Wire wheels* are used on copper or brass grill work to clean intricate recesses, holes, or ribbed areas and to produce a decorative noncontinuous scratch pattern on ornamental parts such as vases, lamps, and kitchenware.
- *Emery cloth or paper* is a common medium for producing a series of linear or circular parallel lines on flat objects with no sudden changes in contour. This type of decorative finish is applied to fireplace accessories, automotive hub caps, and kitchenware and appliances.
- *Polishing wheels headed with greaseless compounds* produce scratch-brush finishes with parallelism of the directional pattern. Decorative items such as jewelry, building paneling, and built-in refrigerator and stove parts can be finished in this manner.
- *Soft tampico and manila brushes* remove soil from scrollwork and embossed areas on ornate tableware serving sets and jewelry prior to final processing.

Table 11 gives the sequence of operations and mediums for scratch-brush finishing several copper alloy products.

Table 11 Suggested sequence of operations for scratch brushing of copper alloy parts

Part	Finish desired	Abrasive	Type of wheel	Size of wheel		Speed, rev/min
				mm	in.	
Black fuse body, yellow brass[(a)]	Dull, smooth, black	None	Tampico	80 diam by 75 thick, 5 rows wide	7 diam by 3 thick, 5 rows wide	1200
Silver-plated red brass lipstick case[(b)]	Semibright	Solution of soap bark and cream of tartar	Nickel-silver wire, 0.100 mm (0.004 in.) diam	150 diam by 75 thick, 6 rows wide	6 diam by 3 thick, 6 rows wide	850
Black-on-bronze bookends, highlights relieved[(b)]	Black background with colored copper highlights	Pumice in water	Cloth, sewn sections	180 diam by 13 wide	7 diam by $\frac{1}{2}$ wide	850
Silver-plated lipstick	Satin	Greaseless rouge,	Loose cloth wheel	150 diam by	6 diam by 2	1800

cap[c]		proprietary		51 wide	wide	
Nickel-plated refrigerator panels or stove parts[d]	Satin	Greaseless compound	Loose cloth wheel	305 diam by 50-510 wide	12 diam by 2-20 wide	1800

(a) Clean brush often by running pumice stone across face of wheel.

(b) Lacquer after scratch brushing.

(c) Lacquer after finishing.

(d) Chromium plate after finishing

Although scratch-brush finishing is useful for producing eye-appealing finishes and as a mechanical means for preparing surfaces for subsequent processing, certain hazards must be recognized. Extreme care and control are required when the part being worked contains patterns with sharp corners or embossments, because the sharpness of detail may be destroyed. In salvage or rework operations, it is difficult and sometimes impossible to blend the original brush pattern into a repaired area from which a defect has been removed by grinding.

Chemical and Electrochemical Cleaning

During fabrication, copper alloys may become coated with lubricating oils, drawing compounds, greases, oxides, dirt, metallic particles, or abrasives. These must be removed by cleaning. The selection of the cleaning process depends on the type of lubricant and other materials to be removed, the equipment available, the environmental restrictions, and the degree of cleanness required. The nature and size of the pieces also influence the selection of equipment or process.

Where permissible, mechanical scrubbing, accomplished by turbulent boiling, pressure spraying, or agitating, aids in the removal of any substances that are not exceptionally adherent. Occasionally, hand brushing may be used for small production quantities.

Lubricants made from animal or vegetable oils or greases, such as tallow, lard oil, palm oil, and olive oil, can usually be removed by saponification. In this process, the parts are immersed in an alkaline solution where the oil reacts with the alkali to form water-soluble soap compounds. Mineral oils that are not saponifiable, such as kerosine, machine oil, cylinder oil, and general lubricating oils, are usually removed from the metal by emulsion cleaning.

Dirt particles, abrasives, metal dust, and inert materials are removed by one or both of these processes. To remove undesirable materials by saponification, emulsification, or similar means, it is necessary to use particular chemicals or combinations of chemicals.

Solvent Cleaning and Vapor Degreasing. Solvent cleaning of copper alloys involves immersion in special naphthas with flash points over 38 °C (100 °F) for the removal of light grease and light oil. An example of this type of naphtha is Stoddard solvent. These solvents are preferred to kerosine and to the naphthas used in paints, because less residue remains on the work after the special naphthas have evaporated.

The straight-chain naphthas are not effective for complete removal of heavy grease, burned-on hydrocarbons, pigmented drawing compounds, and oils containing solid contaminants. Buffing compounds containing tallow, stearic acid, and metallic soaps require cyclic hydrocarbons such as toluol and xylol for effective cleaning. Table 12 gives cycles for solvent cleaning of copper alloys.

Table 12 Cycles for cleaning copper alloy parts with a solvent cleaner

Part	Solvent cleaner	Temperature of solvent		Immersion time, min	Soil removed
		°C	°F		
Dose cap[(a)]	Stoddard solvent or mineral spirits	RT to 49	RT to 120	2	Heavy drawing compound
Brass retainer ring[(a)]	Stoddard solvent or mineral spirits	RT to 49	RT to 120	2	Eyelet machine lubricant
Brass rods	Sawdust, dampened with Stoddard solvent or mineral spirits	RT	RT	5[(b)]	Mill lubricant

RT, room temperature.

(a) Hand cleaning necessary with fragile parts.

(b) Tumbled in barrel

Chlorinated solvents such as methylene chloride (boiling point, 40 °C, or 104 °F), trichloroethylene (boiling point, 90 °C, or 189 °F), and perchloroethylene (boiling point, 120 °C, or 250 °F) have been used instead of naphtha. These compounds are less of a fire hazard than straight petroleum solvents but are much more toxic. Because of environmental constraints their use is gradually being curtailed.

Vapor degreasing effectively removes many soils from copper alloys. Stabilized trichloroethylene is used extensively in vapor degreasing because it does not attack copper alloys during degreasing and because it has high solvency for the oils, greases, waxes, tars, lubricants, and coolants in general use in the copper and brass industry. Perchloroethylene is used especially for removing high-melting pitches and waxes, for drying parts by vaporizing entrapped moisture, and for degreasing thin-gage materials.

Vapor degreasing or solvent cleaning is not effective for removing inert materials and inorganic soils such as metal salts, oxides, or compounds that are not generally soluble in chlorinated solvents. Similarly, vapor degreasing for removal of hard and dry buffing compounds could leave behind the insoluble and hard-to-clean abrasives. Solvent emulsion cleaners, although slow, are highly effective for complete removal of buffing compounds.

Solid particles of metal dust or chips that are held on the surface by organic soil can be removed mechanically by the washing action of the solvent. Removal of these particles is accelerated and accomplished better with solvent sprays or by immersion in boiling solvent than with the vapor phase of the degreaser.

Emulsion and Alkaline Cleaning. Parts with heavy soils such as machine oils, grease, and buffing compounds are treated first with emulsion cleaners to remove most of the soil. After the parts have been rinsed, the remaining soil is removed by alkaline soak or electrolytic cleaning. Precleaning reduces the contamination of the alkaline solution, extending the life of the solution. Thorough alkaline cleaning must follow the emulsion cleaning cycle before the subsequent acid cycles. Extreme caution must be exercised to avoid dragging emulsifiers through the rinses and into a plating solution, especially an acid solution.

Emulsion cleaning may be accomplished by soaking the work for 3 min or less in a mildly agitated solution. Spraying is helpful only when all surfaces being cleaned can be thoroughly contacted. The thin film of oil remaining after emulsion cleaning acts as a temporary tarnish preventive. Some parts may be stored after drying, depending on the composition of the solution and the metal being cleaned; however, brass may become pitted by prolonged exposure to certain emulsifier

films. When emulsion-cleaned zinc-bearing brass parts are cleaned electrolytically by alkalines, sufficient time should be allowed for the dispersal of the emulsifier in the alkaline solution to avoid pitting.

The environmental restrictions placed on the use of chlorinated solvents have resulted in the industry turning more and more to alkaline cleaners for degreasing copper and its alloys. Table 13 lists typical compounds from which these are formulated. A great number of these cleaners, which usually contain proprietary additives, are available on the market. Selection of a cleaner is best achieved by a test program in which several cleaners are evaluated. However, the most critical factor in their effective use is to ensure vigorous flow of the cleaner across the parts being cleaned. Additional information is available in the article "Vapor Degreasing Alternatives" in this Volume.

Table 13 Compounds used for formulating alkaline cleaners

Component	Soak cleaners, %	Electrolytic cleaners, %
Sodium hydroxide	10-20	10-15
Sodium polyphosphates	5-20	5-20
Sodium orthosilicate, sesquisilicate, metasilicate	30-50	30-50
Sodium carbonate, bicarbonate	0-25	0-25
Resin-type soaps	5-10	None
Organic emulsifiers, wetting agents, chelating agents	2-10	1-3

Solutions for soak cleaning usually contain 30 to 60 g/L (4 to 8 oz/gal) of cleaner and are operated at 60 to 88 °C (140 to 190 °F). For every 6 °C (10 °F) rise in temperature above 60 °C (140 °F), the cleaning time is reduced by about 25%. Regardless of the concentration of the cleaning solution, there is a practical limit to the amount of contamination a given volume can accommodate without redepositing soil on the metal. In this condition, the solution should be discarded even though analysis reveals unused cleaner.

Dissolved air in fresh cleaning solutions is frequently the cause of tarnishing of copper alloys. The air can be eliminated by heating the solution to the boiling point for about $\frac{1}{2}$h before use. This procedure may not be advisable with every proprietary cleaner because of constituents that break down at the boiling temperature. Some uninhibited alkaline cleaners may also cause a slight darkening or tarnishing of the work surface. The darkening may be removed by dipping in dilute hydrochloric acid or in cyanide solution.

Electrolytic alkaline cleaning is the most reliable method for cleaning parts for plating. The work is the cathode, and steel electrodes are the anodes. Reverse-current anodic cleaning cannot be used for more than a few seconds because copper dissolves in the solution. Copper alloys will tarnish readily during exposure to the oxygen that is released at the anode, but this can be minimized by the addition of inhibitors. In many electroplating operations, anodic cleaning for a few seconds is used to develop tarnish, because it indicates that all soil has been removed. The small amount of metal dissolved by anodic cleaning exposes a more active surface for electroplating, and the light tarnish formed is readily dissolved by a mild hydrochloric or sulfuric acid solution. Current density during anodic electrocleaning of brass should be about 3 A/dm^2 (30 A/ft^2) at 3 to 4 V. Use of high currents will etch the brass and cause dezincification.

Copper-base materials are electrolytically cleaned by cathodic cleaning followed by short-time anodic cleaning, or by soak cleaning followed by anodic cleaning. Positively charged particles plated onto the work during cathodic cleaning

cause smut, which may lead to blistering and poor adhesion of the plated metal if not completely removed. To avoid this condition, a short period of anodic cleaning should follow the cathodic electrocleaning.

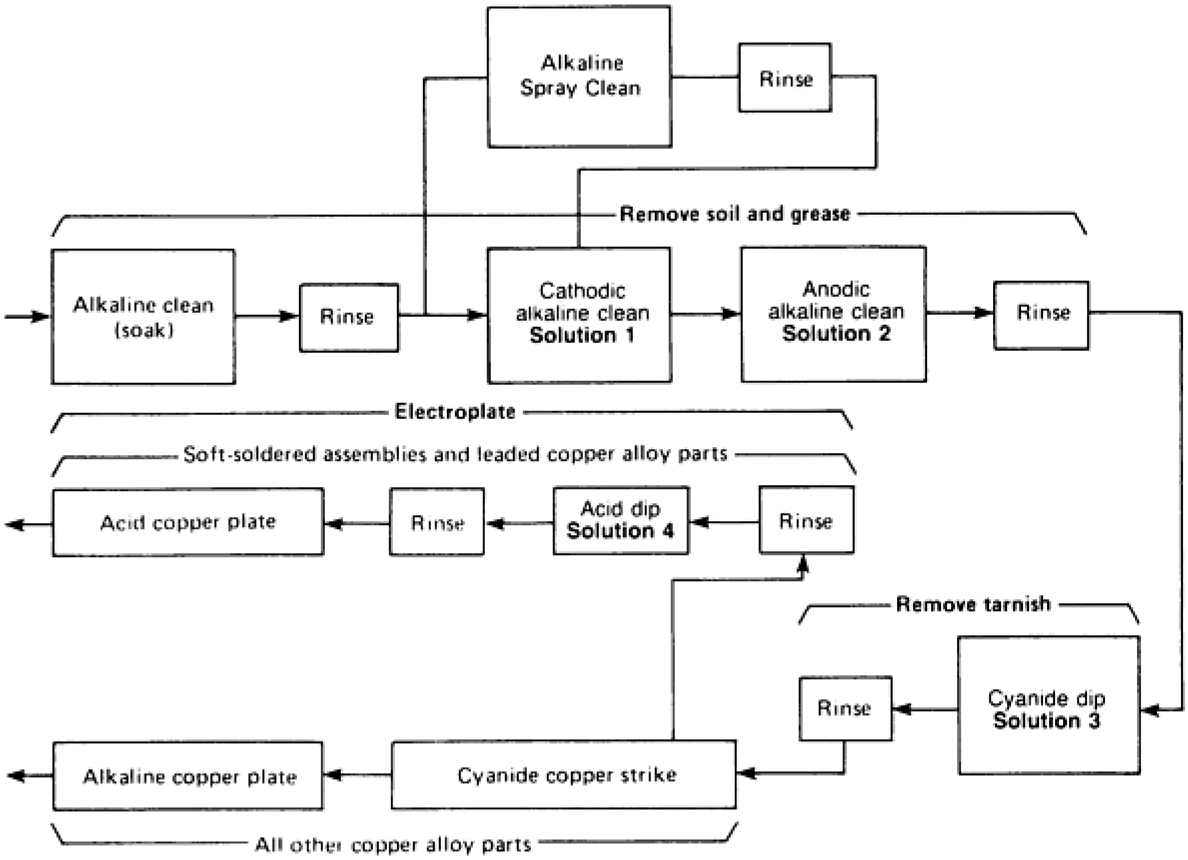
Racks and baskets that are used during the application of chromate chemical conversion coatings should not be used in alkaline cleaning solutions. Contamination of the cleaning solution with as little as 10 ppm of hexavalent chromium can cause poor adhesion and blistering of subsequent metal deposits. To avoid the effects of accidental contamination when chromate treatments are used, sodium hydrosulfite should be added to the cleaning solution at the rate of 14 g ($\frac{1}{2}$ oz) per 380 L (100 gal). The sodium hydrosulfite reduces hexavalent chromium to trivalent chromium, which does not affect subsequent plating. Periodic additions are required because trivalent chromium is reoxidized to hexavalent by the oxygen released at the anode.

Ultrasonic cleaning of copper-base materials is used when the size of particles remaining on the surface is less than 5 to 10 μm (0.2 to 0.4 mils) in any one direction and for removing dirt and chips that cause smudge, as indicated by a white cloth wipe test. Remove much of the surface contamination by other more economical cleaning procedures before ultrasonic cleaning. This increases the life of the ultrasonic cleaning solution and maintains production efficiency. After ultrasonic cleaning, the parts may be rinsed in deionized or distilled water and dried with warm filtered air or in a vacuum oven.

Ultrasonic cleaning is used with alkaline cleaning solutions, solvents, vapor degreasing solutions, or acid pickling solutions to increase the rate of cleaning or to complete the removal of soil from areas not completely cleaned by soak or spray procedures. An example of the need for ultrasonic assistance is the cleaning of fine internal threads on brass parts. An alkaline solution containing 15 to 30 g/L (2 to 4 oz/gal) of cleaner may be used for ultrasonic cleaning of such parts.

Plating and Coating

Preparation for Plating. Before copper alloys are plated, surface oxides are removed and the surfaces chemically activated for adherence of the plate. Heavy oxide scales are usually removed at the mill, so descaling is not normally a part of the preplate treatment. Figures 1 and 2 show sequences of operations required for preparing the surfaces of copper alloys. These operations apply to both lead-free and leaded materials and to soft-soldered assemblies. For many plating operations, where the copper alloy is relatively clean, free of oils, and uncontaminated by buffing compounds, the process can be simplified by eliminating the alkaline soak. If the surface contains buffing compounds, it may require precleaning by soaking in emulsion cleaners. Many plating processes do not use the anodic alkaline clean, especially when an acid dip is used after the cathodic alkaline clean. The acid dip suffices to remove any smut or stain. An acid dip may be simply 15% sulfuric acid or, if the surface needs additional pickling, a bright dip may be used. There are a number of bright dips for copper alloys on the market based on the sulfuric acid-hydrogen peroxide system (see Table 1), in addition to the example in Fig. 2. A chromate bright dip should not be used before plating because of possible chromium contamination of the plating bath, which could lead to blistering, pitting, and peeling of the electrodeposit.



Solution No.	Type of solution	Composition of solution[(a)]	Operating temperature		Cycle time,s
			°C	°F	
1	Cathodic alkaline cleaner[(b)]	$Na_2CO_3H_2O$, 40-50%; $Na_3PO_4 \cdot 12H_2O$, 25-40%; NaOH, 10-25%; Na_2SiO_3, 15-40%	60-71	140-160	60-180

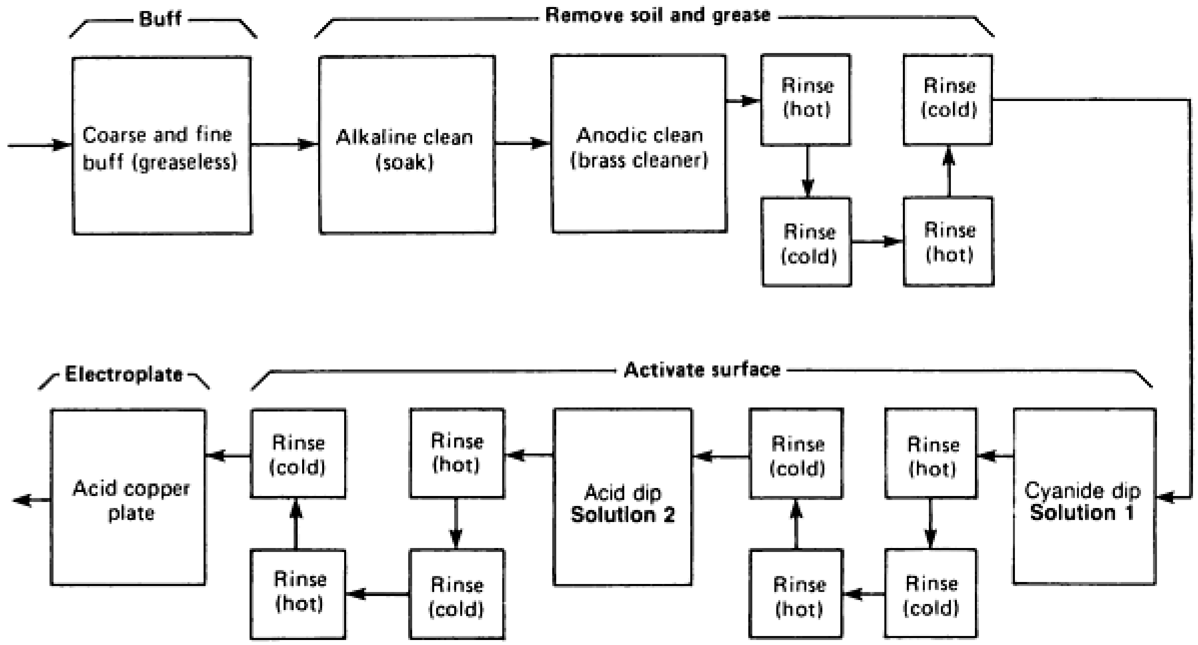
(c) Constant agitation of work

Fig. 2 Surface preparation required for the removal of buffing compounds and for bright dipping before plating of copper alloys

Oxides can be removed from cast or heat-treated copper alloys by either abrasive or chemical cleaning procedures. Castings always require abrasive cleaning; however, they do not necessarily require subsequent pickling or bright dipping for the removal of oxides. If acid treatment is required, thorough rinsing is mandatory to prevent spotting of the plating by entrapped acid. Stampings and drawn parts can be treated in the same manner as castings; however, it may be less expensive to pickle the parts before abrasive finishing if heavy oxides are present. Screw-machine parts made of leaded copper alloys usually require no treatment for oxide removal before plating, but abrasive cleaning can be used when required.

Beryllium Copper. Surface preparation procedures for beryllium copper are the same as for other copper alloys, unless the beryllium copper has been heat treated and still contains surface oxides resulting from that heat treatment. Such oxides on beryllium copper are more difficult to remove than normal oxides on other copper alloys. They can be best removed in strong, hot caustic solutions followed by a good bright dip. The procedure outlined in Fig. 2 should be sufficient if the bright dip cycle is increased to 10 to 15 s. The sulfuric-peroxide bright dips also work well on beryllium copper. The alkaline soak clean and the anodic alkaline clean may or may not be required, depending on the degree of surface contamination resulting from heat treatment. In rare cases, the plater is required to remove scale resulting from high-temperature (>400 °C, or 750 °F) heat treatments such as in solution annealing. The parts must be soaked in a 50% solution of sodium hydroxide at 130 °C (265 °F) for 1 or 2 min before acid pickling in a good bright dip.

Powder Metallurgy Parts. Technology has advanced to a level where parts sintered from metal powders are not as porous and can be easily electroplated. A sequence of operations for surface preparation of powder metallurgy (P/M) parts before electroplating is shown in Fig. 3. Because P/M parts are made from different alloys and because porosity varies, a suitable surface preparation and electroplating technique must be developed for each part.



Solution No.	Type of solution	Composition of solution	Operating temperature	Cycle time, s
1	Cyanide dip	NaCN, 7.5 g/L (1 oz/gal)	Room temperature	30-60
2	Acid dip	H_2SO_4, 3-5 vol%	Room temperature	5-10

Fig. 3 Surface preparation of brass powder metallurgy parts before plating

The methods applicable to porous cast parts can be used for low-porosity P/M parts with densities more than 95% of theoretical. P/M strip stock bonded to steel is an example of low-porosity material. The surface preparation and plating techniques vary for higher-porosity parts with densities 85 to 90% of theoretical.

During plating of P/M parts, the pores act as thermal pumps. Solutions are released from or absorbed by the pores, depending on whether the solution is hotter or colder than the part. Deep and interconnecting pores are likely to entrap cleaning or rinsing solutions, which are released slowly during plating. Porosity must be determined before cleaning, and suitable techniques must be used to prevent solution entrapment. Entrapped solutions may cause precipitation of metal compounds on the work surfaces during plating. The porous nature of P/M parts causes contamination and depletion of all solutions and necessitates that the solutions be closely controlled.

Spotty plating is caused by entrapped solutions that seep out of the pores and stain the plated surface as it dries. Spots may not develop for several days after plating or may appear to be insignificant immediately after plating and subsequently enlarge with time.

A continuous plated coating can seldom be attained on P/M parts unless the pores are closed. Methods for closing the pores include buffing, rolling, burnishing, heat treating, and impregnation. Buffing, rolling, or burnishing are used when appearance is important and dimensional tolerances are not critical. These techniques can be applied either before or after plating. Heat treating is one of the most satisfactory methods for closing pores when surface quality and size are more important than appearance. Occasionally, green compacts are electroplated and then sintered. Another technique is to sinter fully, then to plate and heat treat. This procedure requires washing and acid dipping the parts to neutralize alkalinity prior to heat treating.

Impregnation with copper, lead, tin, waxes, resins, or oils is another method for closing the pores of P/M parts before plating. Thermosetting polyester styrene and silicone resins are suitable impregnating materials. When the polyester-styrene resin is used, the parts are degreased, baked to remove moisture, then impregnated under vacuum and pressure. An emulsion cleaner can be used to remove excess resin from blind holes and threads prior to curing the resin at 120 to 150 °C (250 to 300 °F). Tumbling or polishing can be used to remove excess cured resin.

When silicone resin is used, the surfaces of the powder compact are coated with a thin water-repellent film. Then the compact is heated in air to 205 °C (400 °F), quenched in a solution of 4% silicone (type 200) and 96% perchloroethylene, and baked again for $\frac{1}{2}$ to 2 h. After being pickled in acid, the part can be plated in the conventional manner, preferably in an alkaline bath.

Before being impregnated with oil, the parts are heated in a vapor degreaser and, while hot, immersed in cold oil. After cooling in the oil, the parts are removed, drained of oil, and then rinsed in cold solvent. Parts impregnated with oil have been coated with copper by conventional electroplating processes with resultant satisfactory bonding of the coating.

Evaluation of Cleanness Prior to Plating. The degree of cleaning required for a copper alloy part depends on its intended end use. In some cases visual observation of the cleaned part is sufficient to determine if adequate cleaning has been accomplished. However, cleaning conducted prior to deposition processes must be very thorough, and methods of evaluating the surface cleanness are often required. For metal that has been degreased, this evaluation can be best achieved by spraying the part with water from an atomizer; areas that are clean show up as a continuous film, while areas that have been inadequately cleaned are covered with small water droplets.

Another technique for evaluating the cleanness of small parts involves suspending them in the mouth of a beaker containing a few mils of 10% ammonium sulfide. After an exposure time of 5 to 10 s, a uniform tarnish film will appear over clean areas. Nonuniformity in the color of the tarnish film indicates the presence of residual soils. With practice, the tarnishing test can provide a rapid assessment of the efficiency of a particular cleaning process. For safety reasons the test must be conducted in a fume hood.

It is often difficult to determine if residual oxides remain on a copper alloy surface following pickling operations, particularly if the oxides are of the refractory type. One evaluation method consists of first immersing the part in rosin

flux and then in 60-40 tin-lead solder held at 246 °C (475 °F) for 5 s. The resultant solder coating is compared to the solder coating on a part that is known to be clean. Areas still covered with oxide will appear as areas not wet by the solder.

Electroless Plating

Electroless plating involves the reduction of a metal salt to its metallic state by electrons supplied from the simultaneous oxidation of a reducing agent. The electroless plating solutions are compounded so that the concentration of the reducing salts, metal salts, buffering salts, and the pH controls the rate of reduction of the metal salt and of the oxidation of the reducing agent. If these reactions are not controlled, the metal deposit is reduced spontaneously to a fine powder. The metal to be plated acts as a catalyst and localizes the deposit of the plate to the part itself. Electroless plating completely plates uniform deposits to any thickness desired over intricately shaped parts or assemblies and into deep recesses and long tubular holes. Fine and close-fitting threads can be plated uniformly over the entire threaded area.

On copper-base materials, the process is limited to the plating of nickel, tin, gold, and silver deposits. Solutions for plating these deposits are affected adversely by contaminants, such as cyanides, lead, zinc, manganese, and cadmium. Tin may render the nickel plating solution inoperative; therefore, tin-containing copper alloys must be plated with copper or gold before a final nickel coating is applied.

Because copper is more noble than nickel, it will not act as a catalyst to start the deposition of nickel. This condition is alleviated by contacting the copper workpiece with an active metal such as iron or aluminum that causes the deposition of a thin nickel coating on the workpiece. The nickel coating is of sufficient thickness to continue the oxidation-reduction reaction for further nickel deposition after the activating metal is removed. Another procedure for starting the deposition of nickel is to make the part cathodic and apply a current briefly to the part as it is held in the electroless bath. Electroless nickel plating is particularly useful for coating deep recesses and holes that cannot be adequately electroplated. The article "Electroless Nickel Plating" in this Volume contains further information on the operating conditions of electroless nickel baths.

Electroless plating processes are used to plate copper with gold and silver for decorative purposes. Nickel, gold, and silver are frequently applied to copper electronic components to prevent tarnishing during subsequent processing and to aid in the soldering of semiconductors. Electroless tin plating has been used for copper tubes to prevent corrosion by carbonated waters.

Immersion Plating

Immersion plating, sometimes called galvanic plating, depends on the position that the base metal occupies in the electromotive series with respect to the metal to be deposited from solution. Plating occurs when the metal from a dissolved metal salt is displaced by a more active, less noble metal that is immersed in the solution. As the depositing metal is displaced from the bath, metal from the workpiece dissolves in the solution and becomes a contaminant in the bath. Depleted baths are never replenished, but are replaced with fresh solution.

When immersion plating copper-base materials, only those metals more noble than copper can be displaced from solution, thereby limiting this process to metals such as gold and silver. Immersion-plated deposits are thin, usually in the range of 0.050 to 0.50 μm (0.002 to 0.02 mil).

Compositions and operating temperatures of solutions for immersion plating of gold and silver are:

Gold plating	
Potassium gold cyanide	4 g/L ($\frac{1}{2}$ oz/gal)

Potassium or sodium cyanide	25 g/L ($3\frac{1}{2}$ oz/gal)
Sodium carbonate	30 g/L (4 oz/gal)
Temperature of solution	60 to 80 °C (140 to 180 °F)
Silver plating	
Silver cyanide	7.5 g/L (1 oz/gal)
Sodium or potassium	15 g/L (2 oz/gal)
Temperature of solution	18 to 38 °C (65 to 100 °F)

Electroplating

Metals such as gold, silver, rhodium, nickel, chromium, tin, and cadmium are electrodeposited on copper and copper alloys. Copper electroplating with these metals is used primarily for decorative purposes and for preventing tarnish or corrosion.

Chromium is occasionally plated directly onto copper and copper alloys as a low-cost decorative coating and color match. A plated nickel undercoat is applied when quality plating of chromium is required to produce color depth and resistance to corrosion, abrasion, and dezincification.

Decorative chromium deposits are characteristically thin and porous. Galvanic action between the chromium and base metal may occur during exposure to aggressive environments and result in accelerated corrosion. With copper alloys of high zinc content, dezincification and eventual lifting and flaking of the deposit may result. For added protection, chromium deposits plated directly on the base metal are coated with clear lacquers or with the more durable combination coatings of silicone and acrylic thermosetting organic resins.

Decorative chromium deposits are usually 0.25 to 0.50 μm (0.01 to 0.02 mil) thick. When chromium is deposited directly onto the base metal, the thickness of the deposit is seldom less than 38 μm (1.5 mils), and for many applications a minimum of 50 μm (2 mils) is specified. Additional information can be found in the article "Decorative Chromium Plating" in this Volume.

Hard chromium deposits are used primarily to improve wear resistance and friction characteristics. Because most of the copper-base materials are soft and ductile, the base metal lacks sufficient hardness to support thick deposits of hard chromium against heavy pressures without the risk of scoring or flaking. Hard chromium is electroplated from solutions under conditions similar to those used for decorative chromium plating; however, the deposits are much thicker, frequently dull in appearance, and generally deposited directly on the base metal. To conform to exact dimensional tolerances and to avoid buildup of deposit at corners, an excess of deposit is plated and the final dimension is attained by grinding or lapping. Further information can be found in the article "Industrial (Hard) Chromium Plating" in this Volume.

Cadmium. Copper-base materials are easily electroplated with cadmium from conventional plating baths. A typical bath has the following composition:

Cadmium oxide	22 to 33 g/L (3.0 to 4.5 oz/gal)
Sodium cyanide	85 to 110 g/L (11.5 to 15.0 oz/gal)
Sodium hydroxide	16 to 24 g/L (2.1 to 3.2 oz/gal)
Brightening agent	As required

Usually, applying an undercoat prior to the deposition of cadmium is unnecessary. Cadmium plating is used to minimize galvanic corrosion between copper-base materials and other cadmium-plated metals in the same assembly. Cadmium-plated copper parts are used in aircraft, marine, and military applications involving atmospheric exposure; however, the use of cadmium is being curtailed because of health and safety concerns associated with its use.

Gold is usually applied over an electroplated undercoating of nickel or silver, but may be electroplated directly on the copper alloy. In the electronics industry, nickel is plated to copper before gold plating. The nickel barrier stops migration of copper into the gold layer. The gold thickness is about 2.5 μm (0.1 mil). The nickel barrier is normally a minimum of 1.3 μm (0.05 mil) thick; however, exposure of the gold-plated part to elevated temperatures for extended periods of time may require a nickel barrier 127 μm (5 mils) thick. If silver is the barrier, government specifications for electronic applications usually require a minimum thickness of 5 μm (0.2 mil) of silver and 1.3 μm (0.05 mil) of gold.

When gold is plated directly on copper alloy, a deposit of 3 μm (0.1 mil) or more is needed because of rapid diffusion, especially at elevated temperatures. This rapid diffusion destroys the electrical and decorative properties of the deposit by interdiffusion between the coating and the base metal. Total coverage and freedom from porosity are necessary for corrosion protection.

For greatest adhesion, the part should be plated with a gold strike before the final deposit of gold. One satisfactory strike solution consists of potassium gold cyanide 0.8 g/L (0.1 troy oz/gal as gold) and potassium cyanide 45 g/L (6 oz/gal). To avoid tarnishing, the struck part should be transferred immediately to the plating solution with the current flowing as the work enters the solution. An alternate procedure is to rinse the struck work, then acid dip, rinse, and plate with a suitable current density.

Current density for racked parts varies from 0.2 to 1 A/dm^2 (2 to 10 A/ft^2), depending on the solution used. The rate of deposition depends on the solution and varies from 100 mg/A · min (0.3 A/dm^2, or 3 A/ft^2, for 14.4 min deposits 3 μm, or 0.1 mil, of gold) in most cyanide and neutral solutions to one-third of this rate in most acid solutions. For barrel plating, the limiting current density for all solutions is about one-;third of that used in rack plating.

Cyanide solutions are the most efficient and have the best throwing power, whereas deposits from acid and neutral solutions are less porous and are not stained by incompletely removed solution.

Patented solutions for plating gold contain 0.03 kg (1 troy oz) of gold per gallon, usually added as potassium gold cyanide, and proprietary brightening agents. Insoluble anodes are used with these solutions. The patent-free hot gold cyanide solution is extremely sensitive to impurities, and the deposits lack brightness. The solution is limited in application. Gold metal anodes are used with this solution.

The proprietary solutions are brightened or colored by codeposited base metals, especially silver, nickel, cobalt, and copper. These base metals may be classed as impurities for some applications. When gold deposits of less than 0.33 μm (0.013 mil) are used on a plated item, the deposit should be protected by lacquer or a chromate passivation.

Nickel is plated onto copper-base materials for decorative purposes and as an undercoating for increased corrosion resistance of nickel-chromium coating systems. Because nickel deposits have a yellow cast and tarnish easily, many nickel-plated parts are finished with electroplated chromium. Costume jewelry, lipstick cases, hardware for doors and windows, automotive hub caps, air valves, and plumbing fixtures are examples of copper-base parts regularly plated with nickel, either as a final coat or an undercoat.

Nickel electrodeposits from some solutions reproduce the irregularities in the base metal surface to a marked degree. The base metal must be polished and buffed before plating if a smooth uniform plated surface is required. Polishing and buffing are not required when nickel is to be plated on a reasonably smooth surface from solutions that produce a high degree of leveling of the deposit as it builds up in thickness. Deposits from these solutions are smooth and bright. Nickel plating with high leveling and brightness can provide an attractive mirrorlike finish. Proprietary leveler brighteners are added to the nickel bath to achieve high leveling with nickel deposits as thin as 7.6 to 10 μm (0.3 to 0.4 mil).

Numerous types of nickel electroplating solutions are available. The solutions differ in basic composition, preferred operating conditions, and quality of the deposit. These are described in the article "Nickel Plating" in this Volume.

Most decorative plating is done in solutions that yield bright or semibright deposits. Although dull nickel deposits may be buffed to a high luster, the cost of buffing limits dull nickel to nondecorative or functional uses.

Black nickel is a decorative finish only. It should be plated over a deposit or base metal that is corrosion resistant. Very thin deposits of black nickel are recommended because thick deposits lack the ductility and adhesiveness required to withstand shock.

Rhodium. An undercoat of nickel is used when copper alloys are to be plated with rhodium. For decorative purposes, the thickness of rhodium is usually about 0.25 μm (0.01 mil). Deposits of 25 μm (1 mil) or more are used for functional purposes, but these heavier deposits do not have the brightness or color characteristics of the decorative finishes. Rhodium plating solutions are of the sulfuric acid or phosphoric acid type. Formulas and operating conditions are given in the article "Platinum-Group Metals Plating" in this Volume.

Silver plating is used for decorative and functional purposes. Its useful characteristics for functional applications include:

- High surface conductivity for radio frequencies. A minimum of 3 μm (0.1 mil) of silver is required for these applications.
- Low resistance for electrical contacts. The thickness of silver used for electrical contacts ranges from very thin deposits, such as those produced by immersion coating to electroplates 13 μm (0.5 mil) thick.
- Antiseizing or antigalling properties for wear surfaces.

Silver can be deposited as a dull plate from cyanide solutions or as a bright plate from baths containing suitable brighteners. Details of electrolyte compositions and operating conditions are contained in the article "Silver Plating" in this Volume. Plating times for the deposition of 25 μm (1 mil) of silver, as a function of current density, are:

Current density		Plating time, min
A/dm^2	A/ft^2	
1	10	38
2	20	18
3	30	13
4	40	9

Pollution free, proprietary acid silver sulfate plating baths are now also available.

Tin. As a protective coating, tin is not necessarily anodic to copper alloys. A copper alloy may not always be fully protected against a corrosive environment at the expense of tin. Some corrosion products of tin are more noble than copper and can create the type of galvanic conditions that lead to pitting corrosion. Tin can be plated from alkaline stannate baths or from sulfate or fluoborate acid baths. For compositions and operating conditions of tin electrolytes, see the article "Tin Plating" in this Volume.

Tin-Copper Alloys. The 40 to 50% Sn alloy, speculum metal, has been used as a decorative coating because of its silverlike color. The bronze alloy coatings containing 10 to 20% Sn are producible to match the color of gold and have been used as decorative deposits for this reason. Information on plating bronze alloys is given in the article "Tin Alloy Plating" in this Volume.

Tin-lead alloys can be plated on copper alloys in almost any proportion from a fluoborate bath. An alloy of 7% Sn and 93% Pb has been used for corrosion resistance, especially to sulfuric and chromic acids. The 60% Sn, 40% Pb eutectic alloy has excellent solderability and good electrical properties and corrosion resistance. The eutectic alloy may be applied also by hot dipping, but control of thickness is as difficult as with hot dipping in pure tin.

Compositions of solutions for plating 7Sn-93Pb and 60Sn-40Pb (solder) are given in Table 14.

Table 14 Bath compositions and operating conditions for tin-lead plating

Conditions for operating include a cathode current density of 3 A/dm^2 (30 A/ft^2); anode to cathode ratio is 2 to 1; solution has maximum pH of 0.2 and is mildly agitated at a temperature of 16 to 38 °C (60 to 100 °F); air agitation cannot be used because it will oxidize the tin.

Constituent	Total tin		Stannous tin		Lead		Free fluoboric acid		Free boric acid		Peptone		Anode Composition
	g/L	oz/gal	g/L	oz/gal	g/L	oz/gal	g/L	oz/gal	g/L	oz/gal	g/L	oz/gal	
7Sn-93Pb	7.0	0.94	6.0	0.80	88.4	11.8	100.0	13.4	25	3.4	0.50	0.067	7Sn-93Pb

Chemical or electrolytic polishing imparts a smooth bright finish and removes burrs selectively from certain areas. Usually the same solution will accomplish both purposes, although variations in operating conditions may be desirable, depending on which feature is required.

For electropolishing, the parts are racked and made the anode in an acid solution. Direct current is applied and the process selectively removes more metal from the high points of the surface than from the low. This results in a high polish and the removal of burrs.

Chemical polishing imparts a finish similar to that obtained by electropolishing, but electropolished surfaces are usually smoother and brighter.

Electropolishing for 4 to 6 min will reduce the surface roughness to between one-third and one-half the original value. Electropolishing and chemical polishing will remove minor scratches and defects, as well as burrs.

Selection of these processes is influenced by the following considerations:

- For complex parts, electropolishing and chemical polishing are easier and less expensive than mechanical polishing.
- Copper-base materials that are polished either electrolytically or chemically do not require the use of buffing or polishing compounds. Thus, they do not encounter the difficulties associated with removal of

entrapped compounds and usually do not require any additional cleaning operations other than rinsing.
- Parts racked for electropolishing may be electroplated in the same racks, which results in considerable savings in handling costs.
- Electrolytically or chemically polished surfaces tarnish less readily than mechanically polished surfaces. Some chemical polishing baths can offer passivation and prevent copper from tarnishing during storage.
- Parts that might deform during mechanical polishing or tumbling will not be deformed by electrolytic or chemical polishing.
- Mechanical polishing may result in a deformed surface layer that differs from the base metal and does not accept plating uniformly. Electroplate on electropolished base metal has adhesion superior to that on mechanically finished surfaces

Parts that are electropolished include fishing lures, plumbing fixtures, furniture arms and legs, lamps and lighting fixtures, wire goods, brass appliance parts, jewelry, nameplates, and bezels. Copper-plated parts, such as automobile tail pipes, die castings that have not been buffed, and high-altitude oxygen bottles are electropolished effectively for an improved finish. The thickness of copper plate should be in excess of 20 μm (0.8 mil) before electropolishing. Most of the commercial solutions used for electropolishing copper alloys contain phosphoric acid with additional agents.

A sequence of operations for electropolishing consists of:

- Racking the parts
- Cleaning to remove oil, grease, dirt, and oxide
- Double rinsing in water at room temperature
- Electropolishing for 2 to 4 min at about 65 °C (150 °F), using a current density of 30 A/dm^2 (300 A/ft^2)
- Double rinsing in water at room temperature and drying

If the parts are to be electroplated after electropolishing, the drying operation in the above sequence is omitted and the process continues with anodic alkaline cleaning until the surface is light brown in color. Then the parts are rinsed in water at room temperature, dipped in 5% sulfuric acid solution, double rinsed in water at room temperature, immersed in the cyanide copper strike solution, and plated.

The quality of an electrolytically or chemically polished surface is affected by the following factors:

- *Composition of the material*. Most copper alloys are suitable except those containing appreciable amounts of lead, such as the free-machining alloys. Materials successfully treated include copper, beryllium copper, single-phase bronzes, and single-phase nonleaded brasses.
- *Condition of the initial surface*.
- *Grain size of the metal*. The smaller the grain size the better the finish. A grain size of 0.004 mm (0.0002 in.) yields excellent results; satisfactory results are produced with grain sizes up to about 0.01 mm (0.0004 in.).

Passivation

Passivation refers to the process of forming a protective film on metal. The blue-green patina of copper developed during atmospheric exposure of copper alloys is a protective coating that is aesthetically pleasing. The patina may be artificially produced or accelerated by a solution, developed by the Copper and Brass Research Association, having the formulation:

Ammonium sulfate	2.7 kg (6 lb)

Copper sulfate	85 g (3 oz)
Ammonia (technical grade, 0.90 sp gr)	39.6 cm^3 (1.34 fl oz)
Water	25 L (6.5 gal)
Total solution	27 L (7.3 gal)

A fine spray of the solution should be applied to a chemically clean surface. The film should be permitted to dry before the part is sprayed a second time. Five or six repetitions of the spraying and drying sequence are required. The color begins to develop in about 6 h and at first is somewhat bluer than natural patina. A more attractive color develops as the surface is exposed to natural weathering.

Small copper parts may be coated with an imitation patina by dipping them in or brushing them with the following solution:

Ingredient	**Parts by weight**
Copper	30
Nitric acid, concentrated	60
Acetic acid, 6%	600
Ammonium chloride	11
Ammonium hydroxide (technical grade, 0.90 sp gr)	20

When preparing the solution, copper is dissolved in the nitric acid, and as soon as the action ceases, the remaining three constituents are added. The solution is allowed to stand several days before use. Parts treated with this solution are coated with linseed oil.

Coloring

Copper-base materials may be surface treated to produce a variety of colors, ranging from dark reds to black. The final color depends on base metal composition, solution composition, immersion time, and operator skill. Coloring is primarily an art, and practical experience is necessary to develop the skill required to produce uniform finishes consistently. Copper alloys are colored chemically to enhance the appearance of a product, to provide an undercoating for subsequent organic finishes as with brass, and to reduce light reflection in optical systems. Chemical coloring produces a thin layer of a compound on the surface of the base metal. This layer retains some of the characteristics of the metal surface prior to coloring, such as smooth and lustrous or dull.

The procedures for artificial coloring of metals utilize many of the reactions that occur more slowly under natural conditions. Some colored films not found in nature can be produced artificially. Additional color combinations, such as

oxidized and highlighted finishes, can be produced by successive chemical and mechanical operations, to emphasize or to remove partially the chemically colored film.

Coloring copper alloys is essentially a process for coloring copper, because zinc and tin compounds are colorless. These constituents and their concentrations greatly affect many of the chemical reactions and color tones of the coatings formed. A copper content of less than 85% is required to produce a good blue-black finish on brass by an ammoniacal copper sulfate or ammoniacal copper carbonate blackening or blue dip solution. Other solutions are more suitable for coloring high-copper alloys.

After machining and mechanical surface preparation have been completed, the parts should be thoroughly cleaned to remove dirt, oil, grease, and oxide films. Cleaning is important for the development of a uniform film in chemical coloring. The cleaning and deoxidizing procedures should be selected so that the structure of the metal at the surface undergoes a minimum of undesirable change. Acid dipping or bright dipping using nitric-sulfuric acid solution may be necessary to remove oxides and to activate the surface for chemical coloring. A certain amount of trial and error is usually required to establish the most suitable techniques for surface preparation.

Coloring Solutions. Many types of chemical solutions are used for coloring copper alloys. The formulations and conditions commonly used in commercial applications to produce colors are given in Table 15.

Table 15 Solutions for coloring copper alloys

Desired color	Solution composition	Process conditions	Comments
Solutions for alloys containing $\geq$85% Cu			
Dark red	Molten potassium nitrate	Temperature, 650-700 °C (1200-1300 °F); immersion time, $\leq$20 s; hot water quench	Parts must be lacquered.
Black[a]	Solution A: liquid sulfur, 28 g (1 oz); sulfurated potash, 57 g (2 oz); ammonium hydroxide (sp gr 0.89), 7 g ($\frac{1}{4}$ oz); water, 4 L (1 gal)	Room temperature	Produces a dull black finish; a reddish bronze to dark brown finish can be obtained by dry scratch brushing with a fine wire or cloth wheel.
	Solution B: sulfurated potash, 1.9 g/L ($\frac{1}{4}$ oz/gal) of water	. . .	Solution strength should be adjusted to blacken the part in approximately 1 min; too rapid formation of coloring film can result in a nonadherent and brittle film.
	Solution C: potassium sulfide, 3.7-7.5 g/L ($\frac{1}{2}$-1 oz/gal) of water	Immersion time, $\leq$10 s	Parts must be lacquered.
Steel black	Arsenious oxide (white arsenic), 113 g (4 oz); hydrochloric acid (sp gr 1.16), 240 cm^3 (8 fl oz); water, 4 L (1 gal)	Temperature of solution, ~82 °C (180 °F)	Immerse parts in the solution until a uniform color is obtained; scratch brush while wet, then dry and lacquer.
Black	Sodium hydroxide, 45 g	Temperature, 82-99 °C (180-210 °F);	Adequate ventilation is required. After

anodizing	(16 oz); water, 4 L (1 gal)	current density, 0.2-1 A/dm^2 (2-10 A/ft^2); anode-to-cathode ratio, 1:1; voltage, 6 V; cathodes, steel, carbon, or graphite; anodizing time, 45 s to 3.75 min; tank material, steel	anodizing, the parts are washed in hot and cold water, rinsed in hot water, dried, buffed lightly with a soft cloth wheel, and lacquered, if desired.
Reddish bronze to dark brown (statuary bronze)	Sulfurated potash, 57 g (2 oz); sodium hydroxide, 85 g (3 oz); water, 4 L (1 gal)	Temperature, 77 °C (170 °F); immersion time depends on final color desired	Parts are usually scratch brushed with a fine wire wheel; lacquering is required.
Verde antique	Solution A: copper nitrate 113 g (4 oz); ammonium chloride, 113 g (40 oz); calcium chloride, 113 g (4 oz); water, 4 L (1 gal)	. . .	Verde antique finishes are also known as patina. They are stippled on brass or copper and dried. Parts made of copper or copper plated are usually treated in a sulfide solution to produce a black base color, which results in a dark background. The use of sodium salts in the verde antique solution results in a yellowish color, while ammonium salts impart a bluish cast. Stippling can be repeated, and when the antique green color appears, immersion in boiling water will produce several different color effects. Other color effects are obtained by using some dry colors such as light and dark chrome green, burnt and raw sienna, burnt and raw umber, ivory drop white, and drop black, or Indian red. After coloring, the surface should be lacquered or waxed. A semiglossy appearance of the lacquered surface can be produced by brushing with paraffin, beeswax, or carnuba wax on a goats-hair brush rotated at about 750 rev/min.
	Solution B: acetic acid, 2 L ($\frac{1}{2}$ gal); ammonium chloride, 570 g (20 oz); sodium chloride, 200 g (7 oz); cream of tartar, 200 g (7 oz); copper acetate, 200 g (7 oz); water, 2 L ($\frac{1}{2}$ gal)	. . .	
Light brown	Barium sulfide, 16 g ($\frac{1}{2}$ oz); ammonium carbonate, 7 g ($\frac{1}{4}$ oz); water, 4 L (1 gal)	Room temperature	. . .
Brown	Potassium chlorate, 155 g ($5\frac{1}{2}$ oz); nickel sulfate, 78 g ($2\frac{3}{4}$ oz); copper sulfate, 680 g (24 oz); water, 4 L (1 gal)	Temperature, 90-100 °C (195-212 °F)	. . .
Solutions for alloys containing <85% Cu			
Black	Solution A: copper sulfate, 85 g (3 oz); sodium thiosulfate, 170 g (6 oz); water, 11-19 L (3-5 gal)	Brass parts are placed in oblique tumbling barrel made of stainless steel. The parts are covered with water; the copper sulfate and sodium thiosulfate are dissolved in warm water and added to the contents of the barrel. The parts are tumbled for 15 to 30 min to obtain finish, the solution is drained from	Parts must be lacquered.

		barrel, and the parts are washed thoroughly in clean water. The parts are then removed from the barrel and dried in sawdust or air blasted.	
	Solution B: copper carbonate, 16 g ($\frac{1}{2}$ oz); ammonium hydroxide (sp gr 0.89), 113 g (4 oz); sodium carbonate, 7 g ($\frac{1}{4}$ oz); water, 4 L (1 gal)	Temperature, 88-93 °C (190-200 °F)	. . .
Statuary bronze	Copper carbonate, 16 g ($\frac{1}{2}$ oz); ammonium hydroxide (sp gr 0.89), 113 g (4 oz); sodium carbonate, 7 g ($\frac{1}{4}$ oz); water, 4 L (1 gal)	Temperature, 88-93 °C (190-200 °F). Immerse the parts in the hot solution for 10 s; rinse in cold water and dip in solution of dilute sulfuric acid; rinse in hot and then cold water; clean with soft cloth or sawdust.	Parts must be coated with clear lacquer.
Blue black	Copper carbonate, 0.45 kg (1 lb); ammonium hydroxide (sp gr 0.89), 1 L (1 qt); water, 3 L (3 qt)	Temperature, 54-79 °C (130-175 °F)	Excess copper carbonate should be present; proper color should be obtained in 1 min.
Brown	Part 1: copper sulfate, 113 g (4 oz); potassium chlorate, 227 g (8 oz); water, 4 L (1 gal). Part 2: liquid sulfur, 28 g (1 oz), or sulfurated potash, 57 g (2 oz); water, 4 L (1 gal)	Immerse parts in Part 1 for 1 min; without rinsing, immerse parts in Part 2 for a short time; rinse in cold water; repeat dipping operation in both solutions until desired color is obtained; rinse work in hot water; dry in hot sawdust or with an air blast; scratch brush with fine wire wheel and lacquer	. . .
Light brown (old English finish)	Part 1: liquid sulfur, 14 g ($\frac{1}{2}$ oz), or sulfurated potash, 28 g (1 oz); water, 4 L (1 gal). Part 2: copper sulfate, 57 g (2 oz); water, 4 L (1 gal)	Immerse parts in Part 1; without rinsing, immerse in Part 2; rinse in cold water; repeat dipping operations until light color is obtained. For uniform finish, scratch brush and repeat dipping operations until desired color is obtained; rinse parts in cold and hot water; dry in sawdust; scratch brush on a fine wire wheel; and lacquer.	. . .
Antique green on brass	Nickel ammonium sulfate, 227 g (8 oz); sodium thiosulfate, 227 g (8 oz); water, 4 L (1 gal)	Temperature, 71 °C (160 °F)	. . .
Hardware green on brass	Ferric nitrate, 28 g (1 oz); sodium thiosulfate, 170 g (6 oz); water, 4 L (1 gal)	Temperature, 71 °C (160 °F)	. . .

Brown on brass or copper	Potassium chlorate, 155 g ($5\frac{1}{2}$ oz); nickel sulfate, 78 g ($2\frac{3}{4}$ oz); copper sulfate, 680 g (24 oz); water, 4 L (1 gal)	Temperature, 91-100 °C (195-212 °F)	. . .
Light brown on brass or copper	Barium sulfide, 14 g ($\frac{1}{2}$ oz); ammonium carbonate, 7 g ($\frac{1}{4}$ oz); water, 4 L (1 gal)	. . .	Color is made more clear by wet scratch brushing and redipping.

(a) Alloys blackened by these solutions include silicon bronzes; beryllium coppers; bronzes containing up to 8% Sn; phosphor bronzes of all types; and brasses, leaded or unleaded, with zinc contents up to 35%. Several other proprietary processes are also available for producing a satisfactory black finish.

Post-Treatment. Many chemical films must be scratch brushed to remove excess or loose deposits. In addition, contrast in colors can be obtained by relieving by scratch brushing with a slurry of fine pumice, hand rubbing with an abrasive paste, mass finishing, or buffing to remove some or all of the colored film from the highlights. Clear lacquers are usually necessary for adequate life and service of chemical films used as outdoor decorative finishes. Finishes for exposure indoors are often used without additional protection to the conversion coating.

Organic Coatings

Information on the materials and methods commonly used for organic finishing of metal surfaces with clear or pigmented coatings is given in the article "Painting" in this Volume. Tarnishing or discoloration of copper alloys can be retarded or delayed indefinitely by the application of a lacquer. Lacquers should be selected and applied on the basis of the intended service environment of a given product. For exterior service, a dry film thickness of 38 to 50 μm (1.5 to 2 mils) is recommended. In less severe indoor service, a dry film thickness of about 13 to 18 μm (0.5 to 0.7 mil) performs satisfactorily.

Air-Drying and Thermosetting Lacquers. The performance of thermosetting or heat-cured lacquers is superior to that of air-drying lacquers. The use of the thermosetting types is preferred if ovens are available. Distinction should be made, however, between true thermosetting and forced drying. All lacquers can be force dried after a suitable air-flash period to facilitate handling, but thermosetting materials must be heated to an appropriate temperature, 120 to 205 °C (250 to 400 °F) or higher, for 5 to 60 min, to cross-link the polymers present in them and to develop their inherent characteristics.

The catalytic activity of copper is such that essentially complete curing of thermosetting lacquers is obtained at temperatures lower than those required with inert substrates. Consequently, many thermosetting lacquers discolor copper alloys severely when heated to temperatures recommended by their suppliers. Such discoloration can be minimized by curing at lower temperatures.

Resins are chosen on the basis of service requirements and include:

- Alkyds
- Acrylics
- Cellulosics, such as cellulose nitrates, ethyl cellulose, and cellulose acetate butyrates
- Epoxies
- Phenolics
- Polyesters

- Silicones
- Urea and melamine formaldehydes
- Vinyls
- Urethanes

An epoxy, cellulose nitrate, or alkyd resin provides satisfactory protection for an inexpensive container, such as a lipstick container. The use of a heat-resisting melamine provides satisfactory service at moderately elevated temperatures. Silicone formulated for high-temperature service provides the best heat resistance, but is a more costly material. If resistance to degradation by weather is important, high-quality acrylics provide the best results. General characteristics of these resins are given in the article "Painting" in this Volume.

Surface Engineering of Magnesium Alloys

Revised by James E. Hillis, Dow Chemical Company

Introduction

SURFACE TREATMENTS are applied to magnesium parts primarily to improve their appearance and corrosion resistance. Many factors may be involved in selecting a suitable surface treatment or finishing system, including surface conductivity, wear resistance, the service environment, alloy composition, and the presence (or absence) of dissimilar metals in the assembly.

Environmental exposures involving salt water or condensing moisture in the presence of chlorides, as well as other salts, have in the past proven very aggressive to magnesium alloys. The higher-purity alloys introduced in the mid-1980s, however, exhibit significantly reduced sensitivity to such environments. For example, die cast alloys AZ91D and AM60B, with controlled levels of iron, nickel, and copper contamination, have been used in increasing volumes in automotive applications as a result of their improved road salt corrosion durability, combined with their castability and light weight. In both painted and unpainted applications these alloys provide salt-water corrosion performance equal to or better than that of die cast aluminum and carbon steel. (See the article "Corrosion of Magnesium and Magnesium Alloys" in *Corrosion,* Volume 13 of *ASM Handbook,* and Ref 1, 2, 3, and 4.)

Figure 1 illustrates the contrast in performance of the old AZ91B die cast alloy versus the higher-purity AZ91D alloy, after 240 h of ASTM B 117 salt-spray testing. Figure 2 compares the performance of painted AZ91D and cold-rolled carbon steel after five years at a marine atmospheric exposure site on the Texas Gulf coast. The coating system in both cases consisted of an iron-phosphatizing pretreatment (without a chrome rinse) plus 12 to 20 μm (0.5 to 0.8 mil) each of cathodic epoxy and a spray acrylic top coat. Alloys AZ91E, WE54A, and WE43A are three sand cast alloys introduced since 1985 that offer similarly improved performance in gravity, or low-pressure cast applications (Ref 5, 6).

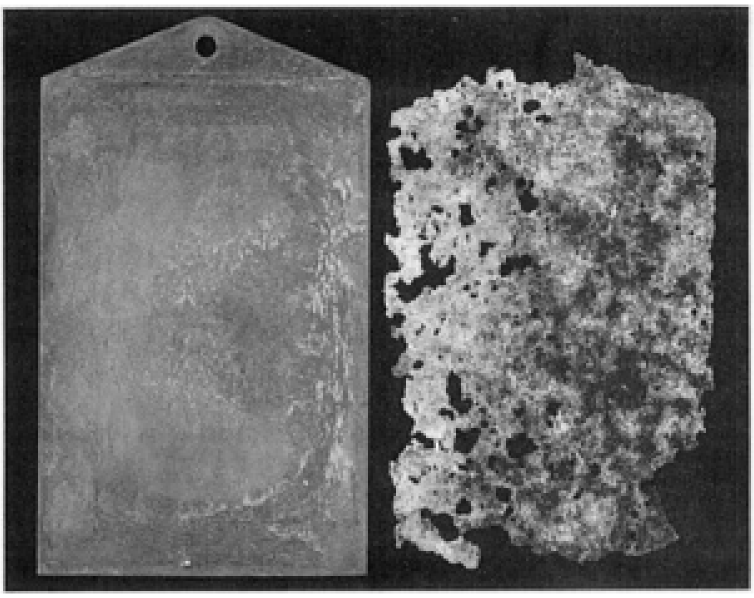


Fig. 1 Ten-day ASTM B 117 salt-spray corrosion performance of high-purity AZ91D (0.1 mm/yr, or 4 mils/yr, left) versus AZ91B (17 mm/yr, or 680 mils/yr, right). Source: Ref 3, 6

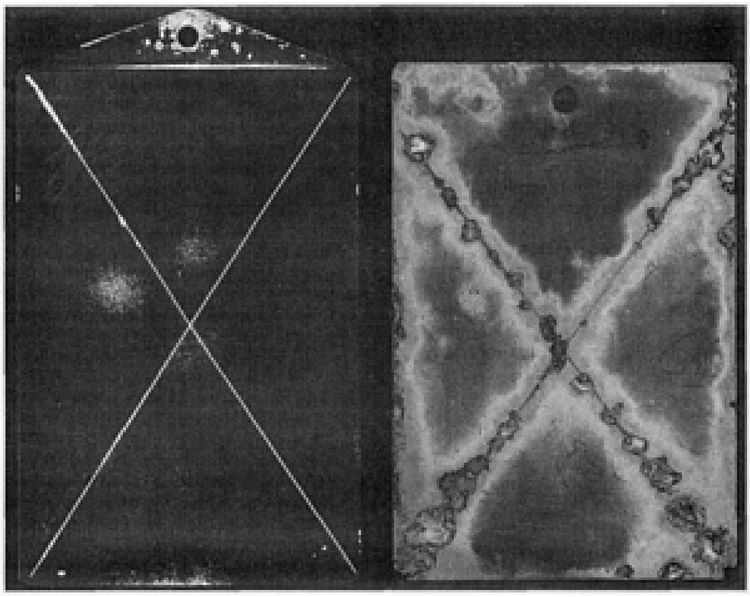

Fig. 2 Five-year Gulf Coast corrosion performance of coated AZ91D die cast magnesium (left) versus cold-rolled carbon steel (right). Both panels were cleaned, iron phosphatized, coated with 18 μm (0.7 mil) of baked cathodic epoxy primer and 12 to 20 μm (0.5 to 0.8 mil) of acrylic lacquer. The test was conducted at the ASTM Brazos River site near Freeport, TX using scribed panels per ASTM D 1654. Source: Ref 1

The following environments are listed in the order of increasing corrosiveness: oil immersion, indoor, rural, industrial, and marine. Magnesium alloys are afforded increasing protection in the following order: bare, pickled, chromate conversion coated, anodized, electroplated, and coated with organic finishes. Anodic coatings are porous and provide no corrosion protection unless sealed with a paint. Table 1 relates applications of various degrees of severity to finishing systems used. It should be noted that damaged paint films allow moisture to migrate through porous anodic coating, resulting in corrosion. Painting over the damage will seal in the moisture, creating further problems.

Table 1 Finishing systems applied to magnesium for various applications

Systems for specific parts	
Aircraft auxiliary component housings, sand cast	Sand blasted, sulfuric acid pickle, anodize or dichromate treatment (No. 7), epoxy sealed, baked epoxy primer, and top coat
Automotive engine brackets, die cast	Wet bowl abraded, no additional finishing
Automotive interior brackets, die cast	Chopped aluminum wire blast
Automotive valve/cam covers, die cast	Wet abraded, alkaline cleaned, iron phosphate treated, electrostatic powder coated (acrylic, polyester, or epoxy-polyester hybrid)
Chain saws, die cast	Wet barrel or bowl abraded, electrostatic powder coated (polyester or epoxy-polyester hybrid)
Computer disk drive component, extruded	Dichromate treatment No. 7 per Fig. 3; no additional finish
Dock boards, wrought	No finish applied
Electronic housing, die cast	Modified chrome pickle No. 20 per Fig. 4; sprayed acrylic, polyester, or urethane exterior coating
Foundry flasks	No finish applied
Line trimmer	Wet abraded, alkaline clean, phosphate treated, and powder coated
Lawnmower deck, die cast	Alkaline cleaned, phosphate pretreated, electrostatic powder coated (polyester)
Luggage frame, extruded	Acid pickled, phosphate treated, powder coated (polyester)
Missile exteriors, wrought	System A: dichromate, vinyl butyrate zinc chromate wash primer, baked phenolic epoxy varnish, 2 coats, enamel, 2 coats
	System B: chrome pickle or anodizing depending on alloy, phenolic epoxy paint, 2 coats
Satellites	System A: dichromate
	System B: anodize
	System C: zinc immersion coating, flash copper plate, 9.1 μm (0.36 mil), silver 0.0025 μm (0.0001 mil), gold, 0.0025 μm (0.0001 mil)
General systems--indoor exposures	

System A	Phosphate pretreat, epoxy, vinyl, epoxy hybrid urethane, polyester, or acrylic finish coat 8-20 μm (0.3-0.8 mil)
System B	Light to medium anodize or chromate pretreat, epoxy or epoxy hybrid, 8-20 μm (0.3-0.8 mil)
System C	Electroplate, 25 μm (1 mil)
Systems for marine or similarly corrosive exposures	
System A	High purity alloy; phosphate pretreat, epoxy, vinyl, epoxy-hybrid, urethane, or polyester coating 12-25 μm (0.5-1.0 mil)
System B	Standard alloy; chrome pickle or light anodize, vinyl wash primer, vinyl or epoxy chromate primer, 2 coats, baked enamel 1 or 2 coats
System C	Standard alloy; anodize, penetrating epoxy sealer, 2-3 coats, epoxy chromate primer, 2 coats, lacquer or synthetic enamel 2 or more coats

Because of its high position in the electromotive series, magnesium is more susceptible than other common metals to galvanic corrosion. However, galvanic corrosion is possible only if bare magnesium is in electrical contact with another bare metal and if the surface of the two metals is bridged by a conductive aqueous electrolyte. Because in many applications such conditions are difficult to avoid, galvanic corrosion is controlled through the use of compatible metals (e.g. aluminum alloys 5052 or 6061, or zinc, cadmium, or tin electroplated coatings on steel fasteners). With dissimilar metal components assembled to magnesium parts, paint, plastic tape, organic sealants, or compatible metal shims, such as 5000 or 6000 series aluminum, are used to prevent direct electrolyte bridging of the components at the interface. (See the article "Corrosion of Magnesium and Magnesium Alloys" in *Corrosion*, Volume 13 of *ASM Handbook*, and Ref 7 and 8.)

Proper and adequate cleaning is an important prerequisite to the successful application of finishing systems to magnesium alloy products. Failure to follow suitable cleaning procedures causes future problems of corrosion and product degradation. Mechanical and chemical cleaning methods are used singly or in combination, depending on the specific application and product involved. Cleaning processes of either type require suitable control to ensure repetitive reliability.

Acknowledgements

Special thanks are due to David L. Hawke, Hydro Magnesium, for his helpful comments and suggested revisions.

Mechanical Cleaning

Mechanical cleaning of magnesium alloy products is accomplished by grinding and rough polishing, dry or wet abrasive blast cleaning, wire brushing, and wet barrel or bowl abrading (vibratory finishing).

Grinding and Rough Polishing. Grinding with belts, wheels, and rotary files is used for cleaning sand castings. Belt grinding, however, usually is used as a finishing operation for the removal of flash and surface imperfections from die castings, or of die marks and scratches from significant surfaces of extrusions. No great danger of surface contamination exists, and no special abrasive or belt backings are necessary.

The possibility of fire resulting from the polishing of magnesium may be virtually eliminated by following the recommendations set forth by the producers of magnesium. These recommendations are summarized in the section "Health and Safety" in this article.

Dry Abrasive Blast Cleaning. Sand blasting is the method of dry abrasive blast cleaning most frequently used on magnesium alloys. Many foundries use flint silica sand with a fineness of 25 or 35 AFS. Occasionally, however, steel grit is used. Usually, castings are blasted immediately after shakeout to reveal any major surface defects. After gates, sprues, and risers are sawed off and other operations are performed to prepare the castings for shipment, a final abrasive blast with sand or steel grit is given just before pickling. Under conventional operating conditions, the two types of abrasives yield equally satisfactory results; but if excessive blast pressure is used, steel grit is more likely to cause surface corrosion, because of the embedding of steel particles in the magnesium surface.

Dry blasting with any abrasive is followed by acid pickling to remove the harmful effects of blasting. Table 2 describes two pickling baths, aqueous solutions of sulfuric acid and of nitric and sulfuric acids, frequently used for this purpose, and indicates conditions for their use.

Table 2 Acid pickling treatments for magnesium alloys

Treatment	Principal applications	Metal removed		Solution						
				Constituents	Amount		Operating temperature		Immersion time, min	Tank material or lining
		µm	mils		g/L	oz/gal	°C	°F		
For cast or wrought alloys										
Chromic acid	Remove oxide, flux, corrosion products	None		CrO_3	180	24	21-100[a]	70-212[a]	1-15	Stainless steel, 1100 aluminum, lead
Ferric nitrate[b]	Bright finish; maximum corrosion	8	0.3	CrO_3	180	24	16-38	60-100	$\frac{1}{4}$-3	Type 316 stainless steel,

nitrate[b]	resistance of bare metal; finishing of die castings			$Fe(NO_3)_3·9H_2$	40.0	5.3		100		vinyl, polyethylene
				O	3.5	0.47				
				NaF						
Hydrofluoric acid	Active surface for chemical treatment	3	0.1	50% HF	230	31	21-32	70-90	$\frac{1}{2}$-5	Type 316 stainless steel, lead, rubber
Nitric acid	Prepickle for ferric nitrate treatment[c]	13-25	0.5-1.0	70% HNO_3	50	6.7	21-32	70-90	$\frac{1}{5}$ - $\frac{1}{2}$	Stainless steel
For wrought alloys only										
Acetic-nitrate	Remove mill scale; improve corrosion resistance of bare metal	13-25	0.5-1.0	CH_3COOH	192	25.6	21-27	70-80	$\frac{1}{2}$-1	3003 aluminum, ceramic, lead
				$NaNO_3$	50.0	6.7				
Glycolic-nitrate	Remove mill scale or surface oxides; improve corrosion resistance[d]	12-25	0.5-1.0	70%	230	31	16-49	60-120	$\frac{1}{2}$-1	Rubber
				$CH_2OHCOOH$	40	5.3				
					40	5.3				
				70% HNO_3						
				$NaNO_3$						
Chromic-nitrate	Remove mill scale, burned-on graphite; preclean for welding	13	0.5	CrO_3	180	24	21-32	70-90	3	Stainless steel, lead, rubber, vinyl
				$NaNO_3$	30	4				
Chromic sulfuric	Preclean for spot welding	8	0.3	CrO_3	180	24	21-32	70-90	3	Stainless steel, 1100 aluminum, ceramic, rubber
				96% H_2SO_4	0.4	0.05				
For cast alloys only										
Nitric sulfuric	Remove effects of blasting from sand	50	2.0	70% HNO_3	77.0	10.3	21-32	70-90	$\frac{1}{6}$ - $\frac{1}{4}$	Ceramic, rubber, glass

sulfuric	castings			96% H_2SO_4	20	2.7			$\frac{1}{6}$ - $\frac{1}{4}$	glass
Phosphoric acid										
Step 1	Remove surface segregation from die castings	13-25	0.5-1.0	85% H_3PO_4	425-866	57-116	21-27	70-80	10-15 s	Fiber-reinforced plastic, polyvinyl chloride, polyethylene
Step 2[e]				NaOH	80-120	11-16	21-27	70-80	30 s	Carbon steel
Sulfuric acid	Remove effects of blasting from sand castings	50	2.0	96% H_2SO_4	30	4	21-32	70-90	$\frac{1}{6}$ - $\frac{1}{4}$	Ceramic, rubber, lead, glass

(a) For removal of flux, solution must be 88 - 100 °C (190 - 212 °F).

(b) For most uniform appearance, die castings must be mechanically finished before being pickled, because the ferric nitrate solution accentuates flow marks and segregation on die-cast surfaces.

(c) Use of nitric acid prepickle increases solution life and decreases treatment time in ferric nitrate pickling.

(d) Nonvolatile glycolic acid reduces costs compared to acetic acid.

(e) No rinsing between steps

Wet abrasive blast cleaning of magnesium alloys is used for final finishing before electroplating, producing a matte surface before chemical treatments, removing carbonaceous or heavy corrosion products, and removing residual paint after stripping operations. Equipment, abrasives, and process controls are the same as those used for many other materials (see the article "Mechanical Cleaning Systems" in this Volume). Remove any contamination by acid pickling, using the sulfuric or nitric-sulfuric baths described in Table 2.

Barrel or Bowl Abrading. Magnesium die cast components are often cleaned of charred and uncharred die lubricants and other surface contaminants using wet barrel, or vibratory bowl, abrading in combination with detergents and surface treatment formulations. The ceramic media employed in these operations serve to both clean and smooth parts. It is important that a good flow of solution is continuously applied to the media in order to keep contaminants from accumulating and recontaminating part surfaces. Abrading is used as both a stand-alone finishing operation with high-purity alloy parts (see the section "Mechanical Finishing," below) and as a pretreatment/cleaning operation prior to painting parts used in applications such as chain saws, lawn and garden equipment, and power hand tools.

Wire Brushing. Magnesium alloy sheet is wire brushed for in-process cleaning and for the removal of oxides before arc or resistance welding. The wire-brushing machine should be adjusted as to the amount of pressure exerted on the sheet. The machine should be designed so that it does not gouge the sheet. The final surface smoothness depends also on the coarseness and composition of the wire. Safety precautions should be observed when wire brushing magnesium as indicated in the section "Health and Safety" in this article.

Chemical Cleaning

Chemical methods for cleaning magnesium alloys are vapor degreasing, solvent cleaning, emulsion cleaning, alkaline cleaning, and acid pickling.

Solvent cleaning and vapor degreasing are used to remove oils, forming lubricants, waxes, quenching oils, corrosion-protective oils, polishing and buffing compounds, and other soluble soils and contaminants. Solid particles such as machining dust or chips are removed by the washing action of the solvent as it dissolves the oil or grease that holds the metal fines to the part. These processes must be used before painting, plating, and chemical treatments, as well as before and after machining and forming.

The same methods, equipment, and solvents are used for magnesium as for other metals (see the article "Solvent Cold Cleaning and Vapor Degreasing" in this Volume). Trichloroethylene and perchloroethylene are the solvents most often used. Methylene chloride is effective in removing the excess organic-resin impregnants from the surface of the castings without removing the compound from the pores in the metal.

Emulsion cleaning may be used for the removal of oils and buffing compounds (see the article "Emulsion Cleaning" in this Volume). The emulsion cleaner should be neutral or alkaline, with a pH of 7.0 or above, so as not to etch magnesium surfaces. Emulsion cleaners incorporating water with the solvent should be tested before use to avoid possible attack or pitting of the metal.

Alkaline cleaning is the most frequently used method of cleaning magnesium alloys preparatory to painting, chemical treatments, or plating. Alkaline cleaners are also used to remove chromate films from magnesium.

Most magnesium alloys are not attacked by common alkalis except pyrophosphates and some polyphosphates, and even these alkalis do not appreciably attack magnesium alloys above a pH of 12.0. Nearly any heavy-duty alkaline cleaner suitable for low-carbon steel performs satisfactorily on magnesium alloys. The pH of alkaline cleaners for magnesium alloys should be 11.0 or higher.

Soak cleaners are usually based on alkali hydroxides, carbonates, phosphates, and silicates, preferably in combinations of two or more, and also contain natural resinates or synthetic surfactants as emulsifying agents. Soak cleaners are used in concentrations of 30 to 75 g/L (4 to 10 oz/gal) and at 71 to 100 °C (160 to 212 °F). Alkaline cleaners used for spray cleaning cannot use a surface-active wetting agent, because the foaming problem would be too great. In this case, the mechanical force of the spray helps dislodge soils.

Cathodic cleaning uses the work as the cathode in the cleaning solution at approximately 6 V dc. Anodic cleaning is not recommended because of the formation of undesirable oxide or hydroxide films. Pitting of the surface of the magnesium may also result from prolonged anodic cleaning.

A simple aqueous bath for soak or electrolytic cleaning of magnesium alloys is made and used as follows:

Trisodium phosphate ($Na_3PO_4 \cdot 12H_2O$), g/L (oz/gal)	30 (4)
Sodium carbonate ($Na_2CO_3 \cdot 10H_2O$), g/L (oz/gal)	30 (4)
Wetting agent, g/L (oz/gal)	0.7 (0.1)
Operating temperature, °C (°F)	82-100 (180-212)

Immersion time, min	3-10

Another formula for soak or electrolytic cleaning, which can be used before electroplating, consists of the following:

Sodium carbonate ($Na_2CO_3 \cdot 10H_2O$), g/L (oz/gal)	22.5 (3)
Sodium hydroxide (NaOH), g/L (oz/gal)	15 (2)
Wetting agent, g/L (oz/gal)	0.7 (0.1)
Operating temperature, °C (°F)	82-100 (180-212)
Immersion time, min	3-10

When either of these baths is used as an electrolytic cleaner, parts are made the cathode at a current density of 1 to 5 A/dm^2 (10 to 50 A/ft^2) at 6 V dc. Many proprietary compounds are better cleaners than the above formulas.

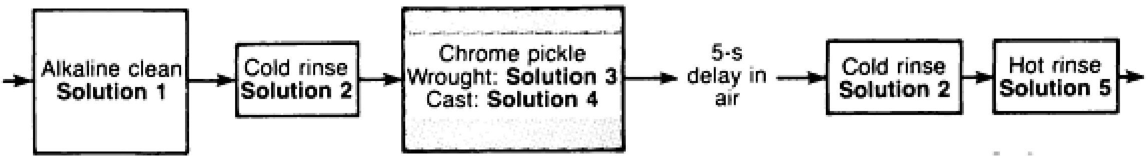
Hard-to-remove soils, such as graphitic lubricants used in the hot forming of magnesium alloy sheet products or in the fabrication of impact extrusions, can best be removed by soaking in the heavy-duty caustic cleaner:

Sodium hydroxide (NaOH), g/L (oz/gal)	98 (13)
Wetting agent, g/L (oz/gal)	0.7 (0.1)
Operating temperature, °C (°F)	87-100 (190-212)
Immersion time, min	10-20

A chromic acid pickle, as shown in Table 2, usually is used after cleaning in the above solution. Cleaners containing more than 2% NaOH attack ZK60A; therefore, the above solution should not be used on this alloy.

Acid pickling is required for removal of contamination that is tightly bound to the surface or insoluble in solvents or alkalis. These contaminants include natural oxide tarnish, embedded sand or iron, chromate coatings, welding residues, and burned-on lubricants.

In selecting an acid pickling treatment, consider the type of surface contamination to be removed, the type of magnesium alloy to be treated, and the dimensional loss allowable, as well as the desired surface appearance. Table 2 gives details of acid pickling treatments used for magnesium alloys. Confining these treatments to alloy types indicated avoids the formation of a powdery black smut on pickled surfaces.



Solution No.	Type of solution	Constituents	Amount, g/L (oz/gal)	Operating temperature, °C (°F)	Cycle time, min	Tank material
1	Alkaline cleaner	[a]	[a]	88-100 (190-212)	3-10	Low-carbon steel
2	Cold rinse	Water	. . .	Ambient	[b]	Low-carbon steel
3	Chrome pickle[c]	$Na_2Cr_2O_7 \cdot 2H_2O$ HNO_3 (sp gr 1.42) Water[d]	180 (24) 180 (24) bal	21-32 (70-90)	$\frac{1}{2}$-2[e]	[f]
4	Chrome pickle[g]	$Na_2Cr_2O_7 \cdot 2H_2O$ HNO_3 (sp gr 1.42) Na_2HF_2, KHF_2, or NH_4HF_2 Water[d]	180 (24) 120-180 (16-24) 15 (2.0) bal	21-32 (70-90) 49-60 (120-140)[h]	$\frac{1}{2}$-2[i]	Type 316 stainless steel[j]
6	Hot rinse	Water	. . .	71-82 (160-180)[k]	. . .	Low-carbon steel

(a) Type and strength of solution used governed by degree of surface contamination.

(b) Rinse thoroughly with adequate inflow of fresh water; agitate.

(c) For wrought materials, all alloys, not to be hot formed, and for wrought materials, all alloys, for which tolerances permit removal of approximately 15 μm (0.6 mil) of stock. When treatment is used on alloys M1A and ZK60A to provide paint base, use fresh solutions.

(d) Use water from steam condensate or water treated by ion exchange, when available, instead of well or hard tap water.

(e) For well-controlled bath, 1 min is standard.

(f) Tank material can be of stainless steel or low-carbon steel lined with glass, ceramic, synthetic rubber, or vinyl-based materials. Racks and baskets for use with Solution 3 may be stainless steel or Monel.

(g) For sand and permanent mold castings of all alloys for which tolerances permit stock removal of approximately 15 μm (0.6 mil); die castings, all alloys, of 3 to 8 μm (0.1 to 0.3 mil). Dip die castings for 15 to 30 s in water 71 to 82 °C (160 to 180 °F) before immersing in solution.

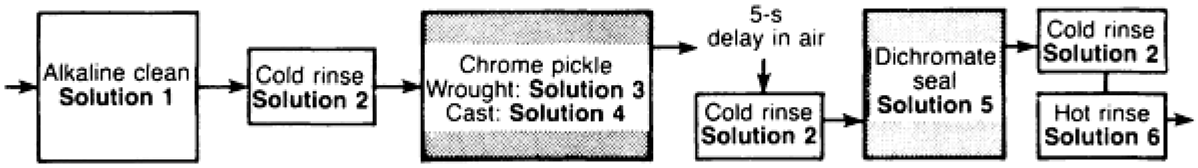
(h) For die castings.

(i) For well-controlled bath, 1 min is standard on all products except die castings. Immerse die castings only 10 s.

(j) Racks and baskets for use with Solution 4 can be type 316 stainless steel or phosphor bronze.

(k) Immerse long enough to heat parts sufficiently to facilitate rapid drying; keep rinse clean with inflowing fresh water.

Fig. 3 Chrome pickle treatment (chemical treatment No. 1; MIL-M-3171, type I). Applicable to all alloys and product forms. Used to provide a base for paint or short-time protection for shipment or storage



Solution No.	Type of solution	Constituents	Amount, g/L (oz/gal)	Operating temperature, °C (°F)	Cycle time, min	Tank material
1	Alkaline cleaner	[a]	[a]	88-100 (190-212)	3-10	Low-carbon steel
2	Cold rinse	Water	. . .	Ambient	[b]	Low-carbon steel
3	Chrome pickle[c]	$Na_2Cr_2O_7{\cdot}2H_2O$ HNO_3 (sp gr 1.42) Water[d]	180 (24) 180 (24) bal	21-32 (70-90)	$\frac{1}{2}$-2[e]	[f]
4	Chrome pickle[g]	$Na_2Cr_2O_7{\cdot}2H_2O$ HNO_3 (sp gr 1.42) $NaHF_2$, KHF_2, or NH_4HF_2 Water[d]	180 (24) 120-180 (16-24) 15 (2) bal	21-32 (70-90) 49-60 (120-140)[h]	$\frac{1}{2}$-2[i]	Type 316 stainless steel[j]
5	Dichromate seal	$Na_2Cr_2O_7{\cdot}2H_2O$ CaF_2 or MgF_2 Water[d]	120-180 (16-24) 2.47 (0.33) bal	99-100 (210-212) (boiling)	30	Low-carbon steel
6	Hot rinse	Water	. . .	71-82 (160-180)	[k]	Low-carbon steel

(a) Type and strength of solution used governed by degree of surface contamination.

(b) Rinse thoroughly with adequate inflow of fresh water; agitate.

(c) For wrought materials, all alloys, not to be hot formed, and for wrought materials, all alloys, for which tolerances permit removal of approximately 15 μm (0.6 mil) of stock. When treatment is used on alloys M1A and ZK60A to provide paint base, use fresh solutions.

(d) Use water from steam condensate or water treated by ion exchange, when available, instead of well or hard tap water.

(e) For well-controlled bath, 1 min is standard.

(f) Tank material can be of stainless steel or low-carbon steel lined with glass, ceramic, synthetic rubber, or vinyl-based materials. Racks and baskets for use with Solution 3 may be stainless steel or Monel.

(g) For sand and permanent mold castings of all alloys for which tolerances permit stock removal of approximately 15 μm (0.6 mil); die castings, all alloys, of 3 to 8 μm (0.1 to 0.3 mil). Dip die castings for 15 to 30 s in water 71 to 82 °C (160 to 180 °F) before immersing in solution.

(h) For die castings.

(i) For well-controlled bath, 1 min is standard on all products except die castings. Immerse die castings only 10 s.

(j) Racks and baskets for use with Solution 4 can be type 316 stainless steel or phosphor bronze.

(k) Immerse long enough to heat parts sufficiently to facilitate rapid drying; keep rinse clean with inflowing fresh water.

Fig. 4 Sealed chrome pickle treatment. Applicable to all alloys and product forms. Used as a substitute for dichromate coating or for more protection than is provided by the chrome pickle treatment

When a magnesium alloy product is used bare or with a clear finish, it is desirable to improve the corrosion resistance of the metal surface in addition to providing an attractive appearance. This can be accomplished by the use of ferric nitrate, acetic-nitrate, or phosphoric acid pickle (Table 2). The ferric nitrate pickle deposits an invisible chromium oxide film that passivates the surface and improves corrosion resistance. The acetic-nitrate and phosphoric acid pickles act as sequestering agents that effectively remove even invisible traces of other metals from the magnesium surface and thus prevent localized galvanic corrosion. Although all of these methods are effective in improving corrosion resistance, ferric nitrate and phosphoric acid pickles give best results.

Mechanical Finishing

Depending on required appearance, the most frequently used methods of mechanical finishing are barrel tumbling, polishing and buffing, vibratory finishing, fiber brushing, and shot blasting. Shot blasting with 0.10 to 0.25 mm (0.003 to 0.009 in.) glass spheres produces a satin finish. Plastic and chopped aluminum wire blasting media are also used. Sand or steel shot blasting should be excluded as means for producing a desired mechanical finish. If these media are used, heavy pickling (1 to 2 mils of metal removal) is required to restore corrosion resistance, and such pickling can seriously alter the mechanical finish produced. Surface contamination by plastic, chopped aluminum, or glass bead media is less damaging and the effects can be easily removed by subsequent mild etching treatments such as ferric nitrate pickling. Wet blasting

with glass beads or aluminum oxide is less contaminating than any dry blasting process. (See the article "Corrosion of Magnesium and Magnesium Alloys" in *Corrosion,* Volume 13 of *ASM Handbook,* and Ref 3, 5, and 9.)

Mass (Barrel) Finishing. The use of dry barrel finishing is usually limited to the production of a final finish on magnesium alloy parts that are small and relatively thin and for which metal removal must be held to a minimum. Wet barrel finishing is used for deburring, grinding, polishing, burnishing, and coloring. Procedures used in wet and dry barrel finishing are discussed in the article on mass finishing.

Vibratory finishing combines smoothing and brightening with cleaning to remove dirt, oxides, thin flash, and casting skin. Ceramic and other media are used depending on the surface condition of the part and the finish required. Acid additives etch magnesium surfaces and should never be used. Proper rinsing and drying are important.

Polishing and buffing are not used for final finishing, but for preparing magnesium alloy surfaces for other finishes, such as chemical treatments, anodizing, plating, or painting. As shown in Table 3, the procedures used to produce a highly polished or buffed surface on magnesium alloys are similar to those used for aluminum-base alloys. However, because most magnesium alloys are appreciably harder than aluminum alloys and tend to drag or tear to a lesser degree, it is unnecessary to use as much lubrication as is usually required with aluminum alloys. When polishing die castings, the metal removal is kept at a minimum to preserve the relatively thin nonporous outer layer of the casting.

Table 3 Procedures for polishing and buffing magnesium alloys

Operation	Abrasive grit size	Wheel				
		Type	Diam		Speed	
			mm	in.	m/s	sfm
Rough polishing[a]	60-100[b]	Canvas, felt, sheepskin	150-360	6-14	15.3-25.5	3000-5000
Medium polishing[c]	100-320[b]	Built-up cloth	150-360	6-14	20.4-30.6	4000-6000
Fine polishing	240-400	Cloth or sheepskin	250-360	10-14	22.9-38.2	4500-7500
Satin finishing[d]	50-320[e]	Full-disk buffs[f]	150-300	6-12	15.3-25.5	3000-5000
Buffing[g]	[h]	Cotton buffs	150-410	6-16	20.4-40.8	4000-8000

(a) For rough surfaces only, such as sand castings.

(b) Aluminum oxide or silicon carbide; grease stick may be used.

(c) For less severe surface condition and before buffing.

(d) For final finish or before plating.

(e) Greaseless compound.

(f) Loose or folded cotton cloth.

(g) A cutdown operation to produce a smooth finish with an intermediate degree of brightness.

(h) Tripoli or aluminum oxide buffing compound

Standard polishing wheels and abrasive belts are used to remove rough surfaces, parting lines, and other surface imperfections from magnesium alloy pieces. Aluminum oxide or silicon carbide abrasives are used, in grit sizes from 60 to 320, depending on the surface roughness and the final finish desired.

Particles of free iron or other heavy metals must not be used in abrasives for the polishing of magnesium alloys, because these metals, when embedded in the surface, can cause cell corrosion effects while parts are in storage or cause a pitting condition in pickling processes used before chemical treatments or electroplating.

Large castings require polishing of significant surfaces before buffing. Fine polishing belts are used on parts with little contour. Parts with more intricate contour are polished on setup wheels or on cloth wheels, using a greaseless compound. Grit sizes from 220 to 320 are most commonly used in polishing operations prior to buffing.

Satin finishing or flexible-wheel polishing is also used on magnesium alloys. This finish is produced by applying a greaseless compound to the surface of a clot wheel as it is slowly revolved. No lubricant is required.

Magnesium alloys can be buffed to a smooth, bright finish using aluminum oxide or tripoli compounds on a light-count sewed wheel. For color buffing, a dry lime compound may be used. Buffing compounds containing free iron or other heavy metal abrasives should not be used.

A ferric nitrate bright pickle, as shown in Table 2, is used on polished or buffed surfaces prior to the application of a clear organic coating. Using a ferric nitrate bright pickle produces a bright, passive surface that increases the adhesion and corrosion protection of the coating; it also serves to prevent blemishes such as spotting, blooming, and worm tracking in the coating after it has dried.

Precautions that must be exercised in the polishing and buffing of magnesium alloys are discussed in the section "Health and Safety" in this article.

Chemical Finishing Treatments

Chemical finishing treatments for magnesium alloys are used either to provide short-time protection against corrosion and abrasion during shipment and storage, or as pretreatments to additional finishing systems.
